BLACKBOARD. (Various recipes in back numbers. If we are to understand that the board is already painted, it will probably be best to go over it with a coat of black paint in which turpentine has been used as the principal vehicle. Some blackboards are first treated to a priming coat, then they have one or two coats of oil paint in which very finely-powdered coke is mixed. Finally, the flatting coat, mentioned above, is put on. These boards bite the chalk well, and it is readily rubbed off; but you want something to "dry quickly," without saying what you mean by quickly. You will find nothing quicker than the turpentine paint which will also answer the other conditions.)—J. TINDAL. (Apparently you are suffering from sciatica, and should consult a medical man. You will find one alleged remedy on p. 575, No. 804—viz., homœopathic pilules of colocynth. A liberal use of lemon or lime-juice is said to ward off attacks.)—J. M. (Heat the bulb and tip the mercury gently down to the top end.)—J. R. (See replies 46510, in recent numbers—No. 893, for instance.)—A. D. D. (If you look to the index of our last volume, you will find more than thirty references to tricycles, and we recommend you to read the papers by "D. H. G.," if you cannot make up your mind by consulting our advertisement columns.) PACKINGHAM-STREET, ISLINGTON. (You do not say what metal the ornaments are made of, and have also forgotten to put a signature. We suspect the copper colour is either a bronze powder laid on with varnish (Bessemer's paint), or else a deposit by the electrical method. See replies in recent numbers.)—G. HARDWICK. (Answered many times. The flow-pipe must rise all the way to the bend. You can heat as many houses as you have boiler-power for, but the pipes must not be all on one level. The furthest point from the boiler must be the highest. See "Reviews" in this number.)—A. B. (If by Clark's you mean all the modifications of the chain-brake, the London and North-Western and the North London use it extensively. The Caledonian, Somerset and Dorset, London and Tilbury, Great Eastern, London and South-Western, and some small branch lines have a few coaches fitted with it.)—A CONSTANT SUBSCRIBER. (If you work such an engine at 100 revolutions per minute with a boiler-pressure of 15lb., it will do the work required. The nature of the question leads us to wonder how long you have been a "constant subscriber.")—LA DAMA. (We are afraid that you have not comprehended the position. Your experiments do not touch the question.)—BONANZA. (Query of too limited interest. You can get the names from any of the dealers; but it is impossible for any one to say whether investigations would be of commercial use.)—W. K. J. (Glue 1, water 2; melt; add 4 parts of glycerine, a few drops of carbolic acid, and sufficient powdered whiting to make the mixture look milky. Pour into a shallow vessel to set and cool. May be modified in several ways.)—INCUMBUS. (Directions for making an incubator on p. 311, No. 793; p. 465, No. 773.)—G. B. (See reply 46977, this number, and the indices of recent volumes.)—GALVANI. (Four. 2. No one can say without trying.)—CYGNET. (See recent numbers. A dynamo-machine would be necessary to make an economical installation.)—G. T. (You do not say what is the material. Silk and cotton require different preparations. See p. 182, No. 810, or p. 273, No. 792. Paraffin oil does not smell when properly consumed.)—CAMBRIDGESHIRE BOY. (Use white-lead (see that you get it) tinged with best Venetian red. Some chemical action was the cause of the change in the other mixture.)—BRAKE-BLOCK. (See the advertisement columns, and read the discussion in the last volume, wherein the subject was exhausted. 2. Messrs. Crosby Lockwood and Co., Stationers' Hall-court, E.C., will publish the book you name.)—B. T. A. (You should procure a copy of the specification. A small scale model would be made only with difficulty, and as to working it by hand, the results would be *nil*.)—A BEGINNER. (Merely the finest plumbago applied carefully to all parts with a camel-hair brush. We suspect that you did not connect the plumbago surface of the cast with the copper wire.)—

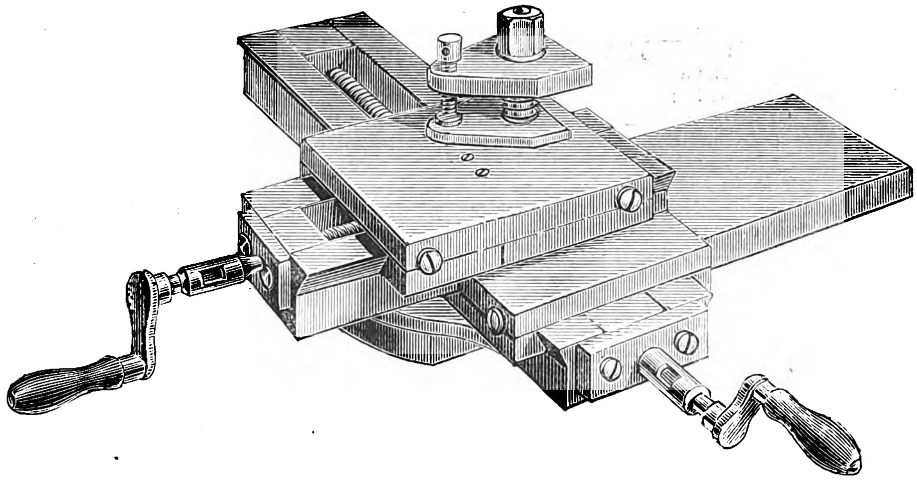
METAL-TURNING SLIDE-REST.

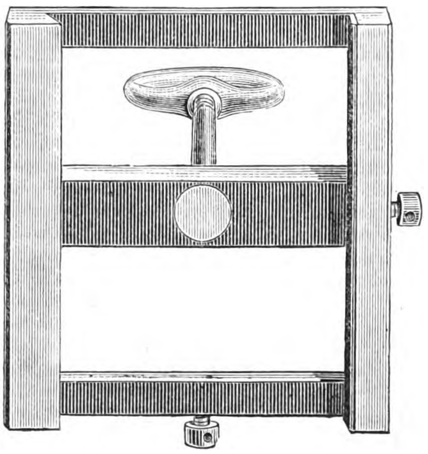
By J. H. Evans.

Having been compelled by pressure of business to delay my articles, I have received in the mean time very many letters asking for information upon a great number of different subjects, and as the metal-turning slide-rest has formed one of the principal topics of inquiry, I have thought it one of the most useful tools to illustrate and describe.

There are, of course, a number of different kinds of this particular tool; but I think the one here shown is the most useful for general amateur purposes. In the first place, it will admit of a larger diameter being turned, and the metal cradle is a surety of its being always square to the bed of the lathe if properly adjusted. It will be seen that the rest is composed of three slides, the first being fitted to a gunmetal cradle, one side of which is planed to an angle, the other being square; and on the latter is fixed a strip of steel: this is pressed against the cast-iron slide by a capstan-head screw. The steel strip has two objects: first, it forms a means of preventing the point of the screw damaging the slide, and it also admits of a certain amount of elasticity in the centre, and does away with the necessity for the extreme accuracy in the fitting between the angular and vertical sides of the cradle. When these are fitted quite closely, the side unprotected (viz., the angle), is likely to be damaged when the rest is being inserted in the cradle. The second slide is held to the lower plate by two bolts, the centre having a circular recess turned out, about 1in. diameter and ¾in. deep, and fitted to a stud, which is screwed firmly into the lower or first slide. Upon this stud the second slide moves when it is required to turn a cone or taper, and to fix it in any position required the two bolts are tightened. There are two ways of arranging the circular motion: either by having a radial slot each side of circular part of the second slide, and the bolts tapped into the lower one, or to turn out a T-groove in the lower slide, and a round hole in the second one. In this case a recess must be cut out in the lower plate to allow the head of the bolt to be inserted; the ends of the bolts project through the second slide, and a hexagon nut, with a thin loose washer, is fitted to the bolts. This mode I much prefer, and usually adopt, as the motion is better, and you can work the rest entirely round if necessary. I make the second slide long enough for the winch-handle to project over the end of the first slide, as if the slide can be turned completely round, as it can if made the latter way, it is much better for taking a surface cut than using the top slide for the same purpose, especially for heavy work. The plate which forms the top of the second slide is cast in the solid with the base of the top slide, and is fitted in the ordinary way, the one angle being planed up true to the lower surface, and the loose slide held to its place by two screws with heads countersunk, and two set-screws to adjust the slide to a perfect fitting. The top slide is fitted in the same way precisely, and on the latter the tool-holder is fixed, this latter being after the pattern introduced by Professor Willis, which is certainly the best at present known; but I will point out that what I consider the best way to fix the tool securely in the rest, is to tighten it by means of the screw at the end of the angular piece of the tool-box, which screw I always make with a capstan-head with lever-holes in it. It will be found that much less force will hold the tool more securely than by using the spanner to the hexagon nut in the centre of the tool-holder, if, when the tool is placed, the nut and screw are adjusted till nearly in a line with the stem of the tool, and the screw then tightened.



The screws are fitted to the slides in the same way as those of the other slide-rests—viz., with a collar on the end, which is countersunk into the gun-metal end plates, which plates are fixed with two steel screws; the screws are cut 10 threads to the inch, and covered with a metal cover to keep the shavings from getting into the nut, and so causing wear and tear that is, to a certain extent, prevented by the latter arrangement. The end of the second slide is usually prepared to take the spiral wheels, so that the rest can be used for cutting screws, or Elizabethan twists, in conjunction with the spiral apparatus. This rest is for the purpose of enabling the amateur to turn such work as would be found extremely difficult without its aid, in fact, almost impossible. Although strictly for metal-turning, there is no reason why it should not be used for roughing over hard woods, and I find amongst my clients that it is used extensively for this purpose; as, by way of example, if a large ivory hollow is required to be turned out inside, by using the rest we have now under notice, the ornamental turning rest is saved a deal of rough usage, and much time also turned to account, as the heavy rest will do the work in much less time.



Having given a brief outline of the tool, and a few examples of its use, I will describe the best way of setting about making it, and I need scarcely say that the first thing to do will be to make the patterns, and as this is always a matter of trouble and expense, it may be saved, as in other subjects upon which I have written, by securing castings from those used at my establishment. Assuming, then, that the castings are at hand, the first part to set about will be the gunmetal cradle. From the engraving it will be seen that it has a strong bar across the centre, which is planed in the same manner as the outside fittings, and should be just free in the centre of the bed. There is no necessity for accurate fitting in this case, as the screw seen in the front is for the purpose of drawing it up square to the bed, and when being used this screw should be adjusted before the binding bolt is tightened to secure it to the bed. The lower parts of the cradle being planed, it must be reversed on the planing-machine and chucked, as it is termed, perfectly square to those parts already done, and then the fitting with the bevel on the left side planed up true, allowing sufficient space for the steel bar on the right-hand side, which will be about an eighth of an inch. By way of a finish to the look of the work, a neat hollow is made on each side. This is easily done by placing a round-nose tool in the machine, and takes but a few minutes. When this part is entirely finished, the lower cast-iron slide, which fits into it, should be planed to fit it. This part is 1ft. 3in. in length, 4in. and ⅞in. at the bottom. It is made sufficiently long to allow the rest to be brought away from the centre, in order to turn a large diameter; the thickness is ⅞in. Having gone so far, it is chucked on a true surface-plate in a lathe, and the hole bored and tapped true to the surface in the end; the radius at the front end, where the divisions are seen, being turned at the same settings. This, of course, can only be turned by a semicircular movement. The hole should be tapped ½in.; and for cast iron, the Whitworth thread will be the best. I consider it the best way to fit in the wrought-iron stud, upon which the second slide revolves, and then turn it perfectly true to the outside. If it is not so when the slide is turned upon it, the two edges will not always coincide. This is important, especially where there are divisions. So far, then, the foundation is well forward. I had better point out that the lower slide—in fact, the whole rest—is held to the bed by the metal cradle. This being the case, we always make the binding bolt of steel.

This, well fitted to a countersunk-hole, and the cast iron fitting the bevel in the cradle, when tightened, the latter will draw the rest flat down on to the bed, and the side-screws being adjusted, it is consequently square all ways.

The casting for the second slide must now be planed, top and bottom, to the desired thickness, 1in. and ⅝in., the bevels on each side planed at the same time. The actual width across the top is 3½in.; but if it should be necessary to take another cut, it does not in the least matter if it is a little less.

The opening in these rests we do not plane out: if the patterns are well cored and cast there is no necessity; they are 1¼in. wide, to allow room for a good substantial nut. When this slide has been properly scraped up, it should be placed on the surface chuck in a similar way to the lower one, and the hole turned out perfectly true to fit the pin that is fitted to the bottom slide, which, by the way, should have the T-groove turned out while it is on the surface chuck, as it is absolutely necessary that it should also be quite true to the pin. The recess should be large enough to admit of ⅜ bolts being used undercut to ¾ for the head. This is, as I have mentioned, the best way of arranging this; but if the radial slot on each side is preferred, being more easily accomplished, they should be set out with dividers; then with a large drill holes are bored as closely together as possible, filed one into the other with a round file, and finished with pillar and crossing files; to those possessed of machinery for such a purpose this may seem a long process, but I take it for granted that most amateurs at all events have not such. I will proceed as if the former plan is adopted; therefore, when the T-groove is turned out, a recess must be cut out at one portion of it, to allow the head of the bolt to pass in freely. This done, a hole in each side of the second slide working upon it must be made exactly opposite the centre of the groove; and the bolts have a plain part which fits into this, and the screw above it; it is better to have a thin loose washer under the nut, which latter should be steel, or iron casehardened. I prefer steel, as casehardening is, after all, only skin deep. This part being so far made, the two slides may be put together, and the lower one held in the vice while the top plate and slide are got up together.

The third slide, it will be seen, is cast in the solid with the plate that forms the top of the second, one side strip being also cast on it. To proceed with this it must be planed wherever a surface and fitting are required, and where the slides work should be scraped up and the bearings well rubbed together; when perfectly true and flat, a little fine oil-stone powder may be used as a finish just to work them well together. The side strips must not be any thicker than will admit of their passing freely over the nuts that hold the first and second slides together. It will be seen that there are two set-screws in the front slide to set up or adjust the slide.

The top plate of third slide is made in exactly the same way, the thickness of these two being ⅜ of an inch, the length 6in., and width 5in. In the corner of the top plate the tool-box is fitted, the one under notice being that introduced by Professor Willis, and is, as stated, the best at the present time in use—the centre pin is made of steel, and is screwed into the cast-iron plate with a ¾ Whitworth screw and home to a shoulder, the latter being 1in. in diameter, and ¼in. thick; the part that extends is screwed ⅝in., and has a long steel nut 1¼in. long. The object of its length is to admit of various cutting frames and wheel-cutting apparatus being used at different times, on the bottom, and resting on the cast-iron plate—a piece of steel ⅜in. thick, and of a triangular form. It is turned out to pass freely over the collar of the steel pin on which it moves, and at the point which is the greatest distance a semicircular groove is made for the point of the capstan-head screw to bear upon. The top plate is ⅝in. thick, and extends over the front sufficiently to allow two steel studs to clamp the centre of the tool, which, for a 5in. lathe, will be about ⅝in. square. In the centre of the top plate a curve is turned, into which a loose washer fitting the same is placed, under the hexagon nut, and between the two, a short spiral spring, to keep the upper one in its place. As I have said, I have found from experience, that the capstan-screw is the best to tighten the tool into its place, and not the hexagon nut. In giving a short explanation of this tool-holder, I wish it to be understood that I do so entirely for the benefit of the uninitiated, almost all mechanics and amateurs being well acquainted with it already, it having been in use for many years.

Having, then, all the slides so far ready, we pass on to the screws, which are ten to the inch, and square threads. To cut these, of course, a self-acting lathe must be used, as they are long, and being square threads, no other means can be obtained. The second slide being 14in., and the top 9in., of course, in cutting such screws, the slender guide must be brought into use to stay the spring and vibration caused by the length. The nuts must form the next part, and these may be made of either cast iron or gunmetal. I must say I prefer the latter, both in theory and practice, and as they will naturally wear more or less as they are used, I should certainly advise the extra caution of splitting the nuts across and fitting in two screws to set them up, in order to take up as much of the loss of time as possible. I have found this answer very well, and do so with all my best slide-rests now. It will also be found that the screw will be worn more towards the centre, as the generality of work is of such a length as to bring into use that particular part of it more than any other. This, I may say, comes under the denomination of general wear-and-tear, and when worn so as to in any way interfere with the work to be turned, it must undergo a course of repair.

The screws made, having, of course, the collars, which fit into the metal end-plates, which latter are ⅜in. thick, and countersunk to ¾in. diameter for the collars to fit, and held to the end of the slide by two screws, as seen in the engraving, I may point out that the boring of the cast-iron slides is a most important matter, and will require great care in laying out, the end at which the point of the screw fits being bored to the size of the bottom of the thread, the opposite, of course, just above the top of the thread, so that a good fitting may be made. The end of each screw projects sufficiently, for what we term a pipe-handle—that is, with a cylindrical hole with a mortice slot for the end of the screw to fit into to keep it from turning round. These we always consider the best for such a rest. We are now drawing to a close with the making of this tool. I think it will be well not to omit the covering of the screw to keep out the shavings. This is done with a piece of tube cut in half, and a semicircular slot cut in the nut between those screws that hold it to the plate or slide. I remember that the rest sent to the engraver for this illustration will not show this, as it has not the covers to the screws, it not being quite finished; but I consider it an improvement, therefore suggest its being done; at the same time it is not an absolute necessary.

And now a few words as to the dividing of the front for turning tapers, &c. A centre line having been obtained on either the first or second slides, one should be divided into degrees of a circle, and figured at every 10. If this division is put upon the second slide, the reading line upon the lower one should be left until the rest is fitted into the lathe for which it is made, and a true and perfect cylinder turned with it; and when this is done, the reading line should be carried on to the other slide, exactly opposite the zero, or starting-point of the division. We generally put the division on the second slide, and read from a line upon the bottom; but it is really not of much importance as long as a perfectly distinct reading is obtained.

I trust these few remarks will be of service to many of our readers who are interested in such work; and those whose abilities are directed to metal-turning will find this one of the most useful additions to the amateur lathe.

SOUND-SIGNALLING AT SEA.

ONE of the most interesting classes of exhibits at the recent Naval and Submarine Exhibition included the appliances used for producing sound-signals employed as warnings to vessels in the vicinity of the coast, and also as a means of communicating amongst themselves indications of their presence and of the directions in which they are steering. All seamen look upon fog with the greatest dislike, for the simple reason that it practically blindfolds them. In the stiffest gale and the darkest night, at least they can catch occasional glimpses of the beacon-lights; but in the state of the atmosphere generally termed fog, the most powerful artificial lights are invisible, and even the mid-day sun is obscured. In the old time, when near a coast, masters of fog-bound vessels invariably adopted the safer plan of lying-to until the atmosphere became sufficiently clear; but with the advent of steamships, and the competition of rival lines, when quick voyages are the desideratum, the over-cautious practice of bygone generations is almost forgotten, and navigators push on through the densest fogs, trusting to dead-reckoning, and, if near a coast, to the use of the lead, to give them an idea of their position. The practice is fairly safe if the vessel proceeds only slowly, and is in parts not much frequented by shipping; but in the busy highways of the sea it is now recognised as imperatively necessary that all vessels, whether under steam or sail, shall give indications of their presence by sound-signals. For many of the devices employed we are indebted to the Americans, who possess a large seaboard which is frequently visited by fogs; but some of the signals now used were invented more expressly for indicating to steamers and other vessels on the large American rivers and inland seas, the course intended to be taken by the signalling vessel. Within the past twenty years or so a great development of sound-signalling apparatus has been made in this country, Prof. Tyndall, as adviser to the Trinity Board, having devoted much attention to the subject, especially as regards the coast-marking signals. International regulations for preventing collisions at sea prescribe, as compulsory for all mercantile vessels, certain signals to be made at frequent intervals whenever the atmosphere is clouded by fog, mist, or snow; and further, steam-vessels have an international code of signals on their steam whistles, which indicate the direction of their movements. The use of these signals is, however, optional on the part of steam-vessels, and as they are given by from one to three short blasts, they are not altogether trusted, for it has happened not unfrequently that they have been interpreted incorrectly, for the simple reason that one of the blasts has not been heard on board the vessel it was desired to warn. Amongst the instruments for making sound-signals on board ship, there are bells, fog-horns, gongs, and whistles, the latter blown either by steam or air. Whistles are generally adopted on steam vessels, and when kept in proper order and attention paid to their utterances by both the signaller and the signalled, are useful devices, especially when means are provided for changing the pitch, but there is liability to choking, and frequently an indefiniteness about the first blast, which is apt to mislead. Sometimes, when the tap admitting steam to a whistle is opened, there is only a rush of water, or condensed steam, and the sound, if any, is uncertain. At other times the sound, though not clear to those on board the signalling vessel, may be distinctly heard by the watch on the other ship; but the signallers are apt at times to repeat, thinking the first was not heard, and then uncertainty and confusion are introduced. For this reason various modifications in the form of the "whistle" have been made, the principal object being to avoid choking. Whistles on the plan of organ pipes have been adopted, and one by means of which two distinct sounds can be produced has been received with favour. Reeds on the principle of both the beating reed used in organs and the free reed, have been adopted to horn bodies with good effect, one of the best being perhaps a recent introduction from America, which is intended for use with a code made up of eight long and short sounds. Compressed air, at about 6lb. to the square inch, is used to produce the sound in this apparatus, but, if necessary, it can be connected to one of the ordinary whistles, every signal being sounded automatically when once set. There is, however, an objection to the use of several sounds of different pitch, owing to the well-founded belief that sailors will not readily distinguish them when the atmosphere is loaded with the watery particles forming fog; hence it is considered by many advisable to limit the number of different pitches to two, which, probably, may most conveniently be separated by the interval of an octave, the code to give the compass signals being built up of long and short sounds on the two notes. In the case of the siren trumpets employed around the coasts, Mr. Holmes has devised a method of construction, by which two notes can be obtained from one instrument, but at present it is not much used. The researches of Prof. Tyndall and the late Prof. Henry, have proved that no appreciable effect towards obstructing the transmission of sound is produced by either fog, rain, or snow, but there are certain peculiar states of the atmosphere, not yet thoroughly understood, when it is said to be acoustically opaque, although it may happen at the time that it is optically transparent. On these occasions, sounds generally heard distinctly to very long distances, seem to be dissipated by meeting with reflecting surfaces, and to fail in carrying-power, a phenomenon confined to no particular weather, but occurring as often during fine clear states of the atmosphere as during fog. A contrary wind has an important effect in connection with the transmission of sound; but, as Prof. Stokes explains, its action is indirect. When a sound is generated in perfectly still and uniform air, it is propagated or spread out in spherical shells; but when a wind is blowing, the difference in velocity of the strata of the atmosphere disturbs the spherical form of the sound-waves, and they are propagated with an upward direction which has the effect, so to speak, of tilting them up over the heads of observers; hence, sounds are often heard at the masthead which are inaudible on deck. These facts are of small moment in the case of vessels meeting one another; but where the object is to warn ships of their proximity to the coast they are of much importance. No fog-signalling apparatus yet devised can be trusted in all states of the weather to give warning to a greater distance than two miles, which is, however, deemed sufficient, as sailing vessels can wear and put about in a mile; but it is of importance that the fog-signals when heard should indicate the lighthouse to which they belong, and that, to a certain extent, is accomplished by varying the periodicity and duration of the sounds. The siren is the most powerful sound-producer known, and since 1874 a considerable number have been placed around our coasts and several on board lightships, which are, however, generally provided with gongs, a distinct and sufficiently powerful signal when the lightships are themselves in deep water, and vessels can approach near enough to hear the sounds. Sirens are, as a rule, worked by compressed air, supplied by hot-air or gas-engines, which also rotate the discs; but some are worked entirely by steam. In Holmes's modification of the cylindric siren, the escaping air is made to rotate the apparatus without the application of a strap from the engine. When steam is used a pressure of about 70lb. is required; but with air 30lb. suffices to give the best result in both cases, though the higher the pressure, and the larger the volume of the blast, the louder is the sound. The siren at St. Abb's Head, on the coast of Berwickshire, is always heard at a distance of two miles, and frequently at the Isle of May, which is distant more than a third of a degree, or 21 nautical miles. The disc in this siren is 12in. in diameter, it has 10 ports, and the pressure of the blast is 20lb. It makes 1464 revolutions per minute, thus giving a note due to 244 vibrations per second. In all cases, whether sirens or reeds, the trumpet attachment is used, and the sound producer is adapted to give its fundamental note. In the case of the reed, which is usually of steel or German silver, 18in. long, $2\frac{1}{4}$in. broad, and tapering from $\frac{5}{8}$in. to $\frac{1}{4}$in. thick at the free end, it is tuned by regulating the length of the vibrating portion, while the siren is adapted to its trumpet by regulating the speed of revolution, and consequently the number of vibrations. Experience has shown that while a musical sound is vastly superior in carrying power to a mere noise—though the latter may be initially much louder—the choice of note is practically limited between 180 to 420 vibrations per second, and the most effective is probably that due to about 250 vibrations. So far as the coast-marking fog-signals are concerned, there is little to be desired except some definite and easily understood system of distinguishing them; but there is room for improvement in the signals used by the mercantile marine, especially by sailing-vessels, and it may be that the late Exhibition at the Agricultural Hall will eventually be the indirect means of introducing a code of sound-signals, and a thoroughly satisfactory apparatus for producing them.

THE ACHROMATIC OBJECT-GLASS.—I.

BY W. BRADBURY ("ORDERIC VITAL").

> Nam possumus sic figurare perspicua et taliter ea ordinare respectu nostri visûs et rerum quod frangentur radii et flectentur quorsumcunque voluerimus.—BACON, "Opus Magus."

MORE than six hundred years have elapsed since that ingenious Englishman, Friar Bacon, wrote the above passage. "For," says he, "we can so fashion transparent bodies, and so arrange them with respect to our eye and the object, that the rays shall be refracted and bent into whatsoever direction we may desire." Thus it appears that even so early as the 13th century, it had been discovered that the direction of a ray of light was generally altered by the shape of the substance through which it passed. If the substance was in the form of a flat plate no perceptible alteration was caused; but if it was wedge-shaped the ray was thrown aside from its natural path. A still more wonderful appearance resulted; if the substance had a bulging or convex form—that is, when it was in the shape of a round disc, thick at the middle and rounding off to a thin edge. Rays traversing it were so disposed as to form at a certain distance behind it, a small inverted image of the object from which they proceeded. Or if the convexity was so great as to make the substance almost globular, the apparent size of small objects seen through it was much increased. Bacon writes:—"We can cause the Sun, moon, and stars to descend nearer to us in appearance." Such results were naturally looked upon as magical, and found a fitting notice in a book devoted to the mysterious and wonderful. But incomprehensible as such appearances were to those early students of nature, they were destined to yield results of momentous import to succeeding generations. They were the germs from which have sprung the modern telescope and microscope, two instruments which have enlarged man's knowledge of his surroundings more than any other scientific instruments ever discovered. By means of the former we can examine those brilliant orbs, of whose system the earth is but a small and insignificant member; while, with the aid of the latter, we can scrutinise those organic beings whose minuteness places them utterly beyond the reach of the unassisted eye, and of whose very existence we should otherwise be absolutely ignorant.

[*] It would be a difficult, if not impossible task, to find out who was the first to hit upon the arrangement of glasses constituting a telescope. In the present instance, we are not concerned with the history of the instrument, but simply with the development of one of its most essential portions. In a telescope there are two agents in operation: one, producing an image; the other, magnifying it. These are termed respectively, the objective or object-glass and the eyepiece. Telescopes may be divided into two classes: if the image-producer is a mirror, throwing back the rays to form an image in front of it, the instrument is a *reflector*; but if it is a glass lens, through which rays pass to form an image behind it, the instrument is a *refractor*.

With regard to the first-mentioned class, exhaustive details of several methods of working mirrors have appeared in the pages of the ENGLISH MECHANIC; and anyone with mechanical aptitude, and plenty of patience and perseverance, has all necessary instructions for the production of a good instrument. But the same cannot be said respecting the refractor. Information relative to the final corrections of an object-glass is scarce, and the extent to which these corrections can be, and are, carried out, constitutes the chief difference between a good and an inferior instrument.

The production of an achromatic object-glass is a much more difficult undertaking than that of working a truly parabolic reflector; instead of one surface, four are requisite, which, though less in area, need equally careful fashioning. A certain proportion of foci has also to be observed, which proportion can scarcely be arrived at, except by experiment on the glasses intended to be used. An eminent authority tells me, that two discs of the best glass, classed in the same brand, seldom give equal results with the same curves and methods of working; a very slight variation in their optical qualities, though both may be equally good, necessitating a change in curvature. But the procedure adopted in the figuring of one optical surface should, to a very great extent, hold good in the case of another; hence I regard the investigations of Mr. Wassell as most important contributions to the literature of the subject; being of extensive application in the general production of optical surfaces, as well as of special service in figuring specula.

During the last five years, I have occasionally contributed to the pages of the ENGLISH MECHANIC, articles on the mathematical treatment of the object-glass. I have endeavoured to explain the rules of Barlow and Coddington, embodying therewith the tabular values of Herschel,* and to arrange them in a convenient form for reference. Opinions may differ as to the value of optical formulæ. Those who cannot understand it, or have no need of it, are apt to look upon optical equations as so much incomprehensible nonsense: those who can use it intelligently, as a guide to practical work, think otherwise. After making a little inquiry, I am able to say that the formulæ above-mentioned are found of considerable service to practical men, though, of course, this does not imply that equally good results may not be accomplished without them. Mathematics, in relation either to optics or to any other science, must be no more than a servant, ready to obey the will of the master. What the mind conceives, mathematics can express in a definite, tangible form; but unless we have a correct apprehension of what we mean by the terms we employ, formulæ containing them can only be a source of confusion.

---

[*] I am indebted for most of the historical matter herein contained to an able article on the Telescope, by PEARSON, in Rees' "Cyclopedia."

But even the possession of correct rules, and the necessary knowledge how to apply them, is only one element in the production of an object-glass. Any one who works a set of curves, calculated by one or other of the preceding formulæ, would probably find the result fall far below his expectations; yet I apprehend he who would use a set of curves merely because some one else found them to answer admirably, would have even greater cause for complaint. It must be remembered that, algebraically, the specified radii produce partial correction only; also, it is further assumed that the optical properties of the glass agree with certain figured values, and that the surfaces can be wrought correctly to certain curves, neither of which conditions can be absolutely satisfied. The values yielded by any recognised formula must, therefore, form the foundation only upon which the superstructure is built, and the goodness of the object-glass will depend upon the extent to which it is possible to employ that delicate manipulation, which raises the production of the artist so far above that of the mere workman.

In the present series of articles I purpose showing, so far as I am able, the theoretical conditions that must be satisfied in the formation of an object-glass. It may seem unnecessary to dwell upon this subject at any great length, but circumstances will probably cause it to be otherwise. It has been suggested to me, that if theory can show approximately the form of surface required, it will be easier for the practical man to explain the mode of working which such a form necessitates, or to show where and how the practical differs from the theoretical form. I am also anxious to place on record some account of the practice of the early artists. Information on such matters is not very plentiful. I have been able to collect but little, yet I trust it may induce others who possess such knowledge, or who may have ample means of reference to published works, to send to these pages whatever details they may have, and thereby render the subject as complete as possible.

I am induced to attempt the preparation of these articles solely by the consideration that there is one who is both able and willing to take up the practical part. Had it been otherwise, I could not have asked our most obliging Editor to grant space for matter which must be wearisome to many and uninteresting to others. I am sure the readers of the English Mechanic have good cause to congratulate themselves that there is amongst the circle of correspondents so accomplished a contributor as "Prismatique." Having been for many years in actual contact with the best work and best methods of working, he can speak authoritatively on the subject of optical manipulation; and readers may rest satisfied that the instructions he has already given, and those which in due time I feel assured he will also give, are such as could, or would, be furnished by very few indeed. I can also count upon the hearty co-operation of Mr. Wassell, whose exhaustive details on specula-working, lead me to think, that we may confidently look to him for simplifications and improvements in the methods of working object-glasses.

---

* I have not been able to give an account of the analysis of Sir John Herschel, as I have not access to the "Philosophical Transactions" for 1821, which contains his paper. Perhaps those who have will send an abstract to these columns.

THE BOLTON RANGE FINDER.

In the annexed engravings we illustrate the application of a range finder, patented by Mr. T. Bolton, of Calcutta, being a modification of the system used by Major Weldon, R.A. It is a small reflecting instrument, light and durable, which is carried as an attachment to the belt when employed for military purposes. A range of 1,000 yards can be taken by two men with the assistance of the instrument in two parts and a tape, in less than 30 seconds; 2,000 yards in 60 seconds, &c., after a few minutes' instruction in the use of the instrument. Size of each, 2in. by $1\frac{3}{4}$in. by 3in., including handle; weight of each, 5oz. Fig. 1 shows the method of taking a range by two men. Both stand facing each other, having decided upon some object, the distance of which is required, and which should be seen reflected in the mirrors of both instruments. No. 1 at A, with the instrument marked "base 1 in 40," and the case containing the tape marked "the Range" stands still, and, presenting the open face of the instrument towards the distant object C, applies his eye near the edge of the open face of the box, and looks through the aperture above the reflector on the opposite side, seeing by direct vision, the instrument held by No. 2, and the reflected image of the distant object, to the right or left, in the mirror below. No 2, with the instrument marked "right angle," faces towards No. 1, and, holding the end of the tape, moves away in a direction at right angles to the distant object C, and is guided by observing that the instrument held by No. 1, as seen by direct vision through the aperture, coincides with the reflected image of the distant object as seen in the mirror. When No. 1 observes in his mirror the image of the distant object coinciding with the instrument held by No. 2, as seen by direct vision through the aperture, he stops paying out the tape, which is being run out by No. 2, and reads off the range in yards. No. 2 in moving out should stop at intervals, and holding his instrument steady, in correct alignment, notice any pre-arranged signal from No. 1, by the raising of his arm a certain height as to whether he should move out further, or come in, to find the correct position B.

Fig. 1.

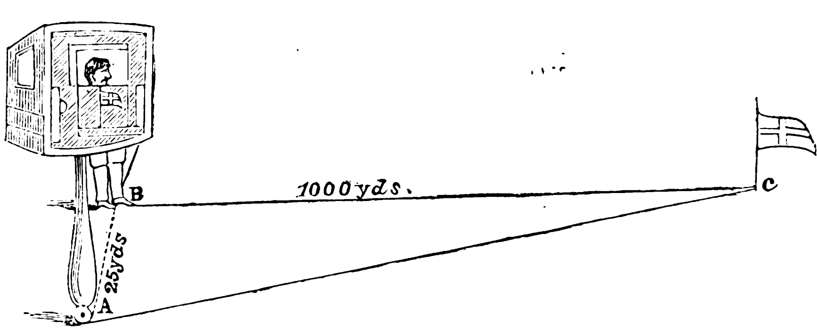


Fig. 2 shows the method of using the instrument, as adapted for one man in survey reconnaissances. Accurate distances can be measured by one person having one instrument, tape, and two staves or poles in a few minutes without any calculation. Size of instrument, 2in. by $2\frac{3}{8}$in. by $3\frac{3}{8}$in. including handle. Weight 8oz. Let the distance of an object O from the observer at A be required; set up the tripod staff at A, and by the upper mirrors or right angle of the instrument lay off the right angle O A B, fixing the spiked staff some 10 or 20 yards distant from A at the point B. Should it be found, on reverting to A, that staff B has not been placed in the correct position, the staff A should be moved a little to the right or left by the adjustment provided on the top of the tripod, till the right angle is correctly formed by the reflected image of O coinciding with the staff B, seen by direct vision; care being taken that the staves are set up perpendicular by the plummets attached. The observer then proceeds to lay off the base A C; he fixes the pin attached to the tape under staff A, and, being guided by the staves A B, he walks backwards in the same straight line, allowing the tape to run from the case as required; and, holding the box to his eye as before, he looks into the lower reflector of the instrument marked "base 1 in 20 or 40" until he gets to position C, when the staves A and B, seen in a direct line through the aperture, coincide with the image of O, as seen by reflection in the mirror, at which place he reads off the range from the numerals on the tape.

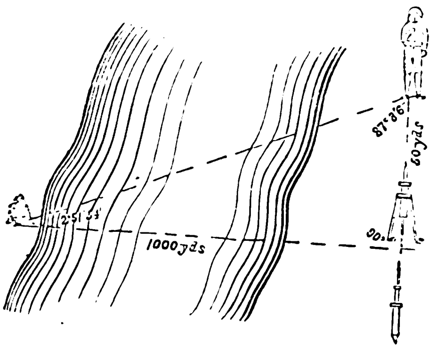
Fig. 2.



The instrument has been officially tested in India by order of the Commander-in-chief, and has been found so simple and efficient that it is being introduced into the British army there and the forces of the neighbouring independent States.

PRACTICAL NOTES ON PLUMBING.—XXXV.*

By P. J. Davies, H.M.A.S.P., &c.

(Continued from page 277.)

Next examine Fig. 202. This is a very handsome lavatory arrangement. The valves are shown fixed, and are of the lever kind, fitted as in Fig. 200, excepting that the pull arrangement is of the crank kind, see D, Fig. 202; this crank is also shown fixed in the skirting at E F G, and attached to the ends of the lever. H is the washer for fixing into the bottom of the basin, as at Q, Fig. 197. J is the straight Hunch trap, shown and described in Fig. 69, A, in the Building News of September 9th, 1881, (page 327, Vol. XLI.); great care must be taken to fix a proper-sized air or vent-pipe at vent, to such a waste-pipe. The water is in this diagram supplied through a lion-head inlet spout, but is not nearly so good as that shown in Fig. 200. The overflow holes are shown at B, and a separate pipe, I, taken right away to discharge over an open head, or otherwise. K is the hot-water valve for hand-washing or shampooing, L the cold; both of these valves are connected to the breeching-piece, and by indiarubber tube to the rose or jet.

Fig. 203. This is an angular lavatory basin showing the arrangement of pipes, valves, &c., together with breeching-piece and union, as at the left-hand side of the figure at ARM, HOT and COLD; it also illustrates the leaden breeching-piece on the right-hand side at cold. The hot water may flow up the pipe at A, whilst the cold may enter at "cold," and from there by the pipe B to the arm of the basin, and out at the shell inlet D. There is a new arrangement added to this lavatory basin—the

distilled water pillar ; this is supplied through a tin pipe ; *a* is also filtered water.

---

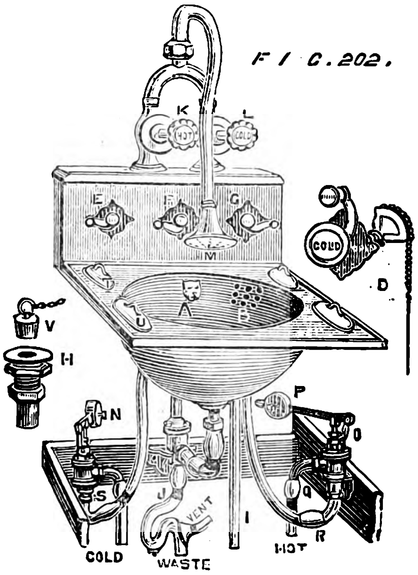

FIG. 202.

FIG. 203.

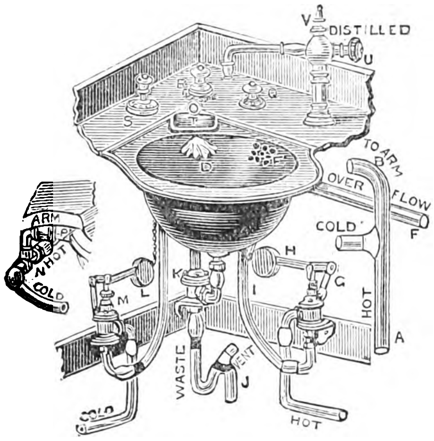

FIG. 204

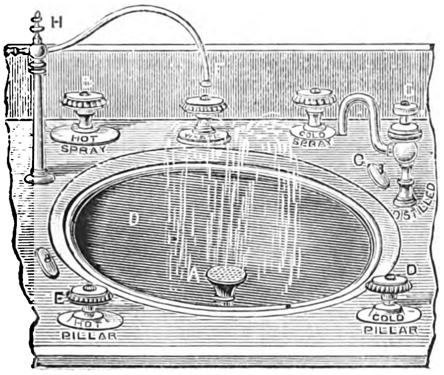

Fig. 204 illustrates the top part of a very beautiful lavatory, having some additional work. This has the usual waste-pipe, as at Fig. 198 (see waste-pull), it also has screw-down valves fitted below the slab instead of the lever arrangement. The reason for the employment of these screw-down valves is, that they may be adjusted to any pressure, so that the water may fountain or spray up at any required temperature or force. A shampooing pillar B is also provided with rubber tube and rose, which can be attached at a minute's notice, and in such a manner that both hands are at liberty to wash, &c. There is also a pillar G, for filtered or distilled water.

The hot and cold water supply valves are fixed below and branched one into the other, so as to allow the water to come up a small pipe fixed *inside* the waste-pipe, but quite separate from the waste-pipe and from each other; the most suitable valve for this work are the ordinary loose valve stop-cocks, fitted with hot-water rubbers and unions, as shown at A B, Fig. 205, or the valves may be of the Shank's, Fell's, or other makers' box pattern, for fixing upon the slab, as illustrated at Fig. 206. A is the cold inlet; B the outlet, which may be taken to the arm of the basin or to the bottom, as in 204; C is the hot inlet; D the outlet, which can be branched into the pipe B; or, as is now the case, be taken separately into the basin. Some plumbers have an objection to the use of valves, especially for hot water. Where this is the case, a good ground-in gun-metal cock must be used, which, under certain circumstances, is far the best. Such a cock, to work with levers, &c., is illustrated at Fig. 207. This is fitted with union A and B. The top of the plug or key has a square hole cored in, so that a square bar of iron will turn the plug or key, instead of having the cock-key K (Fig. 208). When the cock-plug has a square head, and the key K (Fig. 208) has to be used, take care that the rod of the key is not made too long to ride upon the plug of the cock, for, if allowed to do so, it will not only work stiffly, but be apt to jam, so that it cannot be moved to turn the hot-water off or on. Many bath-cocks work stiffly this this account. Occasionally, plumbers will use a three or four-way cock for the hot and cold supply to lavatory basins, such as shown at E J (Fig. 189). When this description of cock is used, caution must be exercised to fix a safe under the plugs, as, in a very short time, especially if working under a high pressure, they are sure to leak, owing to the sudden expansion and contraction of the metal, by reason of the rapid change of temperature caused by the hot or cold water. Another evil will be found if the gland D, in two, three, or four-way cocks, is screwed down too tightly, for these glands are invariably made in such a manner that, on tightening the gland down, the packing is made to *press upon the shoulder of the plug*, which, of course, tends to tighten the plug into the shell, and so cause jamming of the plug or key. It should be remarked that many "cockeys" (cock-makers) call a cock-plug a key (K, Fig. 208), and some a socket; while other firms call it a socket-key, and the handle B is called a lever, cock-lever, bath-handle, &c., &c.

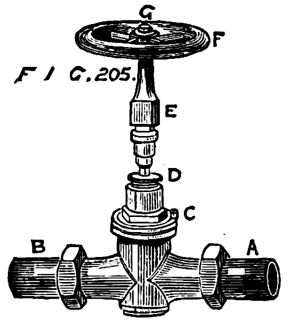

FIG. 205.

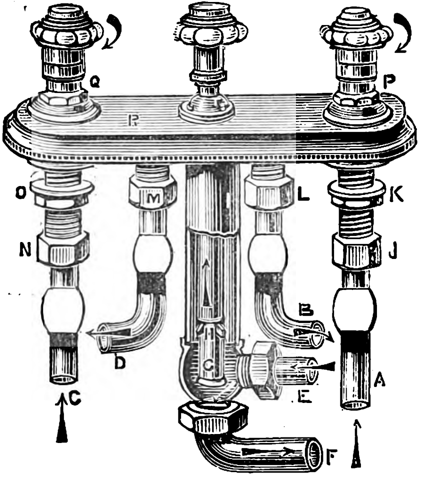
FIG. 206.



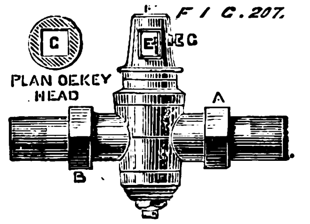


FIG. 207.

FIG. 208

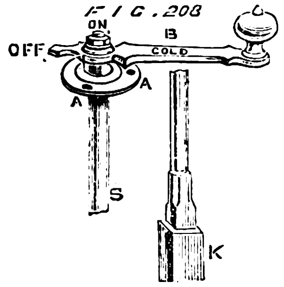

FIG. 209.

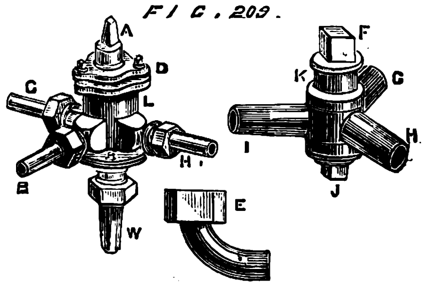

Fig. 210 is a lever having a pointer for indexing when the cock is open, shut, &c., and used for a three or four-way cock.

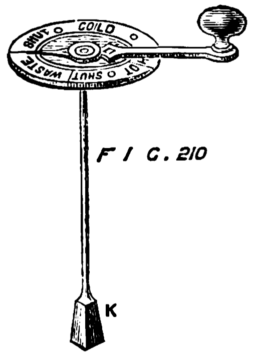

FIG. 210

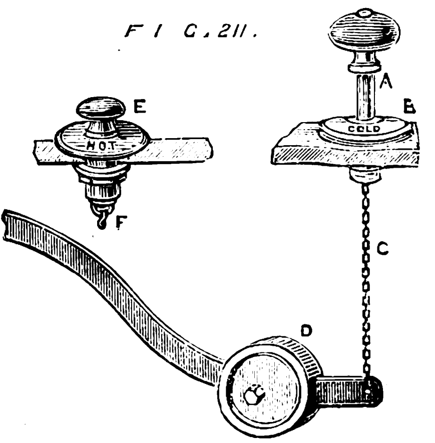
Fig. 211 illustrates a pull for screwing to the slab or top of the lavatory; A shows it when turned round and held up. This is done by a small pin working within a slot. I J H illustrates the pull and the fly-nut G.

FIG. 211.



THE ORGAN: A COMPREHENSIVE TREATISE ON ITS MANUFACTURE, PROCURAL, AND LODGMENT.*

By JOHN WATSON WARMAN,

Associate of the College of Organists, London.

[90, a.] IT remains only to add that there is one way of Cranking the *Key* which may often be found useful,—viz., by what may be termed *Crank-and-Return;* that is to say, each Key is so sawn out that it presents on *plan*, at the desired point, a small semicircular or segmental Arch, of a deflection equal to Key-tail Semitonal distance. The Sticker or the Wire then rises or otherwise proceeds from what we may call the centre of the crown of this Arch, and thus comes exactly over or under the spaces between the Keys of a Set that is not Skewed or Cranked in any way. By this means a set of Wires, or Trackers, or even of Stickers, may pass through one or more Manuals, and yet allow the latter to be Straight and otherwise unaffected,—as when it is desired to have a Drumstick Coupler working to and fro between such Trackers or Stickers running from said "Arches."

An *Instance* of the preceding Treatment—including a Drumstick Coupler—occurs, or did occur, in the fine 4-Manual Organ erected by Hill in All Saints', Margaret-street, London.

INSTANCES AND EXEMPLARIES OF MANUAL KEY SYSTEMS.

b, We now proceed to give a sufficient number of *Instances and Exemplaries* of Manuals, and of the Key and Coupling Actions immediately involved with them (the Injunctions given being, of course, in harmony with the Regulations just laid down),—which Exemplaries will, as I believe, be found the best under all Normal circumstances.

c. WITH ONE MANUAL. — In Instruments having but ONE Manual, the structure of the latter, and of the Action involved with it, is, or may generally be, of so simple and optional a character, that no particular directions will be here required,—considering that the present *Department* is that of *Manuals*.

d. WITH TWO MANUALS.—*No.* 1 *Treatment.*—This is an Instance furnished in the Organ erected by Nicholson of Worcester, somewhere about the year 1864, for the Parish Church of Faringdon, Berkshire. The Manual Sections are of the usual kind,—i.e., Great and Swell Organs. The Claviers are Projectant from the main Body of the Case, but are not Reversed; the vertical distance apart of the Manual Playing Levels is just under 3in. The General Lay-out of the Inside is of the Normal kind, so far as the Manual Sections are concerned, the Great and the Swell Soundboards being at one same level, and with the latter Section set behind the former; the Palletts of the Great-Organ, and consequently their Pulls, are set at that side of their Soundboard which is nearest to the Player, and they thus come nearly close to the Case-front; the regular Palletts and Pulls of the Swell-Organ are set in the same way, thus coming just beyond the Passage-Board which separates the two Manual Soundboards; but there is a second set of Palletts and Pulls, at the back of the Soundboard, to supply its lowest octave; the Pipe-Order of the Great is Semitonal with the Bass Set-off; and the Pipe-Order of the Swell is with Smallest Pipe at middle. The number of Sounding-Stops is 18. Fuller particulars of this Instrument will be given in *Department* ENTIRE ORGAN.

The Great-Organ Keys are of ample length (see here at *r*, *Bis*, ante), and are perfectly Straight on Plan. The Swell-Organ Keys are of such length that their Tails a little overhang the Great-Organ Key Tails, and are on Plan Skewed aside, so that such [Swell] Tails are exactly the Half Semitonal Key-tail distance "out" (to the *right* hand; see here at 93, *s*). Each Swell-Organ Key is, at a point near its Tail end, Notched-out on both of its side-faces, in order to furnish an opening or passage for the Stickers next mentioned,—these latter having to pass between the Swell Keys without touching them, and consequently without deriving any Guiding assistance from the said Notchings in them (see here the more detailed description already given, at *u*, ante).

The Great-Organ Action commences with a sufficiently long and wide flat Sticker, rising from and Wired into each Key-Tail, and passing—as just said—between the Tails of the Swell-Org. Keys. These Stickers, each of which is provided at its top end with a Regulating Button, act under the Noses of a set of Fanned Backfalls which run at once (excepting of course those for the Set-off Pipes) to the Pull-points vertically beneath each Pallett,—the direction of such running being thus from the said Stickers to a point farther into the Organ than are the latter. Concerning the actual width of these Stickers see more definitely at *h*, next, 7th paragraph.

The Swell-Organ Action commences with a Square of the ┬ form, resting on and thus being in direct contact with each [Swell] Key-Tail. It is, of course, the fore Nose of such Square which is so in contact, the vertical Arm of the same being thus behind its Key-tail, and extending downwards in the usual way for drawing a horizontal Tracker; and the remaining horizontal portion of the Square thus projects backward into the Organ,—in order to form a member of the Coupler Manual to Manual. These Squares are not Fanned, but are set square and parallel,—running direct to a "Whole" Roller-Board.

The structure of the said Coupler Swell to Great is made, with the aid of the rear arm of the ┬-Square aforesaid, by a set of Backfalls, a set of Stickers, and a set of Blocks. The Backfalls are all placed square and parallel, and at the Half Semitonal Key-tail distance apart, and are thus, on Plan, exactly correspondent with the Swell-Org. ┬-Squares: the length of each such Backfall (see here at *g*, next, 2nd parag.) is such as to just exceed the horizontal distance from the rear end of the said ┬-Square to the fore edge of the Great-Organ Sticker. These Backfalls are set at as great a height above the Swell-Org. Manual as is practicable (see again *g*, next, 2nd parag., Defect 3; and at *h*, next, last part of 3rd parag.), and at such an area posit that their fore Noses enter just between the Great-Org. Stickers; consequently, the rear ends of these Backfalls come—the Swell Key Tails having (as already said) been Skewed—exactly vertically over the rear ends of the ┬-Squares. A Sticker, having its lower end furnished with a Regulating Button, runs down from each Backfall rear-end to the corresponding rear-end of the ┬-Square, thus uniting these two ends. Affixed to the side-face of each Great-Org. Sticker, and at such a level as to come exactly beneath the fore-Nose of the Coupling Backfall, is the small driving-Block,—Buffed at its top surface. The Coupler is, of course, thrown into or out of Action by the lowering or the raising of the Beam carrying its Backfalls.

The Contact of the Coupler Great to Pedale is made by means of an Ordinary Sticker, Wired into the Tail end of its Manual Key in the usual way (see here again at *r*, *Bis*, ante).

The Contact of the Coupler Swell to Pedale is made (see *g*, next, 3rd parag.) precisely as is the Great to Ped., except that, owing to the presence of the Square Nose directly on the Key-tail, the Wire of the [Swell to Ped.] Sticker is obliged to be kept sufficiently forward to allow the said Nose to be set behind such Wire.

e. The Treatment that has now been described possesses a large number of good points, of which the chief are the following:—(1) There is no actual Crossing of one *Action* by another, the passing of the Great-Org. Sticker between the Swell-Org. Keys being really all the Crossing existent. (2) The Great-Org. Manual easily admits of Regulation at the Front—by means of the Button already mentioned—, and this without disturbing the Regulation of the Coupler Swell to Great. (3) The whole of the Coupler Manual to Manual can be easily and quickly Removed, and taken entirely to pieces. (4) The Swell-Org. Keys, *except* those connectable with the Pedale (see *g*, next, 1st parag.), are also readily Removable. (5) The Manual-to-Manual Coupler, even when taken all to pieces, can be made to retain its Regulation unaltered, because every piece of which its mechanism is composed admits of being Numbered. (6) Simplicity is ensured in the structure, as all the Actions consist of the fewest practicable number of parts. (7) The amount of the work Skewed is slight, being confined to the Swell Keys, and to the Backfalls of the Coupler Swell to Pedale; and the Skew of even these is definite and easy, being *exactly* (see *m*, next, 11th parag.) the Half Semitonal Key-tail distance. (8) The Overhang of the Swell-Organ Key-tails gives an approach to uniformity in the lengths of the Keys of the two Manuals (see *g*, ante). (9) The Man.-to-Man. Coupler is rendered perfectly independent of any Skewing or Fanning in the Backfalls which lead from the Great-Organ Keys. (10) The Fanning of these Great-Organ Backfalls permits of the 1st Stickers of this Section's being made of good length,—desirable in this particular case (see again *g*, next, 2nd parag., Def. 3; and *h*, next, last part of 3rd parag.), and yet for the Wind-chest of such Section's being kept at a level sufficiently low to avoid difficulties through restricted height,—such restriction also being here the fact (see *l*, next, 4th parag.): a *Whole* Roller-board to the Great Organ would, indeed, have been here almost impracticable,—at all events with Wooden Roller-stocks.

These Advantages speak for themselves. As regards the second-named of them, the reader should now turn to certain Heads (as at *m*, next, 11th and 13th parags.) for some abstract consideration of the question of Front Regulation, and as to under what circumstances it is, and under what it is not, desirable. As concerns the seventh named, it is to be borne in mind that the Skewing of the Keys of one of a pair of Manuals, and the consequent "throwing out" of one set of Key-tails relatively to the other set, are not here in one respect of moment, because, as one same Pipe Order is *not* observed in the two Manual Sections, one Setting-out cannot possibly be made to serve for *both* of the Roller-boards of such Sections: also the Skewing of the Swell-Org. Keys here prevents any Skewing in the Backfalls of the Coupler Swell to Great. But the said throwing out interferes with the provision of a *Clear* Coupler (see directly with *Defects*, at *g* next, 1st parag.).

At this point collate the present Arrangement with that of the Hoddesdon Instrument (comm. at *m*, next).

(*To be continued.*)

WATCH-CLEANING AND REPAIRING.

By "A FELLOW-WORKMAN."

(*Continued from page* 277.)

YOU will find that the drill-bow is not satisfactory, as the chuck being rather heavy, it objects to being suddenly stopped and reversed in motion, which should be done very carefully; but a driving-wheel may be easily fitted, by having your standard B about 6in. higher than the rose at A. A wheel may be fitted as shown Fig. 58, which will enable you to turn out some excellent work; but everything depends upon the way in which you go to work; it is the general fault with amateurs to be over-anxious and impatient: they want to get the job done to see how it will work; they don't give themselves time to think about what they are doing. They file away at random, don't stop to see whether they are filing round or flat, offer it when it is too late, then *try* and make a "do" of it, succeed in making a "neetle creeper" of it, then try and do a job with it. After wasting time and material, they come to the conclusion that "they don't believe it is possible for anyone to do it"; but if you will follow my advice, I will show you how to make one of the prettiest and most interesting tools that ever entered a workshop, at a very trifling cost. A, Fig. 54, is made of steel, with brass rose or ferrule; it should be turned up, and drilled in the turns; the standard B should be made of brass, and should be stout and firm, cut out a piece at the bottom so as to fit firmly over the body of your turns, then make a square hole right through and drive in a plug, or wedge R; now cut a slot in B to receive foot J, and dovetail it in, same as in a potence, and make it firm with soft solder; put it in its place in the turns; now put on piece which holds drill H, which should run a true centre; push the drill up against the face of B, and make a centre mark; now remove drill and put in its place a female centre; now take a good pivot-drill, shorten it by cutting it off with a file—don't bend it, as it is necessary that it should be perfectly straight; leave sufficient of the drill to go just through B. Now put the back of drill in female centre, and point of drill in the centre mark on B. Turn the drill gently with a light bow, and press lightly with the bar having the female centre; when you have drilled half-way through B, go through a similar operation on the other side of B, and, if you have worked true, your holes should meet. Now take a piece of steel wire a shade smaller than the hole required, put it in the turns and turn a point at the end (that should be true with the outside) the same size as small hole already made in B. Now make the end, as shown Figs. 59 and 60, the cutting edge should be at angle, A to B, Fig. 59. If you get it too acute it will jabber; you must use a half-round file to get the sides. Fig. 57 is the driving-wheel, A is Fig. 56, B is standard, C handle, D wheel, E pinion, which is held by nut screwed on other side of B, and a little pin to hold wheel from slipping off. The wheel should be made of hard wood, weighted with lead. The groove can be made, after the wheel is weighted, by setting it spinning and holding some sharp instrument against it, unless you can get some friend to turn you up one. Now turn up a harbor for chuck C 57, fit it into chuck and solder it. Now I will return to the barrel: you make the small hole first to fit the small pivot of arbor: if the large hole is in the cover, you can then make large hole; but if the large hole is in barrel you have simply to remove the cover and *enlarge* the other hole.

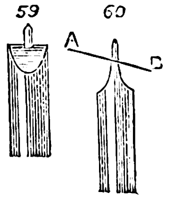
FIGS
59 60



(*To be continued.*)

A LIGHT ELECTRIC MOTOR.

UNDER the heading "Etudes Préliminaires pour la Construction d'un Moteur Electrique Léger," M. Tissandier gives, in *La Nature*, an instructive account of a bichromate battery and experiments made with it. After numerous experiments for determining the best composition of the exciting liquid, the nature of the receivers, the limits of thickness one might give the carbons and the zincs, the number of these latter in each element, in order to a maximum production with a minimum weight, he was led to make a large surface-model, which has so far given satisfactory results. The twenty-four elements mounted in tension, drove a small Gramme motor of half-horse power. The work produced, measured with a Ruffard brake, was about 14 kilogrammetres* per second during an hour, and 10 kilogrammetres in the following hour. The Gramme motor was not specially made to work with the batteries, and the conditions were unfavourable; still, it is proved that bichromate batteries offer much greater constancy than has been supposed.

The new type of battery consists of an ebonite trough 3mm. thick, and measuring 0·35m. long, 0·16m. deep, and 0·14m. broad. In it were placed vertically thirteen carbons and twelve amalgamated zincs alternately. The carbon-plates are 2½mm. thick, the zinc plates about 1mm. These plates are fixed with pincers to longitudinal bands of copper, which, in their turn, are screwed on the outer edges of the ebonite trough. Notwithstanding its lightness, the element thus mounted is very solid, and may be shaken violently without carbons or zincs being the least deranged.

The ebonite vessel has, at its lower part, a tubulure by which it communicates through a caoutchouc tube, with a receiver containing bichromate solution. On raising the receiver above, or lowering it below, the level of the battery element, the latter is filled or emptied; that is, is made to act or stopped. The element contains about four litres of liquid;† and the solution being very concentrated, its electric resistance is less; so that the interior resistance is diminished to advantage of the production. The total weight does not reach 8 kilog.

The production (*debit*) of this battery is variable, and may become very considerable when the exterior resistance is slight. In an experiment with a hot and very concentrated liquid, a mean current of 110 ampères was obtained during 20 minutes, with a difference of potential at the binding screws of 1·68 volt. This represents a yield in disposable work of 18 kilogrammetres per second. The ebullition was so impetuous that the liquid was driven violently out of the vessel, putting an end to the experiment. Under these conditions, the electric energy at disposal corresponded to a horse-power with a weight of 33 kilog. One would not seek to obtain this result practically; but the efficiency in normal conditions is still pretty favourable with a less production; and then the battery will work in a continuous and constant manner during an hour and a half to two hours.

The following figures give a fair idea of what may be obtained; they are the average of a series of experiments made on resistances of variable discharge.

A battery of eighteen elements, mounted in tension, weighs 140 kilogs. In a circuit of 0·54 ohms resistance, it will give a disposable electric energy of 135 kilogrammetres per second during about an hour and a half, with a current of 50 ampères. A suitable motor will yield, at the brake, 100 kilogrammetres of the 135 at disposal in the exterior circuit. The motor will weigh about 50 kilograms; thus the result reached is as follows:—

With a weight of 200 kilogs. battery and motor, it is possible to produce a continuous and constant work of 100 kilogrammetres per second, during an hour and a half.

But this result (the author proceeds) obtained in our preliminary researches is far from being the "last word" in solution of the problem of light batteries with large yield. Some experiments already made enable us to affirm that the production of electricity may be prolonged. (1) By agitating the liquid, which is easy with use of communicating vessels; (2) by adding fresh quantities to the warm and exhausted liquid ; (3) by using M. Reynier's enveloper (or partition) for the negative.

A battery of 18 elements, weighing 140 kilog., the weight of two men, might thus, very probably, furnish, during more than two hours, a work of 1¼ to 1⅓ horse-power, or of 12 to 15 strong men. Such a battery with its motor, would be easily raised in a small elongated aërostat, presenting little resistance to the air.

M. Tissandier further studied the mode of action of a two-vaned screw (2·8m. in diameter), driven by a small Siemens dynamo, weighing 65 kilogs. The vanes had an inclination of about 35°. The motor was actuated by Faure accumulators, made by M. Reynier. With 40 of these, mounted in tension, the screw made 100 turns in the minute, the coil of the motor making a thousand; the work was about 80 kilogrammetres.

The air-current produced was intense at 102 metres from the apparatus, and could be felt distinctly at 10 metres distance.

---

* It may be useful to remind readers that the kilogram = about 2⅕lb. avoird.; the metre 40in.; the millimetre ·04in.; the litre 1¾ pint.

† The composition of the liquid (in weight) is: water, 100 parts; bichromate of potash, 16; sulphuric acid, 37.

THE ELECTRIC ARC IN VACUO.

IN a note communicated to the French Academy of Sciences, MM. Jamin and Maneusier describe some experiments they have made with an electric arc in vacuo, the current being furnished by a Gramme machine. Having taken an egg-shaped glass tube and placed in it two carbons of ·15 metre length and 4 millimetres diameter, arranged point to point, and separated by an interval of 4 millimetres, when the vacuum had attained about 12 millimetres light began to break forth, not only in the form of a highly-luminous arc between the carbon points, but from all parts of the carbons, and similar in appearance to that ordinarily seen in Geissler tubes. Each carbon was surrounded by a blue aureola, that of the positive carbon being the paler. The carbons subsequently became heated, reddened, and then got white hot, not only at their ends, but throughout their length; they were then rapidly volatilised by the combined effect of the heating and the electrical currents. Whatever be cause of this volatilisation it is certain that carbonaceous matter is given off in a vaporous state. The vessel or tube is filled with a blue gas somewhat similar to the vapour of iodine which gradually deepens to the colour of indigo. Afterwards the vapours are condensed on the sides of the vessel, which become opaque, and that ends the experiment. The deposit thus collected resembles finely-divided carbon, and dissolves with effervescence and incandescence in nitric acid. Is it pure carbon, or is it a composition of hydrogen and carbon? This is a question which is reserved for further experiments. To avoid this summary termination of the experiment, the single carbons were replaced by two bundles of similar carbons. In this case, the currents divided into a large number of flows, less intense than the single flow; all the carbons gave light at the same time, and, heated the less, the more numerous they were. There was hardly any volatilisation, and the effect was prolonged as long as one wished. The carbons were then replaced by copper rods ·003 metre diameter. The same effect was produced with still greater success. If the current was too strong the copper melted. It always partly volatilised, and was deposited in a thin layer on the glass. It is plain that the experiment can be varied by using different metals, different gases, and by operating under different pressures.

WHY WE COUGH, AND HOW WE COUGH.

EVERYBODY coughs sometimes, and, judging by the quantity of patent cough medicines sold, many people must be coughing all the time. Most persons suppose that a cough is a cough, the world over, and what will cure one will cure another; and so they prescribe for themselves and their friends all sorts of sirups, home made or proprietary, with the consoling assertion that "it can't do any hurt if it don't do any good." How do you know it can't do any hurt? Do you know its ingredients, and, if so, have you studied their effects upon the system in health and in disease? Do you know the condition of the patient you are prescribing this for—his constitution, his habits of life, his past history?

Let us see what a cough is. It is a sudden and forcible expulsion of the air from the lungs, preceded by a temporary closure of the wind-pipe to give additional impulse to the current of air. The effect of these spasmodic expirations is the removal of whatever may have accumulated in the air-tubes, whether a foreign body from without, as when a particle of food finds its way into the wind-pipe, or an accumulation of mucus secreted by the air-passages themselves.

Coughing is in part a voluntary act. We can cough whenever we wish to, but frequently we are compelled to cough when we don't wish to. Nerves are divided into two classes, sensory and motor nerves. The former carry intelligence to the brain; they report any disturbance on the frontier to headquarters. The motor nerves then carry back the commands of the general to act. You tickle a friend's ear with a straw, and his hand automatically proceeds to scratch the itching member. A tickling sensation is produced in the throat by any cause whatever; the brain then sends back orders to the muscles concerned to act so as to expel the intruder, in other words to cough. And that is how we cough.

The source of the impressions may be various. Frequently it is due to an irritation of the respiratory organs by foreign bodies, dust, and acrid vapours, admitted with the air in health, or to damp, cold air itself, if the organs are particularly sensitive, or to the presence of mucus, pus, or blood, in disease. Inflammation, from whatever cause, acts as a source of uneasiness.

There are, as we all know, many different kinds of cough. Thus we have the dry cough without expectoration, and the moist cough with expectoration. We have the short, hacking cough, resulting from slight irritation, and the violent, spasmodic, and convulsive cough, caused by a greater degree of irritation or some peculiar modification thereof. Then there are the occasional, the incessant, and the paroxysmal cough, terms that explain themselves. Hoarse, wheezing, barking, and shrill coughs are due to the tension or capacity of the rim of the wind-pipe or other portion of the tube. The hollow cough owes it peculiar sound to resonance in the enlarged tubes or the cavities in the lungs, if such exist. Sometimes the exciting cause of a cough lies not in the lungs and respiratory organs, but in the stomach, liver, or intestines. In other cases there seems to be no real cause; it is purely nervous or hysterical.

Cough remedies should be suited to the kind of cough in question, and attempt, if possible, to remove the cause. It is evident that a cough may be lessened either by removing the source of irritation, or by diminishing the excitability of the nervous mechanism through which it works. Both methods are generally employed, and most of the popular cough medicines consist of an expectorant and a sedative, in some mucilaginous or saccharine menstruum. Sedatives lessen the excitability of the nerve centre through which the act of coughing is produced. Opium in sufficient quantities will stop any cough, but if the secretion goes on accumulating, the patient must be allowed to cough, or he dies of suffocation.

Glutinous and saccharine substances lessen irritation, and as it frequently happens that much of the irritation which occasions the cough exists at the root of the tongue, and in portions of the throat which can be reached by troches and lozenges slowly dissolved in the mouth; hence these often afford relief, especially in dry, hacking coughs and the so-called tickling in the throat. Iceland moss, marshmallow, and gum arabic belong to this class. Their power is probably due to their covering the inflamed and irritatable surface directly with a mucilaginous coat, and thus protecting it from the action of the air and other irritants. An inflamed surface, whether within or without, is rendered worse by friction; therefore, in bronchial troubles, the inflamed surfaces are greatly irritated by the very act of coughing. Hence, persons are advised to "hold in," or try to refrain from coughing. All coughing beyond what is absolutely necessary for the removal of the accumulated mucus should be avoided, because it injures the parts affected by friction, and because it exhausts the patient; or the muscular exertion involved in a violent fit of coughing is very considerable indeed, and the muscular effort exerted by a patient with a bad cough during the twenty-four hours is really more than equivalent to that of many a man in a day's work. Both sedatives and mucilaginous substances can be employed, then, to check the excessive amount of coughing over and above that required to relieve the lungs and bronchial tubes of their accumulated mucus. To facilite the removal of this, expectorants of various kinds are administered, according to the necessities of the case.

The difficulty in the way of recommending any one kind of cough remedy is that different coughs require different treatment, and what will relieve one may aggravate another. Then, too, the general health of the patient must be attended to, and the secretions kept open, etc. In short, the maxim, "What is one man's meat is another man's poison," applies here as elsewhere, and induces us to protest against the use of any nostrum simply because it cured a neighbour.—*Medical Weekly* (U.S.)

SOME NOTES ON ALLOYS.

In a recent work on "Metal Alloys," published in Germany, the author, M. Guettier, gives a few suggestions on the subject of fusing the metals:—1. The melting-pot should be redhot (a white heat is better), and those metals first placed in it which require the most heat to fuse them. 2. Put the metals in the melting-pot in strict order, following exactly the different fusing points from the highest degree of temperature required down to the lowest, in regular sequence, and being especially careful to refrain from adding the next metal until those already in the pot are completely melted. 3. When the metals fused together in the crucible require very different temperatures to melt them, a layer of charcoal should be placed upon them, or if there is much tin in the alloy, a layer of sand should be used. 4. The molten mass should be vigorously stirred with a stick, and even while pouring it into another vessel the stirring should not be relaxed. 5. Another hint is to use a little old alloy in making new, if there is any on hand, and the concluding word of caution is to make sure that the melting-pots are absolutely clean and free from any traces of former operations.

Soft Alloy.—This alloy will adhere so firmly to metallic, glass, and porcelain surfaces that it can be used as a solder, and is invaluable when the articles to be soldered are of such a nature that they cannot bear a high degree of temperature. It consists of finely pulverised copper or copper-dust, and is obtained by precipitating copper from sulphate, by means of metallic zinc. Twenty, 30, or 36 parts of this copper-dust, according to the hardness desired, are placed in a cast-iron or porcelain-lined mortar, and well mixed with some sulphuric acid having a specific gravity of 1·85. Add to the paste thus formed 70 parts (by weight) of mercury, constantly stirring. When thoroughly mixed the amalgam must be carefully rinsed in warm water to remove the acid, then laid aside to cool. In ten or twelve hours it will be hard enough to scratch tin. When it is to be used it should be heated to a temperature of 375° C., when it becomes as soft as wax by kneading it in an iron mortar. In this ductile state it can be spread upon any surface, to which, as it cools and hardens, it adheres very tenaciously.

Alloy for Small Articles.—This alloy melts at a lower degree of temperature than the one just described, and is very hard without being brittle. Bismuth 6 parts, zinc 3 parts, and lead 13 parts. The three metals, after having been well melted and stirred together, should be poured into another melting-pot and melted again. This alloy cools with remarkably clear-cut edges, and if the articles made of it are dipped in diluted nitric acid, then rinsed in clear water, and polished with a woollen rag, the raised parts of the surface will have a fine polish, while the sunken parts will have a dark grey, antique appearance, which forms a pretty contrast. The proportions of the different metals, dividing the alloy into 100 parts, are: bismuth 27·27, lead 59 09, zinc 13·64.

Alloy for Small Castings.—Bismuth 6 parts, tin 3 parts, lead 13 parts. This alloy should be melted, run into bars, and laid aside till wanted, when it should be remelted. Bismuth 3 parts, tin 1 part, lead 1 part. This second alloy for small castings is harder, and yet it is not brittle. It can be finished with a contrasting surface of bright polish and dark grey, if it is washed in nitric acid, well diluted, rinsed, and polished with a woollen rag, as described in the alloy for small articles, given above.

White Alloy.—This amalgam can be turned, filed, and bored; does not adhere to the mould, and will retain its polish a long time after exposure to the air. Cast iron 10, copper 10, zinc 80.

Alloys for Medals, Coins, &c.—Kraft's alloy, melting point 104° C. Bismuth 5, lead 2, tin 1.

Homberg's alloy, melting point 122° C. Bismuth 3, lead 3, tin 3.

Rose's alloy, melting point 93° C. Bismuth 2, lead 2, tin 2.

Amalgam for Coating Plastic Castings.—Tin 1 part, mercury 1 part, bismuth 1 part. The quicksilver is to be mixed with the white of an egg, and added to the tin and bismuth when they are thoroughly melted and blended. The alloy while still hot forms a pasty liquid, which should be applied with a brush.

THE GREENWICH VISITATION.

The annual visitation of the Royal Observatory Greenwich, took place on Saturday last. The Astronomer-Royal, Mr. W. H. M. Christie, presented the annual report to the Board, which stated that the course of observation which his predecessor in office, Sir G. B. Airy, had carried out for so many years had been continued without essential alteration in the main features. No alteration has been made in the subjects of observation, which continue to be the sun, moon, planets, and principal stars, with other stars from a working catalogue of 2,500 stars. It is proposed soon to prepare a new working list, extending the catalogue to stars of the sixth magnitude. About 1,600 stars were observed in 1881. Observations with the transit circle made in the year ended May 20 were as follows:—Transits, the separate limbs being counted as separate observations, 4,374; determinations of collimation error, 304; determinations of level error, 312; circle observations, 4,283; determinations of nadir point, 311; reflection observations of stars, 394. Fifteen observations of Comet *b*, 1881, four of Comet *c*, 1881, and six of Comet *a*, 1882, have been obtained on the meridian S.P., the latter being continued. A new determination of the flexure was made on January 2 last, the resulting value being + 0 03″. The mean of time determinations since the beginning of 1879 is + 0·13″. The following observations have been made with the altazimuth for the year ended May 20:—Azimuths of the moon and stars, 697; azimuths of the azimuth-mark, 404; azimuths of the collimating-mark, 410; zenith distances of the moon, 404; zenith distances of the collimating mark, 406. The number of places of the moon observed is, with the transit-circle, 108, or 8·8 per lunation; with the altazimuth, 190, or 15·4 per lunation. The diameter has been measured, with the transit circle, three times in R. A., 13 times in N. P. D.; with the altazimuth, 13 times in azimuth, 35 times in Z.D. Thirteen occultations of stars by the moon (10 disappearances and three reappearances) and 30 phenomena of Jupiter's satellites have been observed. Comet *a*, 1882, has been observed on seven nights with the Naylor equatorial. The solar eclipse of May 17th was observed for determination of the corrections to the moon's R.A. and N.P.D. and to the diameters of the sun and moon. During the eclipse, which only lasted an hour and 12 minutes, 18 differences of R.A. of cusps, 10 differences of N.P.D. of limbs, and 9 differences of N.P.D. of cusps were observed. A few sketches of Mars were made last December with the south-east equatorial, and on December 30th a measure was obtained of an object supposed to be Deimos, the outer satellite. The sun's chromosphere has been examined with the half-prism spectroscope on 36 occasions, and each time prominences were seen. On one day, a detailed examination of the whole spectrum of the chromosphere was made at 24 points of the sun's limb. Several prominences have shown great changes in the course of two or three minutes, and large displacements or contortions of the bright lines have been noted. In particular, a prominence examined on May 13th was observed to rise through a space of about 30″ in less than two minutes, being at the rate of about 110 miles a second, while the C line showed a displacement towards the red, gradually increasing from 1¼ to 11·4 tenth-metres, corresponding to a motion of recession increasing in two minutes from 36 to 330 miles a second. A comparison of the successive determinations of the motion of Sirius indicates a progressive diminution from about 22 miles a second, in 1877 and 1878, to about seven miles a second, or less, this year, and, as other stars do not show anything similar, it appears likely that the change is due to the orbital motion of Sirius. Photographs of the sun have been taken on 200 days, and 352 have been selected for preservation. There were only two days out of 200 on which the sun's disc was observed to be free from spots. There has been a large increase in the number and size of spots and faculæ, the mean of the daily arrears for each in 1881 being nearly double those for the year preceding, and the increase is still continuing, though with well-marked fluctuations. A very remarkable outbreak of spots occurred in April last. The following are the principal results for magnetic elements for 1881:—Approximate mean westerly declination, 18° 27′; mean horizontal force, 3·915 in English units, 1·805 in metric units; mean dip, 67° 33′ 45″ by 9in. needles, 67° 34′ 54″ by 6in. needles, and 67° 35′ 5″ by 3in. needles. On September 12 and 13 and April 16 and 19 magnetic storms have occurred, the latter being of more marked character than any that have taken place since the great storms of the year 1872, and it is a significant fact that exceptionally large spots made their appearance on the sun shortly before. Smaller magnetic movements are now also much more frequent, exhibiting a marked constrast to their general appearance some two or three years ago. In regard to the long-period variation of about 11 years, it can now be stated definitely that the *minimum* as regards diurnal range of declination occurred at the commencement of 1879, while, as regards diurnal range of horizontal force, it occurred unmistakably earlier, about August, 1878. The mean temperature of the year 1881 was 48·7°, being 0·6° lower than the average of the preceding 40 years. The highest air temperature was 97·1° on July 15th, and the lowest 12·7° on January 17th. The mean temperature was below the average 6·7° in January and 4·8° in October; and above the average 5·9° in November. In other months the temperature differed little from the average. On four days in July the temperature rose above 90°. The mean daily motion of the air in 1881 was 291 miles, being 12 miles greater than the average. In January and September the mean daily motion was 70 miles and 72 miles below the average respectively; in April, August and November it was 70 miles, 60 and 71 above the average respectively. The greatest daily motion was 999 miles, on October 14th, the day of the great storm, and the least, 59 miles, on May 25th. A velocity of 61 miles an hour was recorded on October 14th, and one of 58 miles on April 29, these being both greater than any recorded in previous years. The greatest pressure was 53lb. on the square foot, on October 14; on April 29 a pressure of 49½lb. was recorded at a time when the hourly velocity was 50 miles. The number of hours of bright sunshine recorded by Campbell's sunshine instrument during 1881 was 1,301, which is more than 100 hours above the average of the four preceding years. There has been only one case of accidental failure in the automatic drop of the Greenwich time-ball. On four days the ball was not raised on account of the violence of the wind. The Deal ball has been dropped automatically at 1h. on every day throughout the year, with the exception of 15 days, on which there was either failure in the telegraphic connection or interruption from telegraphic signals continuing up to 1h., and of one day when the current was too weak to release the trigger without the attendant's assistance. On three days high wind made it imprudent to raise the ball. The Westminster clock has continued to perform well, its errors having been under one second on 40 per cent. of the days of observation; between one second and two seconds on 44 per cent.; between two seconds and three seconds on 14 per cent.; and between three seconds and four seconds on 2 per cent. Time-signals, originating in the Observatory, are distributed at 10 a.m. and 1 p.m. to all parts of the country by the Post-Office telegraphs.

ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.—XI.*

Varnishing the Negative—Printing.

THERE are many printing proceesses, all of which may be studied with advantage by the amateur. Each one has certain advantages, and some are especially suited for certain purposes; but the process which, on the whole, has held its own against all others, and which for general purposes seems not likely to be soon superseded, is that known as "silver printing on albumenised paper."

"Ready sensitised" albumenised paper is now an article of commerce, and its convenience is so great that we should recommend its adoption by the beginner, and shall here describe the manipulation of such paper before we give instructions in the sensitising of paper for immediate use. When the photographer has thoroughly mastered the process of printing, he will probably find that he can gain a higher degree of excellence by sensitising his own paper; but certainly at first the contrary will be the case.

It is advisable to take a trial print from every negative before the process of varnishing is performed, and, in fact, if ready sensitised paper, which is always quite dry, be used, varnishing is not absolutely necessary. It is very advisable, however, and we shall describe the process before entering on the subject of printing.

After the negative is thoroughly washed and quite dry, take it by that corner which, were it a printed page, would be the left-hand bottom corner. Let it be warmed gently over a gas-burner till it feels just warm enough to be pleasant to the touch. If a gas-burner fixed above the level of the operator's head be used, a good criterion of the proper temperature is gained by watching the moisture which condenses on the plate from the water formed by the gas-flame. When the moisture at first condensed is dispersed, and no more will condense on the plate, it is just at the right temperature. Let the plate be now held level by the corner mentioned between the finger and thumb of the left hand, whilst the varnish bottle is held in the right hand. Let a large pool of varnish be gently poured on to the centre of the plate. This pool should cover about half of the area of the plate. Let this plate be gently "tipped" so as to cause the varnish to flow first to one corner and then to another, beginning at that opposite to the one by which it is held. When the varnish comes round to the bottom right-hand corner, let the plate be tipped slowly up to a vertical position, so that all the excess of varnish may flow back into the bottle. The plate must be rocked from side to side during this part of the process to prevent the formation of crapey lines. When all the excess of varnish has flowed off, the plate must be again warmed—this time till it is about as hot as the hand can bear. When it is cold it is ready to be printed from. There is a vast difference between plates as to the ease with which the varnish will flow over them. The process is one which should in no case be performed over a choice carpet.

In printing with albumenised paper a printing frame is used. The apparatus is of various forms, but all these forms have the same object. They keep the paper in close contact with the negative, and are so constructed that one half of the print can be examined at any time, whilst the other is kept in contact with the negative to prevent it from slipping. In frames made at the present day the necessary pressure on the backs is gained by the use of springs. For small negatives, the frame is usually made exactly to fit the plate. In the case of large negatives—above whole-plate, for example—the frame is generally made somewhat larger than the negative for which it is intended, and is fitted with plate glass, against which the negative is placed. The pressure of the springs would be liable to break a large negative were it not thus protected. In the case of large negatives it is also necessary to use a pad of felt between the paper and the back of the frame to insure contact.

We shall suppose that our beginner has purchased a printing frame and a certain amount of ready sensitised paper. Let him cut the paper to about the size of the negative he has determined to print from. Now let him place a piece of paper under the negative in the frame, and place the whole outside in a bright diffused light. It is not generally advisable to print in full sunlight. After the operation has gone on for a short time—say five or ten minutes—the result may be ascertained by taking the frame into a weak light and examining the print, one half at a time. The print must be made considerably darker than is required finally. The exact amount of depth that is lost in the after processes can only be learned by experience, but we may roughly say that it is necessary to print for about twice as long a time as that required to give a pleasing result in the frame.

When the desired number of proofs have been printed, the paper should be trimmed to the correct size. This is generally done with scissors, using "cutting moulds," or thin plates of glass, which can be had of any size. Many prefer to trim their plates after they have gone through the various processes of toning, fixing, and washing; but there are various advantages in trimming before toning. The clippings, if kept, become, when a large quantity has accumulated, of value; there is a saving of toning solutions, and the trimming is far easier to do before washing, as the paper lies flat; whereas, afterwards, it curls up in a way which makes it difficult to manipulate.

The following solutions should be prepared for toning:—

Chloride of gold..........	15 grains
Acetate of soda	1 ounce
Water	15 ounces

The chloride of gold is purchased in small sealed tubes holding fifteen or thirty grains each. One of these tubes is placed in a bottle capable of holding the whole solutions; when there it is broken by striking it with a glass rod, due care being taken not to break the bottle, which is quite possible. The acetate of soda is then added, and the water being poured in, the whole is shaken till the acetate dissolves. The solutions must be kept at least twenty-four hours before being used, and must not be exposed to a strong light. It should be labelled, "Toning solution, one grain to the ounce." The other solution which is required is one of three ounces of hyposulphite of soda to each pint of water, and should be labelled "Fixing solutions for prints."

---

* Condensed from the *Photographic News.*

USEFUL AND SCIENTIFIC NOTES.

M. PODEK, of Breslau, finds that the chief poisonous agent in illuminating gas is carbonic oxide.

M. DAUBREE, as president, and the members of the committee appointed by the French Government to consider the best means calculated to prevent accidents from explosions of fire-damp in collieries, have addressed to the Minister of Public Works a report. It will be found to be, in many respects, instructive, especially in pointing out the illusory character of many of the safety lamps and fire-damp indicators which have been recommended.

Balloon Experiments in Germany.—A new steerable balloon, the invention of Herr Baumgarten and Dr. Wölfert, was recently tried at Charlottenburg. It is of huge size, having a capacity of about 473 cubic yards, and is ellipsoid in form, the longer diameter about 58ft. It differs in principle from all other aërostats in that, although inflated with hydrogen, it has no ascensional force; its total weight is about 2 1-5lb. above that of the air it displaces. The means of displacement, in the horizontal or the vertical direction, are a helical system of vanes actuated by machinery in the car. Hence, in making land, the balloon does not requie to be partly emptied, and on reaching the ground it has nearly the same quantity of gas as when it rose. Another novelty consists in the mode of connection of the car. This is rigid. Thus the dangerous bounds or jerks to which the ordinary balloon-car is liable in landing are to some extent avoided. The car being usually suspended by ropes, the system is suddenly relieved of its weight when it touches the ground, so that the balloon shoots up again, giving a series of violent shocks. With a rigid connection the total weight cannot be thus temporarily diminished. The mechanism has a double action; one helix of vanes, or screw propeller, driven in one direction or the opposite, produces ascent or descent, while a couple of screws give horizontal propulsion; in a pretty calm atmosphere the horizontal direction may be modified by working one of the couple alone. The first experiments, it appears, were quite successful. The weather was exceptionally calm. In a second trial a slight accident ruptured the envelope of the balloon, and the car-mechanism was also injured. The experiments are soon to be resumed. The motor, it may be mentioned, has a force of four horse-power and weights 80lb. The cost of charging, each time the ballon is filled, is about £20.

SCIENTIFIC NEWS.

COMET WELLS makes its perihelion passage to-morrow, and may possibly be observed in full daylight with large refracting telescopes on the 10th and 11th inst. The comet seen by the eclipse observers, and photographed on their plates, has not, up to the time of writing, been again detected.

The death is announced of Mr. D. Campbell, the analytical chemist, who was at one time demonstrator to Prof. Graham.

The Midland Union of Natural History Societies holds its fifth annual meeting and conversazione at Nottingham on June 15, excursions being made to Castleton and Belvoir Castle on the following day. On the morning of the 15th parties will be made up for visits to the Hemlock Stone, near Nottingham, and others to visit the public buildings and factories of the "lace" district.

The council of the Society of Telegraph Engineers and Electricians have offered three prizes for the best original papers sent in on telegraphic or electrical subjects by any person not a member of the council. The prizes will consist of scientific books or apparatus, and will be called the Society's Premium (value £10), the Paris Electrical Exhibition Premium (value £5), and the Fahie Premium (value £5), the council reserving the right to withhold them if none of the papers are deemed worthy of the award. The first award will be made in 1883, for the best papers sent in between the present time and May next.

Mr. E. Berliner, of Boston, Mass., says he finds that a Planté battery is rapidly "formed" when 5 per cent. of alcohol is added to the ordinary acid solution. In practice he connects both lead-plates to the carbon-pole of several Fuller cells, and a carbon electrode to the zinc-pole, thereby developing both lead-plates simultaneously. The carbon electrode is subsequently removed and the lead-plates connected to different electrodes. One hour is sufficient to create a heavy oxide surface capable of taking a large charge.

A new lamp combining gas and electricity is said to have given good results. A small strip of platinum foil is so arranged in connection with the burner that when the gas is ignited the platinum becomes heated, and then offers so much resistance to a current of electricity that it becomes incandescent, and in turn heats the gas to a high temperature. It is stated that a light equal to 30 candles can be obtained from two cubic feet of gas per hour when a small current is used in aid.

From Mr. H. C. Russell, B.A., F.R.A.S., Government Astronomer, New South Wales, we have a paper on the Transit of Mercury, read recently before the Royal Society of that colony, and a copy of the Results of the Rain and River Observations during 1881. The latter is accompanied by a map, indicating the amount of rainfall, and by a chart showing in curves the heights of the rivers during the year. These observations are of very great importance to the colony.

From Mr. T. Fisher Unwin we have another of the "half-holiday handbooks—" "Round Bromley and Keston," a district which takes in a village rendered famous as the residence of Darwin. A neat little map shows the roads clearly, and the notes will be welcomed by the holiday rambler as well as by the naturalist.

Mr. Wragge has established a meteorological station at Stafford, under the charge of Mr. McCullum, the borough surveyor, and his brother. The station is supplied with standard instruments verified at Kew.

The Vienna Electrical Exhibition, which opens in the Autumn, will be held in the Rotunda in the Prater. Count Wilczek has accepted the office of president.

A subterranean forest has been exposed on Lord Normanton's estate near Crowland, Peterborough. It is about 10ft. beneath the surface, and some of the trees are in excellent preservation.

The Friday evening discourse at the forthcoming meeting of the British Association will be delivered by Sir W. Thomson, the subject being "Tides."

Mr. Ranyard, we hear, appears to have missed his ship from Egypt of the 25th ultimo, but is expected home by the next, which arrives about the 13th inst.

The phenomenon of the dark ligament is not peculiar to the transit of planets over the sun's surface. MM. Gonnessiat and Marchant have called attention to an example of it which they observed during the recent eclipse, when a ligament appeared between the indenting limb of the moon and each of three spots just before contact. It was less dark than that in the case of the Venus transit (but darker than the penumbræ round the spots). It did not sensibly affect observations. The dimensions and intensity vary with the aperture of the instruments employed. The authors hold that the phenomenon of the ligament, hitherto thought singular, is to be regarded as resulting from interference of luminous waves which form the focal image, and treated as such. They note the utility of the new case of ligament formation for observation of the Venus transit.

The Photographic Society of Berlin have announced the following subject of prize competition for 1882:—Communication of a method of preparing gelatine, uniform in all circumstances, for emulsion purposes, whether directly from raw materials or from ordinary commercial gelatine. The prize consists of a gold medal and premium. Foreigners may compete; and papers may be written in German, French, or English. They must be sent in before 1st Oct., 1882, to Dr. Franz Stolze, Schwerin-strasse No. 23, Berlin.

With the view of obviating the inconvenience experienced in Paris last year from the summer drought, the municipal authorities have taken measures to increase considerably, this year, the resources for watering, so as to economise the water indispensable for domestic use. Twenty pumps, worked by locomotive steam-engines, will be located at different points, chiefly on the banks of the Seine, and it is estimated that by working these fifteen hours a day, it will be possible, if required, to furnish a daily supply of 6,000 cubic metres, in addition to the normal quantity. The total expense of the new scheme, including purchase of 100 new water-carts, is about 500,000 francs.

Several French railways have adopted systems of electric intercommunication in trains. In that recently introduced on the Chemin de Fer de L'Est (described in *Annales Industrielles*), the general arrangement of circuits is the same as in the Prudhomme system. A special feature is the mode of junction between carriages. A cable bears a ring having the shape of a U with a cross bar. This ring engages in a hook having two jaws, the lower fixed and presenting a groove in which the cross bar catches, the other movable, but pressed down always on the lower and the bar of the ring by a strong spring. In case of rupture of the train, the ring raises the upper jaw of the hook. The alarm-bell is so arranged as not to be set in action by motion of the train. The passenger desiring to signal pulls out a knob on a box fixed to the ceiling (producing electric contact), and it cannot be replaced by him. The act informs the guard of the exact compartment whence his attention is called.

Most methods of determining the carbonic acid in the air require the slow passage of a pretty large volume of air (50 litres at least) over absorbents of carbonic acid; and to the traveller, the size of the apparatus and slowness of the process may be inconvenient. M. Mascart has lately proposed a method, based on direct measurement of the diminution of pressure in a mass of air, at constant temperature and pressure, when its carbonic acid is removed. By this method (of which some details are given in *Comptes Rendus*), the traveller may collect samples of air amounting to about 500 cubic centimetres in glass vessels sealed at a lamp, and afterwards make his analyses at leisure.

A crusade is now being carried on by the Citizens' Sanitary Society of Brooklyn, against the ailantus trees which shade many of the streets of Brooklyn and New York. The tree was introduced from China some forty years ago, heralded by extravagant praises, which led to its extensive use for tree-planting. It was popular for a time because of its hardiness and very rapid growth, but of late years it has been gradually disappearing; the blossoms in spring have a peculiarly unpleasant odour, which it is now reported, is unwholesome, besides causing "prostration of the nervous system," an "oppressive feeling in the throat," "swollen joints," and other afflictions. Under these circumstances, it is not surprising that twenty-two "eminent medical men" and over fifty householders, have signed petitions against the trees.

In a telephone-call which has been brought before the French Physical Society, an electric bell is liberated for action by the movements of the diaphragm. The apparatus is figured in *La Lumière Electrique*. The strong vibrations necessary are produced by means of an ordinary Siemens' whistle at the calling station. They let a plate fall, which acts on a lever and frees the bell. When the call signals have been exchanged, each interlocutor sets up his lever again by pressing a knob. The principle is the same as that of the Ader signal.

At Athens, during a recent congress of Greek medical men, the monuments of the Acropolis were brilliantly illuminated with the electric light.

In view of the Universal Exhibition to be held at Turin in 1884, application has been made by Signor Ivaldi and others to the Communal Council of that place, for the exclusive right to establish on the Po, between the Rocca mills and the ninth bridge, a service of electric boats, driven by special accumulators. They have also applied for gratuitous use, during the exhibition, of the hydraulic force of the river in the locality of the Rocca mills, where their motors will be set to charge the accumulators.

A horse-shoe is now supplied by Herr Schneider, in Berlin, which is claimed to afford horses an elastic and sure footing on stone and asphalte, while the price is not much higher than that of the ordinary kind. The calks, or prominences, are of caoutchouc, instead of iron or steel. The shoe itself is of malleable cast iron, and has pockets, into which the calks are compressed, and fixed by means of rods, which run parallel with the hoof-sole, through the pockets and the calks, and are nutted exteriorly. For horses that have heavy loads to draw, a less elastic material than caoutchouc may be used—*e.g.*, natural or artificial leather. Repeated and long trials have shown that the caoutchouc is worn out uniformly with the iron; but where it may be desired to substitute fresh calks, this can be easily done by the driver himself. A depression in the front part of the shoe serves to receive a short screw-calk when snow or frost sets in.

The progress of the electric light has given a healthy stimulus to the art of gas-illumination; and among recent developments of the latter may be noted a device of M. Clamond, the principle of which consists in burning gas with air raised to a temperature of 800° to 1000°C. The combustion takes place within a cone of magnesia, of special make, which, under the influence of the heat, becomes incandescent, and forms a light-centre of great fixity and remarkable brightness. With small burners, a luminous yield of 1 carcel per 33 litres of gas is obtained; with more powerful, 1 carcel per 27 litres. Certain burners of 4 carcel power require only 100 litres of gas, corresponding to 45 litres per carcel; the consumption of air is about 500 litres per carcel. The magnesia employed resists the excessive temperature about 52 hours; it is then necessary to replace it, but this is done with great ease.

After arriving at an exact method of quantitative analysis of fats, Herr Lebedeff recently experimented with reference to the deposition of fat in animal bodies. He first, it appears, starved two dogs for a month, so that they lost 40 per cent. of their weight, and as earlier observation proved, all their fat. Then they were fed with certain fats of foreign nature, together with small quantities of lean meat. Having in three weeks recovered their normal weight, they were killed. From the tissues of one of them, which had been fed with linseed oil, were obtained large quantities (more than 2½lb.) of a liquid oil, not solidifying at 0° C., and closely agreeing in chemical behaviour with linseed oil. In the fatty tissue of the other dog, which was fed with mutton-suet (melting point over 50° C.), was found, both in subcutaneous parts and the inner organs, and in the muscle fat, a fat almost identical with suet. The experiments are considered to prove a direct passage of foreign or food fat into the cells of fatty tissue of the animal system.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made Payable to J. PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

> "I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."

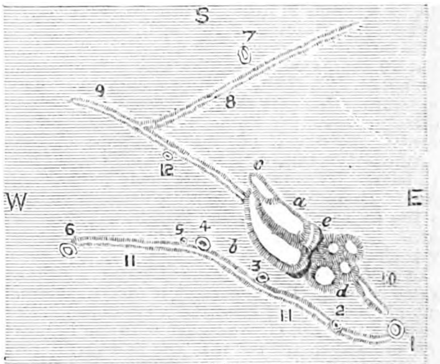
SELENOGRAPHICAL—PICO—HELICON—HEVELIUS.

[20120.]—IN No. 868 (Nov. 11, 1881) of the ENGLISH MECHANIC there is an interesting letter of Dr. G. W. Royston-Pigott, in which he refers to the remarkable mountain, Pico. Having, for some time of late, given a good deal of attention to this subject whenever opportunities offered, I am induced to send you the results I have obtained, hoping they will interest your selenographical readers, and induce them to make further observations. For their encouragement I may say that I have not found this to be a more "difficult object to define" than most others on the moon's surface. I am, therefore, inclined to believe that his disappointment with his 6¼in. refractor by Wray was caused more by an improper state of the atmosphere, than from difficulties inherent to this mountain, or from imperfections in his instrument. You will observe that the positions I give to the craterlets near Pico differ but little from those given by Nasmyth and Carpenter, though they agree more closely with the positions given by Dr. Schmidt.

I now copy from my observing-book:—

Pico.—March 30, 1882. 9h. p.m. Air rather unsteady, but clear. Pico is an agglomeration of large, elongated rocks, most of which are closely packed together. As a whole, they run in a N.E. and S.W. direction, with a slight curving southward. It is composed of at least eight mountains, three of which look like hillocks, stand quite isolated, lie on the east, and are of a greyish colour. Of the remaining five the largest is *b*, situated on the N.W. side, and looks like a high ridge about three times as long as it is wide. Its highest point is on the N.E. extremity, and from there it seems gradually to slope down to the plain as it runs south-westward. A round mountain, *d*, lies N.E. of this ridge, so close that at times it looks as if it was its continuation. But on the present occasion a depression between them with shadow was clearly seen. The round mountain *d* is perhaps higher than the highest part of the ridge *b*. Close to this ridge, and along its S.E. side, runs another ridge, *a*, perhaps somewhat higher than the first, but not so long. At the S.W. extremity of this last ridge an elongated hillock *c* lies also close to it. These three objects slope south-westward towards the plain. At the opposite extremity of ridge *a* there is another mountain *e*, forming a kind of step. Doubtless this is not so high as the ridges close to it. Several craterlets and very low ridges are to be found around Pico. Ridge 10, which is the highest, runs on the N.E., and at its extremity is crater 1, easily seen. A second, but very faint ridge, runs from crater 1 to crater 6, and on it are craterlets 2, 3, 4 and 5. They are very small, but chiefly the last. Another ridge, or perhaps only a

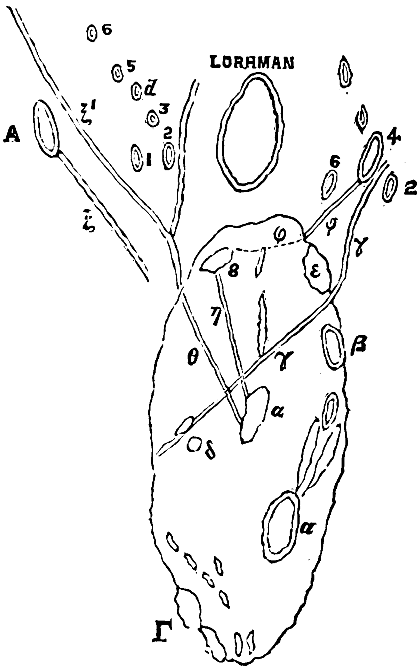


PICO. MAR. 30. 1882 9^{h} P.M. C. GAUDIBERT.

streak 9, runs from Pico south-westward, and on it is craterlet 12 exceedingly small. A last ridge 8 runs from 9 eastward, having crater 7 on its south side. This crater is easy.

Helicon.—E. of Helicon there is a small crater given by Beer and Mädler. On the 1st of April last I found a faint ridge connecting this small crater with Helicon, and on which about midway I found a very minute craterlet.

Hevelius.—As there has been much uncertainty about the positions of the various clefts situated on the floor of this formation, I send you an outline of the same, showing how they appeared to me on April 11, 1882, 11h. p.m., air fluttering. Cleft γ was seen first running from between craters 2 and 4 S.E. of Hevel. forming a curve and running across the floor of Hevel. in a S.E. and N.W. direction. It crosses first some hillocks on the S E. of the floor, passes a short distance from central mountain α, crosses what I took to be an expansion S. of craterlet δ, and reaches the W. side of Hevel. Cleft η was seen next. It runs in a N. and S. direction from the central mountain α to hillock 8 near the S.S.W. rampart. It therefore crosses the rill γ a short distance S.W. the central mountain α. Cleft θ runs in a straight direction from the N.W. side of crater 4 up to the rampart of Hevelius. This portion of the cleft was easy; but from the rampart of Hevelius to hillock 8 on its floor, its continuation was only suspected. It is shown by a dotted line, another cleft θ, only strongly suspected on the above date; but seen without doubt on a subsequent date, runs from the S.W. side of Hevelius, as if it were the continuation of cleft ζ', and reaches the W. side of the central mountain. As these objects have been seen by me only twice, the last time when the moon was very low and the air not satisfactory at all, their positions may require some slight alterations. I hope, therefore, observers will keep a look out on this formation, and report.



Astronomical.

I am sorry I have not been able to answer in time, on account of bad weather, (the question put to me by Mr. Mills (Eng. Mech., No. 891, p. 152), about the position angle of the companion to ζ Cancri. I have had only one occasion just to see this companion, and I estimated its position between 75° to 80°. The power used, when I split this double with 5in. and 5½in., was about 400.

I am sure every reader of the "E. M." interested in astronomy must have read with great interest the letter of Rev. Jevon J. Muschamp Perry in No. 896, p. 260. On May 31, 1882, I looked at some of the stars of his list to try what my mirror could do on some of his most difficult objects. The air was good, but might have been better. I first tried 42 Comæ Berenices, and with power about 300, the highest the air would bear, I recorded "a black division between the discs." Now, as my mirror is only 8½in. diameter, and this star is stated to be 0·4″, it ought to be quite out of its reach. Is it certain the distance is not greater than stated? I next tried 25 Canum Ven., taking care not to look at the position of the companion. After a good and steady gaze, I thought the companion was 160 +. On looking at Mr. Perry's position and distance, I did not believe my eyes. I again looked at the star, and there was the minute companion seen as an elongation of this difficult double. I hope Mr. Perry will continue to give other lists as occasions offer. My mirror is a With-Browning one.

June 2. **C. Gaudibert.**

WELLS'S COMET.

[20121.]—On several occasions during the visibility of this object, I have had some very interesting views with my 3·7in. achromatic, and have been particularly struck with the clearness and star-like brilliancy of the nucleus. The object seems to have steadily increased in brilliancy with its approach to the sun, at first of course slowly, but latterly in a very marked degree; and yesterday morning (5th), when I last had an opportunity of observing it, although at a rather low altitude, it was certainly fully equal in brilliance to an ordinary 2nd mag. star. I could see it distinctly with the naked eye in the strong morning twilight up to 2.40 a.m., having some minutes earlier lost all trace of β Aurigæ, with which I had previously compared it.

I think some of your correspondents who appear to have been rather disappointed with this object, were probably led to expect a more regular gradation in the increase of brilliancy, not sufficiently taking into consideration the close approach of the comet to the sun at perihelion, which accounts for the higher ratios manifested, the period of which is, however, very limited, and the benefits, so far as a general view is concerned, must inevitably be almost entirely lost to us.

London, June 6. **W. T. N.**

ζ HERCULIS — Σ 1884 AND Σ 1883 (BOÖTIS).

[20122.]—In looking over the XXXII. Vol. of your journal I remarked a letter from "F.R.A.S.," p. 59, in which he refers to "ζ" Herculis as a test for 3¼ telescope. I have been examining this star myself on several occasions lately with my 4in. Cooke achromatic, under extremely favourable atmospheric conditions, and found little difficulty in dividing it with powers 225 and 350. I should be inclined to conclude from this that the distance of the *comes* has increased since 1880. I am of opinion, however, that the distance now cannot be more than 1·3″; the *comes* is very close to the disc of the primary, and falls in my telescope on the first diffraction ring, which gives it an elongated and mis-shapen appearance. I asked a friend, quite unaccustomed to observing, to examine it a night or two ago, and he at once described the position of the *comes* without any previous knowledge of its whereabouts. The latest measure with which I am acquainted is by Burnham, epoch 1879·709 (see "E.M.," Vol. XXXII., p. 85). Will "F.R.A.S." please say whether he has examined this star lately, and if so, whether he has now been able to divide it? I cannot do anything with δ Cygni, and if I recollect aright, "F.R.A.S." has divided it with his Dallmeyer achromatic.

I would like to call the attention of your astronomical readers to the stars Σ 1884 and Σ 1883. Webb calls both distance 1·2″. The magnitude differs very little as given in "Celestial Objects," but I think anyone examining these stars cannot fail to notice that the components of the latter are *very decidedly* fainter and closer than in the former. Σ 1884 was easily divided last night, power 350, with perfectly round discs and a very decided dark interval between them; whereas Σ 1883 was not fairly divorced with this power; discs about in contact, but much fainter and generally more difficult. Of course, the latter object was not nearly so favourably placed as regards altitude as the former, but I think the difference in their appearance was greater than could be accounted for by this fact. The colours of Σ 1884 were well shown, A yellow, B blue. **David Simms.**

Limavady, Co. Derry, June 1, 1882.

P.S.—I have just now discovered that Mr. Burnham gives a measure of ζ Herculis, epoch 1880·47, p. = 114·3° D = 1·38″. See English Mechanic, Vol. XXXII., p. 233.

MERCURY.

[20123.]—Acting on the excellent instructions of Mr. Fleming (letter 20068, page 259), I, on the 27th May, caught Mercury very easily with a small telescope, and soon after with the naked eye. I brought a larger instrument to bear, to be certain I had the right object. A power of 120 on a 4in. Gregorian satisfied me on the point. I have read of the extreme difficulty of seeing Mercury, and that a celebrated astronomer, in his whole life, never once succeeded. If this is so, I think it worth recording that he was an easy naked-eye object in the smoky atmosphere of North London on May 27th. I saw him again still more plainly on Sunday, the 28th, and on the 29th a few miles from Birmingham, and caught him again on the 31st. I think the difficulty of seeing him consists in not knowing exactly where to look. Venus, at this time, forms a first-rate pointer; for, with a low-power opera-glass, both will be in the field at once. I am much obliged to Mr. Fleming for his thus enabling me to have a look at so interesting an object as the planet Mercury.

Edwin Holmes.

THE BLUE PROCESS FOR ASTRO. SKETCHES.

[20124.]—I send you some of my sketches. My plan for using the "blue process" for astronomical drawings is, I think, original. I append a short description. After preparing a rough sketch from the field of the telescope, noting magnitudes and other matters of importance, a tracing is made on tracing linen. Here I may say that it is difficult to get good tracing material. It must be free from specks, as they make white spots, which may be mistaken for small stars. Nebulæ and the tails of comets are made with fine plumbago and the point of the little finger. Having prepared the tracing, a stencil is made from some material entirely impervious to light. Mine is made of two pieces of white paper, with black shellac varnish between. The field is cut out, and the design for the name and date. The tracing is laid upon a piece of sensitive paper and the stencil on it, covering the whole with a piece of plate-glass, and exposing to the rays of the sun for about five minutes. I need not describe the "blue process," for, probably, your readers are familiar with it. (See p. 477, No. 774.) **Francis G. du Pont.**

Wilmington, Delaware, U.S.A.

ASTRONOMICAL EYEPIECES.

[20125.]—If "Paugul's" errors affected only himself and his pupils, I should not think it worth while to disturb his serenity; but as his statements may possibly mislead readers who have not the opportunity of testing their correctness by experiment, I will lay before them the result of a series of my own, and shall be glad at some future date to describe the simple means by which it was determined.

All rays cross in the object-glass, and are refracted to a focus at a distance from it, proportional to its curvature. At this focus an inverted image of the object is projected, from whence the rays proceed in diverging paths to infinity. The image forms a blunt apex to the cones thus formed on either side of it; but the formation of the second cone may be arrested, and its rays bent into a continuation of the first, by the interposition of another lens, such as, for example, the field lens of the Ramsden eyepiece. It then terminates in a second apex, as shown in my diagram (on page 259). This apex differs from the first, in that it is now no longer the point where the image is formed, but is a curious reproduction of the object-glass inverted in every particular—that is to say, it is not only upside down, but its convexity is rendered concave, and its effect in all respects appears to agree with a lens of that character.

In the Huyghenian eyepiece the apex proper is not reached until it is at the focus of the eye-lens. From this position the rays have, more or less,—according to the power of the field-lens—a tendency to run parallel. The difference is, however, so slight, that it can hardly be said to alter the form of the cone, which is continued to an apex as before.

As in the matter of "terrestrial eyepieces," lately under discussion, it would have spared our readers some rather unparliamentary language if "Paugul" had previously taken the trouble to assure the correctness of his position, so now I should advise him to obtain better practical information in "matters he is accustomed to teach" before he again asserts that the image must necessarily form the apex of the cone in a telescope eyepiece, or that apex and focus must always be convertible terms. **Aldebaran.**

ON THE ACTION OF EYEPIECES.

[20126.]—The action of an eyepiece does not seem to be well understood. Your correspondent "Ascalon," has elicited an interesting reply from "Aldebaran"; but I altogether fail to follow the reasoning of your esteemed correspondent. If I venture to criticise his letter adversely, I trust he will not take it amiss and think that I wish to set up my knowledge as superior to his. I want to arrive at the truth, and if he considers my conclusions wrong, I hope he will not spare them.

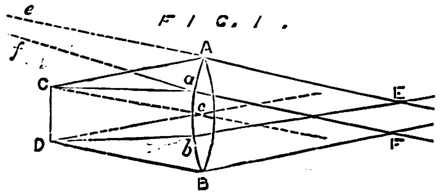
In his third paragraph (letter 20069), after alluding to the two sets of rays, he says:—"After the image has been projected, it matters little or nothing whether the cone that conveys it is refracted sooner or later to a focus." Now, if we both attach the same meaning to the words "cone of direct rays," this strikes me as being a rather glaring error. The apex of this cone is the focus of the object-glass—it is one point in the image; the aggregation of an infinite number of such apices forms a curved surface, which gives us the impression of an aërial image. The completion of this cone and the formation of the image are simultaneous, one cannot exist without the other; hence the "projection" alluded to cannot take place till the apex is reached.

Your correspondent represents the combination as *inverting* the image; but this, though literally correct, is not what occurs when the appliance is used as an eyepiece. It is usual to speak of the Ramsden and Huyghenian as inverting eyepieces; but this is incorrect if understood as applying to their *action*. The inversion is produced by the object-glass, and these eyepieces allow it to remain so, their effect being solely that of magnification. Of course, we can get a re-inverted or erect image by holding a screen at some distance in the rear; but the emerging rays are seized upon and modified by the eye before this image is formed.

In the telescope we have two essential parts—an image-producer and an image-magnifier. Rays diverging from an object pass through the object-glass, and form an inverted image at its focus, this focus being the apex of the cone of rays transmitted by it. Similarly, the eye is an image-producer; diverging rays are by it converged on the retina. It is usual to speak of rays entering the eye as parallel, because the distance of the object is generally very great compared with the diameter of the pupil. But, strictly speaking, they are divergent, and the point of greatest divergence is the least distance of distinct vision. It matters not whether the rays fall upon the eye naturally or are transmitted by a lens or eyepiece; they cannot have a greater amount of divergence than this in order to be utilised for purposes of vision. Evidently the difference between parallelism and this slight divergence is scarcely distinguishable; and as it simplifies matters, it is usual to say that to produce vision the incident rays must be parallel.

But it must be carefully remembered that *it is only those rays issuing from each point separately that are parallel among themselves.* All the rays entering the pupil are not parallel to the axis of the eye; most of them cut it, in the centre of the pupil. It is probably here that that the confusion arises, therefore I will try to make my meaning clear by means of a diagram. Let A B (Fig. 1) be a convex lens, and C D an object at its focus. Rays from the point C will fall upon every part of the lens, and all or any part of them, as A *a*, on emergence, will practically be parallel to the line C*c*. Similarly those from the point D will be parallel to the line D*c*. Now it is evident that the rays after their passage must intersect, yet as the individual members belonging to each point of the object have no vergency, the general condition is said to be that of parallelism.

FIG. 1.



If the eye were placed close behind the lens, the condition of vision would be such as to require the rays A E and *a* F to separate very slightly; so that their prolongations A *e* and *a f* would meet at a point about 10in. distant from the eye.

When a lens or combination of lenses is used in this way, magnification only without inversion is produced; they act upon a telescopic image in the same manner as they would upon a real object.

In the Ramsden eyepiece the image must be formed in front of the field-lens, the precise point being that which will give the requisite divergency to the final emergent rays. The apex of the objective cone is at this point, and not behind the eye-lens.

In the Huyghenian eyepiece the telescopic image would be formed just in front of the eye-lens, but the refraction of the field-lens brings it nearer to the latter, the precise point of adjustment being that which allows the eye-lens to give the necessary form to the emergent rays.

The four-lens pancratic eyepiece is, in reality, an inverting eyepiece; the inverted image formed by the object-glass is reinverted by a pair of lenses, and being thus brought into its natural position, it remains so when viewed through the second pair, which form a Huyghenian eyepiece.

In a telescope with a concave eye-lens a different action occurs. Convex combinations lengthen the telescope, more or less, because the rays from the objective must be brought to a focus before the eyepiece can be employed. But in this case the objective cone does not terminate—it is shortened by an amount equal, practically, to the focus of the eye-lens. Rays from the objective are converging, but being intercepted by the concave glass, they receive just so much divergency as fits them for the purposes of vision.

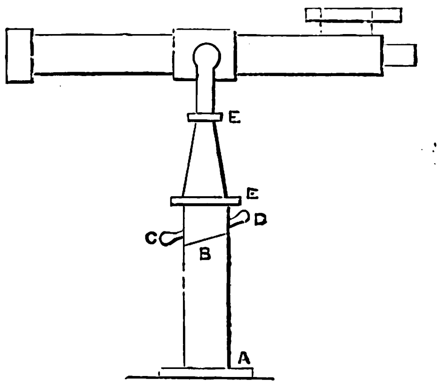
Hence it appears that whatever form of eyepiece we employ, its position or adjustment must be such as will allow the emerging rays to enter the eye naturally.

The acuteness of vision is in a great measure owing to the perfection of the definition of a very small image; and in practical optics, I think it would be advantageous if attention was devoted to this matter, rather than to mere enlargement.

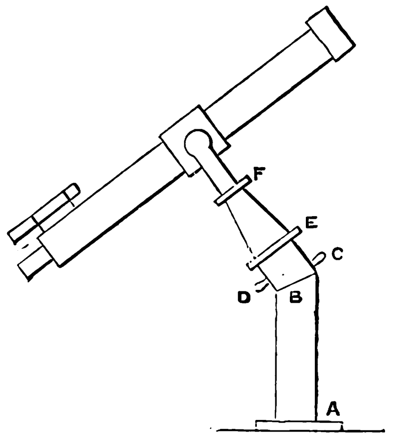
May 29th. **Orderic Vital.**

NEW COMBINATION OF ALTAZIMUTH AND EQUATORIAL MOUNTING.

[20127.]—Having been present at the last scientific meeting of the Royal Dublin Society, when Mr. Grubb, F.R.A.S., exhibited "a new form of combined altazimuth and equatorial mounting for small telescopes," I have thought a rough sketch from memory and a short description of the instrument might interest the readers of the "E.M."



The telescope, which is of about 5in. aperture, has been constructed for the Royal Irish Yacht Club, and intended primarily for viewing terrestrial objects, for which purpose the altazimuth is, of course, the most convenient mounting. To enable it, however, to be used astronomically whenever desired, with the maximum of comfort, Mr. Grubb has devised a most ingenious method by which the instrument can be converted into an equatorial, or vice versa, in two or three seconds. The lower half of the pillar (from A to E in sketch) is cylindrical, and at B contains a section making an angle with the horizon equal to half the co-latitude of the place. To effect the conversion, the portion of the pillar above B is turned round bodily by means of the handles C and D, which in the process change places. Thus the upper part of the pillar becomes either perpendicular or a polar axis. Of course, there is an arrangement at B to prevent the telescope from toppling over when an equatorial. The motion in R.A. or azimuth, as the case may be, takes place above F. The sketches show the telescope in its two characters, but I have omitted the declination circle for simplicity. It may be mentioned that the novelty in this telescope consists not in the upper part of its pillar being reversible, but in its being reversible by one movement, and with such facility.



More Light.

DIVISION-PLATE FOR A LATHE, THE CONSTRUCTION OF WHICH PREVENTS ONE BEING MADE ON THE PULLEY.

[20128.]—Some years ago, a gentleman was kind enough to show me his lathe and its addenda, made for him by the talented designer of the Saltair lathe. I was particularly pleased with a division-plate which he showed me, designed for use on an ordinary engineer's screw-cutting lathe, in which it would be difficult to fit a division-plate, as the front of the large cog-wheel must not be covered up, as doing so would interfere with the back-gearing arrangements.

I made a rough sketch of the arrangement, which I am sure would be appreciated by many of your readers, and I believe it is within the power of most amateurs to make it for themselves. It consists of a brass face-plate, having on its front surface a flange, or projecting ring, for the purpose of acting as a guide to a cast-iron plate which is fitted to the brass one.

FIG. 1.

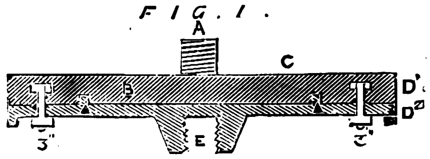


Fig. 1, which is a section of the complete arrangement, will, I think, make this clear to all.

FIG. 2.

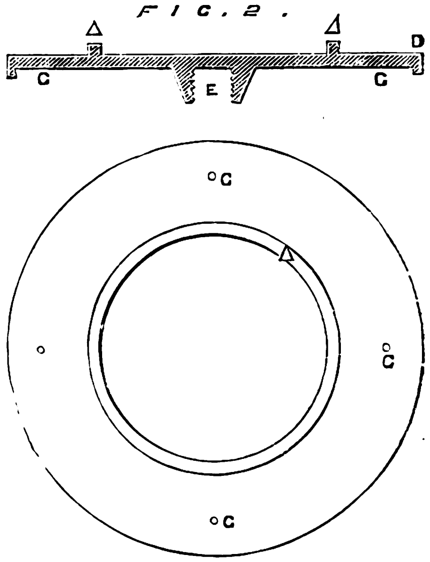

Fig. 2 is the brass face-plate in plan and section.

FIG. 3.

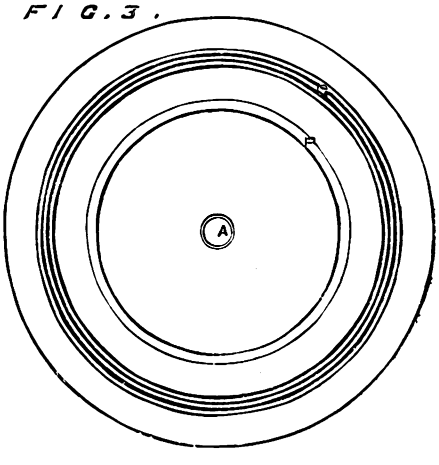

Fig. 3 is the cast-iron plate in plan. This plate, it will be observed, has a groove turned in it, into which the brass flange or ring fits easily, but without shake (A). It has also cast in it a T-slot, to enable it to be fixed firmly to the brass face-plate by bolts, the holes for which are shown in Fig. 2.

The edge of the brass plate in the chuck I saw was divided into 144, and that of the cast-iron plate into 8.

The nuts clamping the two plates together, and the screws with T-heads working in the dove-tail slots, are clearly shown in Fig. 1 at the back of the brass plate. By slacking these, the position of the two plates may be changed circumferentially without interfering with the work. The iron plate carries a false mandrel-nose, the counterpart of that on the nose of the mandrel, so that all the ordinary chucks can be screwed to it.

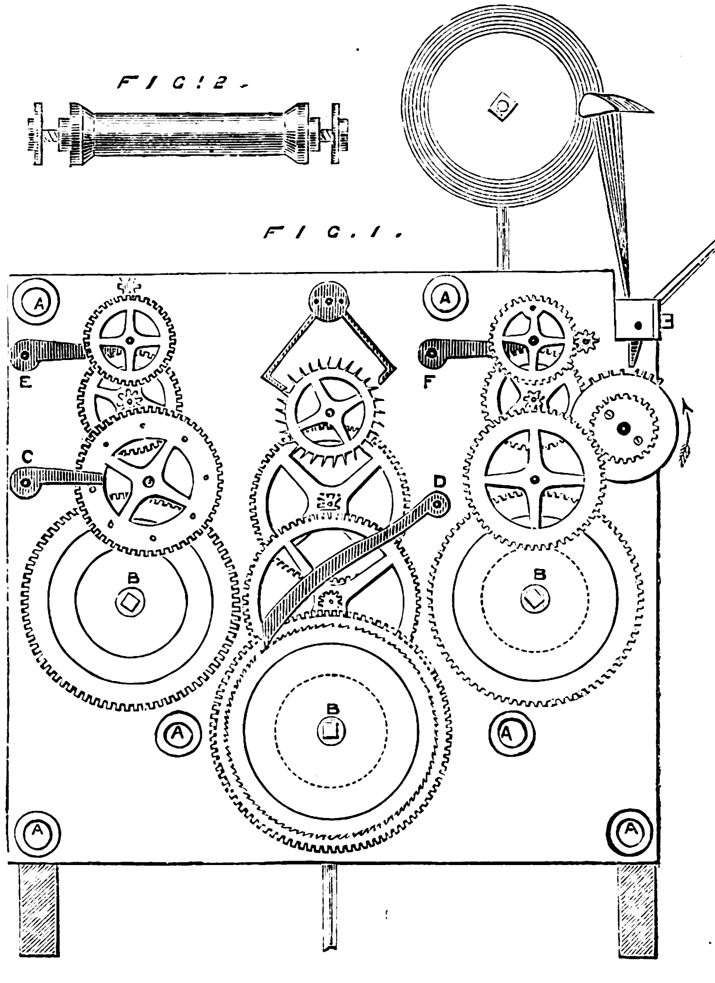
I am sure that for many pieces of work this chuck would be very useful.

Reference to Figures.—T is a section of the complete chuck, the upper half of cast iron, and the under half of gunmetal. A, false mandrel nose; B, section of iron plate, with undercut circular slot in it for the bands of the T bolts, *g*, which also pass through holes in the brass plate and are fixed by a nut; C is the plain surface of the chuck without break, but it may be tapped with holes to take shut-screws for fastening work to it directly; D^1, edge which is divided by straight lines across the face into 8; E, boss on lower gunmetal plate for screwing in lathe; △, raised ring which fits into upper plate to insure its being central; D^2, edge of gunmetal plate, divided at edge next the iron plate, by straight lines into 144, further back holes may be drilled as in other division plates; E shows the bolt and nut which fix both plates together. Fig. 2, Section and plan of gunmetal plate shown separate, same letters as in Fig 1. Fig 3, Iron plate in plan, showing G, the groove which is undercut, as shown by dotted lines; F, groove which takes the brass raised ring; A, false nose for taking chucks.

Gereb Admi.

CHIME CLOCK-MAKING—NO. I.

[20129.]—In fulfilment of my promise, I now send instructions for making a chime clock. The clock I propose describing chimes the quarters on either eight bells or the Westminster chimes, both sets of changes being on one barrel, so that you can have either set of changes at pleasure. The hours are struck on a gong; the clock has a dead-beat escapement, with a one-second pendulum; but if anyone prefers a gravity essapement, it can easily be made so by putting a cock above the frame to carry the pallet pivots.



FIG! 2.

FIG. 1.

Fig. 1 is a view of the movement (half-size) with the front frame removed to show the positions of wheels, pinions, &c. In designing this movement I have adopted the locking-plate plan, it being very much simpler than the rack, and consequently easier to make.

We will now proceed to the construction of the clock. The first thing to engage our attention is the frames; these are of stout sheet brass, 11in. by 10in., No. 8 B.W.G.; they must be got perfectly flat by hammering on a smooth stake. Having done this, put the two plates together with the two edges matching one another as closely as possible, drill two small pinholes near the edge, drive pins into them to hold the frames together while the edges are filed up perfectly square, now mark off from the drawing the pillar holes A A A A A A, barrel holes B B B, hour hammer C, maintaining power click D, and locking arbor holes E and F, drill them right through the two frames with a small drill, keeping the frames pinned together while this is being done, drill out the pillar holes to the right size and turn the pillars up, leaving them 2½in. long between the shoulders (this of course will be the distance between the frames), drill them up at each end; tap and fit screws and washers, as in Fig. 2; fit them into the frames, numbering them and the holes they fit into, so that the same pillars may always be put into their proper places; fasten with the screws and washers. Care must be taken to make all the pillars the same length, or a great deal of trouble and annoyance will be the result. The frames being mounted, we are now ready for the wheels and pinions, but these I must leave for my next.

In giving these instructions it may happen that some small details may be omitted. I shall be most happy to remedy such omissions if anyone finding themselves in a dilemma will kindly communicate with me. I therefore append my address.

W. Baldwin (A Clerkenwell Clockmaker).
110, Richmond-road, Dalston, N.E.

CHEAP RESISTANCE COILS.

[20130.]—In accordance with my promise, I will now describe a method of making a set of resistance-coils which, though simple, are perfectly reliable, and are easily within the reach of any possessing the few tools necessary. 1st. As to the coils themselves. These consist of frames of wood as shown (Fig. 1) preferably of oak, or some other hard, strong wood. A and B are 6in. long, half an inch deep, and rather over ¼in. thick. Joining A and B are C and D, also of oak ½in. deep (the drawing shows them rather less), and rather thinner than A and B, so that they do not come up flush with A^1 and B^1. The tops of A and B are grooved, as shown at A^1 and B^1; then at intervals (varying with the size of wire to be used) are cut notches, as shown along A. These are for the wire to be wound into. If the size of wire is not larger than about 24 or 26 B.W.G., these may be about ⅛in. apart. The number of frames must be regulated by the number of ohms resistance it is required to make up; but of this more afterwards. On to these frames must next be wound uninsulated German silver wire. This may be bought at any ordinary metal warehouse. Fix one end by means of a screw to a point on C, and commence winding, keeping the wire tight, and taking care that the wire goes to the bottom of the notches cut for it. Where the coils are not likely to be subjected to very powerful currents, we may begin with No. 28 for the smaller resistances, and as the resistances get larger we may use wire as fine as No. 40 B.W.G., for, although this might be too fine for ordinary coils where the wire is massed together, in these the whole wire is exposed to the air, and thus keeps cool. When these frames are wound, they must be soaked in hot paraffin wax till thoroughly saturated, and then the excess drained off. The next thing to do is to give the coils their true value. To do this, some standard is, of course, absolutely necessary. I must, therefore, assume that such a standard can be got at. What we next need is a simple form of Wheatstone bridge. Perhaps the simplest and best for our purpose is made as follows:—Take a board, about 5ft. long, and fix a piece of wood about ½in. thick at each end. Now, from the tops of these

FIG. 1.

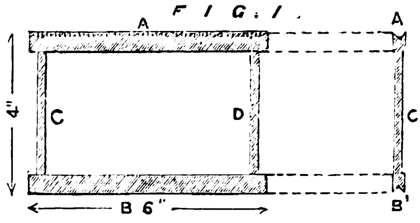


FIG. 2.

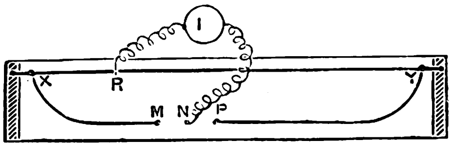

FIG. 3.

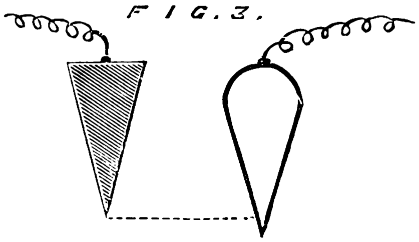

FIG. 4.

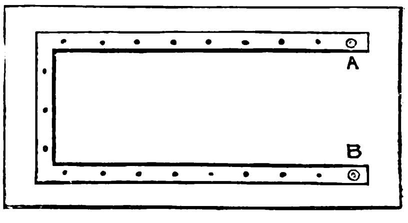

Fig. 5.

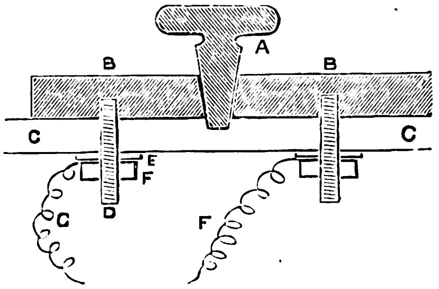


pieces of wood, stretch a piece of German-silver wire tightly, and fix firmly by means of screws. To two points, X Y, near the ends of the German-silver wire, solder two stout copper wires, leading to two binding-screws M P, at N between them is another screw; now make two clips of stout brass, as shown, Fig. 3, in elevation and section. To one of these solder any piece of copper wire, to the other solder a stout piece. Then place the clip with the thin wire, so that it clips the wire X Y at any point; let the wire connected with it go to one terminal of an astatic galvanometer, whilst the other terminal of the galvanometer is connected to N. Next let the standard, which may be a piece of wire, having a resistance of 1 ohm, be placed between M N, and to P connect the end of the wire on one of the coils we have wound. Let us suppose we wish to find what point of the wire on the coils gives 5 ohms: divide the wire X Y into six parts, and set the clip so that five parts are on one side, and one part on the other; then X R : R Y :: 1 : 5; also our 1 ohm standard is between M and N. (I should have said before connect a battery to X Y, say, about six Daniell cells, though less will do—it is better to have as many as possible.) Now, having P connected to one end of a coil, connect the end of the stout wire on the other clip to N, and put the clip on different points of the wire, wound on the coil, till no deflection is got on the galvanometer; this point shows the ends of the 5 ohms. To this point a stout copper wire is soldered. I have described this rather fully, so as to make it all clear, but it will be seen that I am only describing an ordinary Wheatstone bridge, so those who understand it may miss all this out. Similar trials, altering the ratio of X R to R Y, will enable us to get any number of ohms resistance accurately marked out. This being done, a box rather larger than the frames of the coils should be made; into this the coils are put, having pieces of cork fixed at the corners, so that no contact takes place between the coils. On the top of this box, as shown Fig. A in plan, a piece of stout brass ½in. by ¼in. is placed; at intervals of about 1in. a hole is bored, then this hole is made taper with a reamer; plugs of brass are then turned so that the taper corresponds with the taper of the hole. At A and B a binding screw is fixed; underneath, between every two holes, a small hole is bored, and a short piece of wire screwed in and fitted with a brass nut and washer; these serve both to bolt down the pieces of brass, and to fix the resistance coil wire to. Finally across the centre of each hole the brass is sawn right through. Fig. 5 shows a section through the plug A, the pieces of brass B, the top of the box C, the pieces of wire screwed into B, the nut and washer E and F, the wire G being clipped between them. Between each pair of pieces of brass is clipped some resistance; when all the plugs are in, the current will go from A B (Fig. 4) round by the thick brass at the top; if a plug is drawn, the current has to pass through the resistance that connects the two pieces of brass, thus left without a plug.

It is convenient to have things arranged so that we have plugs putting in the following resistances:—1 . 2 . 2. 5 . 10 . 10 . 20 . 50 . 100 . 100 . 200 . 500. By this arrangement we can get any integer between 1 and 1,000.

In conclusion, the drawings are not to scale, but are merely diagrams; also, if I have left anything not very clear, I shall be glad to answer queries on this subject. **Ll.B.A.**

ELECTRIC VERSUS GAS-LIGHTING.

[20131.]—Your correspondent, M. Jonson (20104), has adopted a very misleading method of comparing the relative cost of electric-lighting with gas-lighting. He takes the *selling* price of gas and compares it with the first cost of electricity. Instead of three shillings and four pence per thousand feet, he should have stated no shillings and no pence per thousand as the prime cost of gas *at the works*; seeing that, where there is no wasteful outlay, the by-products—coke, ammonia, naphtha, &c.—cover the cost of making the gas.

If gas-production were subject to ordinary competition, we should be supplied at one shilling per thousand cubic feet, which would pay the expenses of conveying the gas to our houses and fair interest on the capital outlay.

In some of the towns where the corporation has bought the gasworks, they are supplying at about half the price of London gas, and are able to make out of that a profit that is paying off the exorbitant price that was extorted for getting rid of the monopoly, and, in addition to this, are paying for municipal improvements.

My statement, as to the prime cost of gas, is based upon their experience of the working of the *extensions* of the gas-works made since they paid off the old company. The cost of these extensions being only equal to legitimate value, they alone supply fair data for estimating the fair cost of the gas.

I have had much and early experience in the electric light, and some experience in the distillation of coal, and have no hesitation in denouncing the present gambling in electric light joint-stock companies' shares as a miserable delusion, wherever it is not a deliberate swindle. When all the calls are paid up, and all the debentures are "floated," and all the devices of license granting to offshoot companies are played out, the justice of my denunciation will be understood by the public in general and the victims in particular.

W. Mattieu Williams.

ELECTRIC METERS.

[20132.]—The interesting account given in your last issue of the meters of Messrs. Sprague and Edison reminds me that I also have an idea on that subject.

It is well known that a current of electricity passed through acidulated water decomposes it, evolving hydrogen and oxygen. Why not utilise the gases to rotate a wheel, and so measure the quantity of electricity which has produced them? The motion of gas in and out of a chamber is made to do this in a coal gas-meter, and I do not see why the same could not be done to measure electricity. It would be a very simple matter to arrange a wheel so that the ascending gases would impart a circular motion to it which (by means of suitable wheels, &c.) could be made to actuate hands indicating units, tens, thousands of current. The quantity of gas evolved would be proportional to the strength of the current and the time during which it had passed, and for pretty powerful currents at least the resistance introduced by passing the current through acidulated water could not make much difference. The meter would be more sensitive than weight meters (if I may use the term), owing to the fact that the volume of gases evolved would be so much greater than the weight of the gases themselves, and consequently better able to overcome a resistance and move a wheel than the small weight of copper deposited would be to sink a float.

It would also be economical, as the mixed gases (oxygen and hydrogen) could be collected and utilised by limelight workers, &c., or even used to drive a motor by their explosions, somewhat as the gas-motors are driven by the explosions of coal-gas and air.

The value of any metal deposited from its solution is, on the other hand, comparatively very small, and the solution of the metallic salt costs something, whilst water is cheap enough. I hope some of our practical workers will discuss the idea, and tell us what they think of it, though candidly I do not think (theoretically at least) that any electric meter could surpass that of Mr. V. Boys, described some time ago before the Physical Society.

Dublin, June 2. **Clement J. Leaper.**

A BENNETT BATTERY.

[20133.]—Mr. Bennett's paper on a new form of battery, which appeared in the *Electrical Review* of the 24th of last February, a résumé of which you published shortly afterwards, contained so many points of interest, that I determined to give it a fair trial; and having a large number of Swiss-milk tins by me, I utilised them in its formation, and as it may interest some of your readers, I give you the details of construction with the cost.

The tins are 3in. diameter and 3in. high, the porous cells are 2in. diameter and 4½in. high, fitted with a cork bung ⅝in. thick; the zincs are stout-sheet, 3in. square, cut with a projecting strip 1¾in. long by ¾in. wide, which passes through the bung: these zincs are bent lengthwise into an S-shape, so as to pass inside the porous cell. The negative element is ordinary cast-iron borings, such as are used for making rust-joints. On the outside of the tin is soldered a piece of copper-wire cord 3½in. long, on the end of which is one of my clips, described in your paper of the 13th June, 1879; another of these clips is soldered to the projecting end of the zinc outside the cork bung; the connections from cell to cell being a piece of the same cord 3in. long, with a clip at each end at right angles to the cord. The exciting fluid is a saturated solution of American potash, its causticity improved by boiling in an iron pot until dissolved, and adding some air-slaked lime.

My battery consists of thirty cells, the tins for which having been opened according to the printed directions, the hole through which they were originally filled remains in the bottom, so, fearing that the potash might in time eat away the solder, I painted the bottom of each tin inside with paraffin—on which the potash seems to have no effect. About 1in. of the top of the porous cell is saturated with melting paraffin—the cell being previously heated in an oven: the bung is also well saturated with the same. The cell was nearly filled with the cold solution, and the bung pressed in while soft and warm; and then the outside of the top, and the joint of the bung painted over with the hot paraffin. (From some recent experience I think the sealing of the porous cells ought not to be perfectly hermetical, but as near to it as possible.) The bungs were all fitted to the cells beforehand, as were the zincs to the bungs; but had to be removed in order to soak the bungs, and were replaced while the latter were warm; the clips were soldered on afterwards. This completed the porous cell, which was then placed in the centre of the tin, and firmly packed thereinto with the iron borings, which were previously damped with the potash solution. As to the cost of this battery—the tins were valueless:—

	s.	d.
26lb. iron borings	3	0
30 porous cells	5	0
7lb. potash	3	6
4lb. zinc	2	0
30 bungs	1	3
½lb. paraffin	0	6
Lime, wire, gas, &c.	1	6
	16	9

or 6¾d. per cell.

The preparation of the potash solution is the most unpleasant part of the manufacture; the 7lb. of potash took over six quarts of water, and I used about 1lb. of lime; thoroughly dissolving the potash first, added the lime cautiously, and boiled it for a quarter of an hour; let it settle, and drew off the clear liquor with a siphon, filtering the muddy portion; the specific gravity of the saturated solution was 1270·5. When filling the cells I kept a basin of acidulated water by me to dip my fingers in, as the potash has a serious effect on the cuticle.

I think this battery is as well entitled to the name of its inventor as is a Daniell, a Grove, or a Bunsen; it is for many uses peculiarly handy and convenient; its durability has yet to be found out; mine has reduced little, if anything, in three weeks. There is no need of amalgamation, and there is not the ugly messing and crystallising of the copper attendant on the Daniell and some others; and, being entirely sealed up, it can be carried about without danger. As to its strength, Dr. Guthrie, of South Kensington, has most kindly tested two of my cells for E.M.F. One (A) gave 1·14 of a Daniell, (B) giving 1·19, the internal resistance being 0·838 of an ohm. The Daniell being taken as one volt, on leaving one cell in short circuit for some hours, whilst the E.M.F. was much reduced at the time, the internal resistance was increased to over one ohm; but the cell recovered its strength afterwards.

Prof. McLeod, of Cooper's Hill College, has also favoured me with the results of an extensive set of experiments he has made with a somewhat larger cell than mine. The tin was 5·4 diam., by 5in. high, and the porous cell 2½in. diam., by 6in. deep, charged with a solution of 4oz. caustic soda. At the commencement the E.M.F. was 1·005 volts; in 64 hours this had gradually increased to 1·213 volts, internal resistance being 1·007 ohms, and the deflection in a tangent galvanometer 56·0-1, which varied, according to length of time of connection, from 42° to 54°, the E.M.F., at time of disconnection, varying from ·647 volt to ·938; but when left standing for two days it rose to 1·045 volt, the internal resistance also varying from ·818 of an ohm to 2·606; but the law of its increase awaits some further experiments. It is too soon to draw a comparison between this form of cell and the Leclanché; but, so far as experiments go, they compare favourably as to E.M.F., and their relative recuperative powers, their cheapness, ease of construction, and of renovation, and their handiness, are much in their favour.

Robt. J. Lecky.

SOURCES OF ELECTRICITY.

[20134.]—Some years since, I recollect reading of an experiment in which a bar of iron was coiled round with a *small* pipe, through which high-pressure steam was allowed to pass, upon which the bar became magnetic, and would then attract a needle some inches away. Now, whether this is a great, or small force, it is uncertain to say; but if the pipe should be insulated from the bar, and also from adjoining coils, no doubt there would be an increase of power; but this is not all, for if the ends of the pipe were made to complete a circuit by means of a wire, the power would possibly be further increased, and made available for the electric light or other purposes.

Now, remembering the hydro-electric machine of Armstrong, a still further conservation of energy might be had by suitable arrangements. But before dealing with this fully, I will refer to the experience of engineers in respect to expansion of steam in the cylinder. In this case it is often found that much steam is condensed therein, and herewith also ensues a cooling of the cylinder. Now, taking into consideration the theory of latent heat which would be supposed to be given off to the cylinder; how, then, is the cooling accounted for? At the risk of much adverse criticism, I venture to put forward a theory of my own—namely, that when a certain degree of expansion occurs, the heat is isolated, and then exists as electricity, and passes away to the earth; and that this accounts for the apparent anomaly. Presuming this, another idea occurs—namely, that with a number of metallic points set within the condenser, and further communication with each other insured, all the water required for condensation might be saved through the escape of the said electricity. To avoid condensation in the cylinder (which is a great evil), it should be insulated, for, possibly, the opportunity for escape has an influence here in bringing about the condensation. To confirm this, observe how the rain forms and falls, just after a cloud has discharged its electricity as lightning.

To return, now, to the magnetic experiment: it is quite possible that the boiler and condenser are in opposite electric states. If this be so, by insulating the boiler, and the bar with its coil-pipe, which connect with a chamber for a condenser, also insulated, we may then have a shunt for using electricity for any purpose, between the boiler and the condenser, and, at the same time, the energy augmented by the interposition of the iron bar.

We here have dispensed with the steam-engine and the dynamo-machine, and, so far, with all visible motion (being steam internally); that is, if these premises turn out correct, and will only further observe that insulation may possibly account for obstinately-heated bearings; and conclude with hoping that my critics may be merciful.

Barry-road, S.E. **J. H. Huxley.**

REFRIGERATION—E. MAGNETIC MOTORS, &c.

[20135.]—"LL.B.A." (20080) says, referring to Refrigeration (20055), that no heat would be lost, as it "does no work in expanding," whatever that may mean. Possibly he means that no equivalent co-relative force is produced; but such is not the fact, for the expansion of the included air helps to work the pump.

Did "LL.B.A." never hear of a Dr. Black, who made experiments with heat, and found there was such a thing as latent heat; and does he not also know that expanding gases in air have "a greater capacity for latent heat" and consequently *sensible* heat is absorbed, and its absence proved by the falling thermometer, and hence cooling? I might, in my former letter, have used this illustration; but as it was intended for others beside B.A.'s, I preferred to use the more familiar fact of the snow-line.

Mr. Ponton (20016), as to my E. motor (19997), speaks of the "friction of the particles of iron," whatever that may mean. If he means the atoms, I must tell him that we absolutely know nothing about internal friction of atoms, although, judging by the free behaviour of electricity among them, we might conclude there is plenty of room. As the indicated construction of the E. motor is founded on fact, and there is no theory *assumed* to throw doubt on its feasibility, and the train of reasoning leading thereto, and as I still have no doubt of the force being *great* in proportion to the space in which it acts, I think Mr. Ponton's observations have no bearing on the matter.

As no one has noticed Mr. Buttershaw's assertion (19909) that he can, at one setting of the slide-rule, give the answer to $\sqrt{5 \cdot 5^3}/11 \times 53/37 \times 17$, perhaps he will kindly enlighten myself and others as to "how it's done." I can set three terms to find a 4th term, but am not clever enough to set more on at once.

Mr. Blanco (20083) gives me the credit of making a discovery in evolution (19898). I did not claim this. I only endeavoured to make the matter plain to ordinary readers, which I should hardly think is the case in the worked example *he* has given.

Barry-road, S.E. **J. H. Huxley.**

THE BERLINER VIOLIN.

[20136.]—I send you a violin, and trust it will arrive in good condition. It is one of a lot of cheap instruments which I bought last year in Germany for experimental purposes, and which cost me about 40 dollars a dozen. I selected this on purpose to show what my invention will do on such an instrument. It has been strung up for about a week, and is therefore a fair sample of a cheap and entirely new violin. The resonator is of metal (steel or iron), and weighs 4¼oz., but I have found that it can be reduced to 3¾oz. The inside is fixed similarly to the published drawings. I should like to have this violin submitted to some of your correspondents, and solicit criticism as the safest way to ultimate success. Mr. Julius Eichberg, Director of the Boston Conservatory of Music, has most favourably expressed himself on my invention, and has ordered an instrument for himself.

Boston, U.S.A. **E. Berliner.**

[If "Fiddler" and any other of our violin correspondents would like to try the violin and report, they are welcome to do so, if they will undertake to fetch it themselves and return it in good condition. —Ed.]

CANADA AND THE TRANSIT OF VENUS.

[20137.]—As a constant reader of your highly useful issue on this side of the Atlantic, I shall be much obliged if you will grant me a little space to allude shortly to the important geographical position of the Dominion of Canada at the approaching Transit of Venus. As the Dominion Parliament has made an appropriation to contribute its share to the numerous staff of observers placed by England, France, Germany, and the United States in different parts of the globe, the question at once arises, Where, in the Dominion, may be found the places most suitable for fixing the different instruments, so that the observations to be taken may be of the greatest use to future science? In looking at this important part of the subject, the great diversity of climate which prevails at the date of the approaching transit (6th December) has to be closely considered, for at some stations the transit may be entirely invisible from beginning to end. In this connection it may be noticed here that at the last transit in 1874, the Australian colonies organised four parties for the purpose of taking observations, and at some of their stations, owing to cloudy weather, the observations were not full and complete. Now, surely the Empire colony of Canada may be expected, on the approaching occasion, to do as much as Australia for this the sublimest of all the sciences.

At the last transit in 1874, the base-line lay greatly between stations in the southern part of Siberia and that region of the globe, with stations in Australia and New Zealand, an arc of over 6,000 miles. At the coming transit in December the circumstances are still more favourable for separating the chords of transit on the sun than any which have yet occurred; hence, action ought to be taken, so that the opportunity may not be lost. It may now be observed that, from a close examination of the terrestrial sun illumination at the instant of the first internal contact, it is only at some point or region on the eastern boundaries of the Dominion that sure and reliable results can be expected and obtained in this, the most essential and critical part of the work. Hence, we suggest that one of the best places in Canada to observe the first internal contact, and to follow the transit by photography, is at a place called *Nain*, on the eastern shores of Labrador, in latitude about 55° N., longitude 4h. 8m. slow of Greenwich time; and for safety, in case of unfavourable weather, another Equatoreal telescope might be used at Cape Breton or Halifax, which is considerably south of Nain, and not far west of the same meridian. For the last internal contact at egress, seen in Canada, which takes place in the afternoon, the Equatoreals in the colleges at Kingston and Woodstock may be of great use, provided they have the other instruments to obtain their absolute time and their true latitude and longitnde, for without that knowledge observing in this case is merely an eye gratification, and nothing more. Moreover, there is another feature connected with the transit observations in Canada which should not be overlooked, and which is worthy of the attention of the Dominion authorities—viz., when we take into account the great extent of the Dominion territory, which is known to be equal to the entire area of all Europe, and to the circumstance that as yet we have not a single meridian established through it which could be relied upon as a sure point of reference at this transit, it will appear obvious that in promoting our knowledge of astronomy, as in this case, we are also, at the same time, adding greatly to our geographical knowledge of the Dominion; and the value and importance of this fact soon appears when we look at what it has cost the United States within the last twenty years to complete their present great network of meridians for the determination of longitude over all the Union.

From a close inspection of the earth's sunlit hemisphere at the first internal contact, and at the last internal contact, as seen in Canada, it may be observed that a base-line can be formed with the Canadian observations above-mentioned, extending even to the Antarctic Circle, which is an arc in latitude of over 120°. We allude here to a place called Graham's Land, forming a base-line with Nain nearly equal to what Winnecke used to obtain the parallax of the planet Mars. At all events, we may be certain that many good observations will be taken as far south as Cape Horn, and on some of the surrounding islands, so that we have reason to hope that they will lead to improved results.

It may be added, in reference to the chances of having a clear sky along the western shores of Lake Ontario and the banks of the St. Lawrence on the 6th of December, and about the time of the first internal contact at ingress, that from a carefully-kept register of the morning weather since the last transit eight years ago, it has been found that only two out of the seven mornings could have furnished the scientific results sought for and required at the first internal contact of Venus.

M. Turnbull.

Toronto, Canada, May 18th.

GRINDING AND POLISHING GLASS SPECULA.

[20138.]—Mr. Wassell, in his very explicit description (letter 20032) of the use of the Foucault test, recommends the employment of a lamp-shade with a triangular aperture. I do not think this can give such accurate indications as a truly circular one. The mirror repeats the form of the radiant point, and if this be angular, it does not seem so easy to decide upon the accuracy of the convergence, as when a luminous disc is viewed, having a regular outline. I believe the circular luminous point is in general use in the optical trade for testing purposes: perhaps "Prismatique" will favour us with his opinion on this matter. Mr. Wassell is describing the shadow test, and doubtless the angular hole will show the general character of the surface; but I do not see how it can indicate the accurate convergence of rays from point to point. I may appear to attach too much importance to a small matter; but I think the form of the aperture is one of the chief points in optical tests.

In answer to your esteemed correspondent's query (letter 20044), the rule for aberration, if correct in one case, should be so in another, no matter what may be the particular aperture and focus of the mirror.

While thanking Mr. Calver for his reply (20019), I must say I am somewhat disappointed. My suggestion was not made with the object of inquiring whether he made use of diaphragms in working: as a matter of fact, it is of no interest to me what particular method he uses. All I and Mr. Wassell wished to know was, the difference between the central and marginal foci of a truly parabolic mirror when tested at the centre of curvature. This is a matter independent of any peculiar method of working; mirrors of equal perfection should give results in precise agreement. As the information is not forthcoming, I trust some reader will accede to the request of Mr. Wassell. **Orderic Vital.**

THE CONCENTRIC MICROSCOPE.

[20139.]—I must apologise to Mr. Moss, and withdraw my statement as to his being at the meeting (R.M.S.) on Nov. 10, 1880; but my having been misinformed as to this point is not material to the question. The question is, Who first published *the principle* of throwing the two axes of motion into one plane, so as to intersect at the object, and then concentre all the motions of the microscope round the intersection — thus enabling the centres of the object and of the lamp-flame to be converted into two points in an ecliptic plane, and superseding a host of swinging-sub-stages and other contrivances, which were complicated, expensive, and unmanageable? Now, Dr. Edmunds described this principle fully on Nov. 10, 1880, and the abstract of his remarks was published in the *Journal*, R.M.S., on Dec. 13, 1880. Mr. Moss filed his "provisional specification" on Dec. 22, 1880, and his "specification" on June 22, 1881. Mr. Wenham filed his "provisional specification" on Jan. 12, 1881, and the "specification" to which he refers on July 22, 1881. No amount of dust-throwing will alter these dates.

Will Dr. Edmunds at once publish his drawings in "ours," instead of keeping his designs in his cabinet until he finds leisure to make a model stand with his own hands?

Another F.R.M.S.

WENHAM'S NEW MICROSCOPE.

[20140.]—Dr. Edmunds having now come forward personally with some sort of claim to the new microscope, I have only to say, by all means let him grasp what credit he can. I shall not enter into any discussion with him, as matters of much more importance to me now engage my attention.

F. H. Wenham.

MICROSCOPE POWER.

[20141.]—Your correspondent, "Antares" (letter 20074, pp. 261-2) gives many valuable notes on the practical determination of the principal numerical data relating to the outfit of a moderately well-furnished microscope. It must of course be understood that his tabulation of data refers to the particular objectives and eyepieces specified, and therefore in itself is only of value to the possessor of the actual instrument. But the system of tabulation appears to me excellent and exhaustive, and I would cordially recommend its adoption by all in whom a love of accuracy is a factor in their microscopy. The careful working out of the needful measurements, and the due consideration of the why and wherefore of each operation, cannot fail to fix in the mind a comprehension of the instrument which will be a source of pleasure in itself, and which will assuredly give weight to any detailed account of special investigations the worker may engage upon.

"Antares" devotes paragraph (*d*) to the apertomer of Prof. Abbe.

He mentions an experiment with this apparatus which he has found somewhat perplexing. I quote the experiment:—

"Suppose an oil-immersion o.g. is tested by the apparatus, and in the first instance focussed *dry*, and the reading taken, then let a drop of pure water be interposed; the readings instantly increase considerably, and the field becomes brighter. Next, let the water be completely removed, and oil of cedar substituted. The readings generally increase again, to some extent; but not much; and oil-immersion o.g. are to be met with, and good ones too, which show no increase of aperture whatever, by this apparatus, with oil as compared with water."

The perplexing part of this experiment to "Antares" seems to be to account for the non-increase of the reading when he substitutes oil for water as the immersion medium in measuring the aperture of certain oil-immersion objectives.

It appears to me the matter can be thus explained:—

Assuming that the oil-immersion objective measured by "Antares" has a numerical aperture of 1·25 (say, 110° in crown-glass), let us follow the experiment with a running commentary.

On taking the measurement with the lens used dry on the apertometer-disc, the reading is of course limited to slightly less than 1·0 N.A., because 1·0 N.A. = twice the critical angle from glass to air. In this case the critical angle is, say, 41°. So long as the medium between the plane surface of the disc and the plane face of the objective is air, the effective critical angle must obviously be that between glass and air, and no measurement can be recorded greater than twice the critical angle.

On interposing a drop of water, the reading is 110° (= 1·25 N.A.) The former critical angle has vanished; the critical angle now effective is that between glass and water, say, 61°. Twice this figure would be 122°, which is 12° in excess of the aperture we are measuring, and hence presents no obstacle to the record. The substitution of oil for water in this case cannot increase the reading, because we have already measured the maximum aperture of the lens.

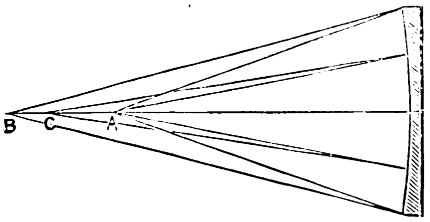
If instead of trying the experiment with an objective of 1·25 N.A., "Antares" could try it with one of, say, 1·4 N.A., the result would be as follows:—

Used dry the reading would be just less than 1·0 N.A. (= 82° in crown-glass); with water interposed it would be 1·33 N.A. (= 122° in crown-glass); with oil, 1·4 N.A. (= 134° in crown-glass). In this case, the objective has an aperture even exceeding twice the critical angle from glass to water, hence the water limits the measurement, and the true reading of the aperture requires a more highly refractive immersion medium to be used such as oil of cedar-wood. **Akakia.**

MR. WASSELL'S SPECULUM TESTING.

[20142.]—MR. WASSELL is at present engaged in the testing of specula, with the object of finding out, if possible, some definite rule or formula by means of which may be ascertained the correct distance of the focal point for parabolic rays from the centre of the spherical curvature when tested by the Foucault test. This is a line of research of the greatest importance, and I would urge upon all our readers who have the requisite mathematical knowledge to assist Mr. Wassell in his investigations.

Let the speculum, of which A is the centre of curvature, be converted into a parabola; the marginal rays will then be reflected back to a greater distance, B, and the intermediate ones will fill up the interval, as may be shown by C. The thing is to find out the rule which applies to the case, so that when testing, the amateur may know with absolute accuracy the exact fraction of an inch beyond A, at which not only each zone, but any point on the speculum, at any distance from the axis, should give a correct focal image.



I believe Mr. Wassell is at present testing the truth of the rule which he himself enunciated a week or two ago; but that rule appears to me rather empirical. I incline to the opinion that the case is one of pure mathematics, and that an absolutely accurate formula can be prepared which shall apply to specula of any focal length, and to rays of any angle of deviation, as, indeed his does; but what we want is a rule which can be proved to be mathematically exact. In a recent communication, Mr. Wassell requested owners of specula by good makers to send him some for experiment, and in reply to that I sent him one of 8in. diameter, and am pleased to hear from him that others have done the same. This is gratifying, and shows the interest which is being taken in the subject.

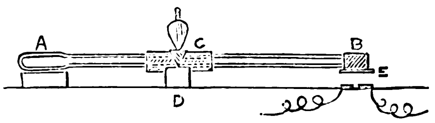
I have no doubt that if those of our readers who are equal to the task would investigate the theory and supply a formula, Mr. Wassell would willingly put it to the test. He has been supplied with some mirrors of undoubtedly good parabolic figures, so that we have now a capital opportunity of laying a firm foundation, upon which all aftercomers may build. We cannot be too much obliged to Mr. Wassell for his kindness in undertaking this investigation, as well as for the numerous and able letters which he has contributed to the ENGLISH MECHANIC on speculum matters.

In the diagram the distance between A and B is enormously exaggerated, and the cone of rays shortened for convenience of insertion.

Thos. K. Mellor.

A SIMPLE AND CHEAP FIRE DETECTOR.

[20143.]—A B is the thermometer sliding tightly in a brass tube, C, which is balanced on knife edges, on the block D, and having at E a small plate of platinum or other metal, fixed on, face downwards. Directly under this plate are the terminals of two wires leading to an electric bell. The thermometer is adjusted in the tube C, so that when the temperature rises to the desired point, the end B, overbalancing the end A, descends, completes the circuit, and rings the bell. This occurs, of course, by the mercury expanding and causing the end A to become lighter, and the end B to become heavier.



Broughty Ferry. **Robert S. Baxter.**

AMERICAN ORGAN.

[20144.]—I SHOULD like to help Mr. Floyd by any information I could give to his inquiries (20108, p. 285) concerning reed-voicing; but I am afraid I can tell him but little. The object sought in bending the reeds is to attain the diapason tone, and the man who can do this best is the one who could give the reeds any other tone that is possible under the conditions. If you take an ordinary tube-board, and bend and twist the reeds about in any and every way, you will not get any great variety, as they are all of the reed, reedy. The tubes in these boards, it may be assumed, are correctly proportioned to develop a diapason tone, and of sufficient area to make the most of the reed. When I set out my large board (page 219), I adopted this scale for the full-sounding sets; the others I got by experiment—that is, making a specimen tube, and trying it in a similar position to that it would occupy finally. I cannot give any scale for them, as I do not know of any: but some of the tubes are so small that there is only sufficient room for a small puller in the tube to withdraw the reed.

Then as to length. It is certainly an advantage in a soft stop to obtain a long tube, for it mellows the tone considerably; but how long they can be made with advantage is a question I cannot answer, as you would have to build your instrument without regard to space, if you carried this point very far. Judging by your letter, I should think you are not going to confine yourself to space; and, if such is the case, you will have a fine opportunity to test the efficacy of long tubes. Another point that demands attention is the windway, or mortise-hole, over which the reed is placed. Roughly speaking, you may not enlarge it, especially in the treble, but may contract it *ad libitum*. Do not forget that these long and narrow tubes are more troublesome to cut than the others, as the same tool will not do for them. In trying your hand at bending the reeds, I think you will find that the reed that has the most bend and twist is the soft windy one, the one that is so treated without being overdone—i.e., does not waste the wind, has the full round tone; from this to the straight tongue, are the different degrees of reediness; and the one that is bent only, has the string tone. Try a set of the latter in ordinary tubes; give a good bend and lift the heel portion of the tongue a little.

When you have decided to build an instrument with pedals, and provided a blowist, I suppose you may as well have a constant pressure in the bellows; but by so doing you destroy one of its best qualities—viz., expression. If I were to build such a one, I should not confine my pedal to one stop, but have two at least, as the extra labour would not be much. When you have settled on the specification, why not send it on for publication, as you may get a little advice and perhaps help.

Joiner.

MEDICAL REPLIES.

[20145.]—SKIN DISEASE (47047).—"Sunflower" probably suffers from a chronic and often infectious disease of the skin (Pityriasis versicolor), which will be cured by a borax lotion (1oz. of borax to a quart of water). Dab the lotion on to the part affected so as thoroughly to saturate the skin, every night on going to bed. This will probably erase it in a few weeks, and can do the skin no harm. Pityriasis versicolor is allied to sycosis, inasmuch as it depends upon the skin being infested with a cryptogamic growth. The vitality of the spores is destroyed by the borax.

KNEE-JOINT DISEASE (47068).—If rheumatism, treat locally and generally for rheumatism, which is a constitutional disease producing local manifestations in various joints. If joint disease, properly so called, from mechanical injury or scrofula, must be treated generally for scrofulous diathesis, and locally for the trouble in the joint. Read former replies on both subjects. Detailed advice and treatment cannot be prescribed for such cases in these columns, nor can such details be safely settled unless upon the results of skilled examination and accurate diagnosis.

FITS (47080.)—Querist is suffering from epilepsy. Must get carefully examined by a competent physician and undergo suitable treatment. Many of these cases are perfectly curable if taken in time. After long continuance, local changes are produced in the nervous system, which are too often irremediable, and the patient is then incurable.

DIABETES (47083.)—This is a disease in which probably some failure in assimilating starch and sugar occurs, and the sugar is treated as a foreign body in the blood and thrown out by the kidneys. With the sugar a vast quantity of water is also excreted as a vehicle for carrying off the sugar. Hence all the symptoms:—1. Intense thirst, in consequence of the continuous elimination of water by the kidneys. 2. Emaciation, because one of the main elements of the food, instead of being oxidised in the body as a source of power after being absorbed, is treated as a foreign body and excreted. 3. Wearing out of the kidneys from overwork of those organs, whose duty ought only to be that of eliminating waste salines and nitrogenous débris. 4. In the exhaustion of system and kidneys which thus arise other phenomena occur to usher in death. I cannot undertake to prescribe in detail for such a case without seeing it.

James Edmunds, M.D.

Grafton-street, Bond-street.

STEAM LAUNCH.

[20146.]—THERE are a few things in this specification (letter 20115), that are perhaps worth further consideration: *Keel.*—If she is to lie in a tideway and take the ground at times, she would be better without a keel; the same strength and stiffness can be got with a double kelson below and above the floors and checked into them. *Planking.*—Yellow pine is so soft that every dint and scratch shows, and elm or other hard wood of thinner scantling above the bilge would be, I think, better. *Coamings* of coach-roof would be better framed, say, of cedar, varnished—of top and bottom rail 4½in. and munnions 6in. long, sliding glass windows 12in. by 6in., alternating with panels. *Bulwark.*—A 3in. mahogany would be a nuisance. The deck, if laid flush with the coving board and well arched, would throw rain and spray over as fast as it came inboard. A half-round hard wood rubbing piece screwed to the outside edge of the coving-board would save sides from injury. *Engine.*—Willan's engine is a most compact and ingenious machine, but I should prefer a simpler type of engine in which the vital parts are all visible and comeatable. A single reversed cylinder with a good heavy balance-wheel, for instance.

Robinson Crusoe.

TRICYCLE.

[20147.]—SEEING my name mentioned on p. 210 in the last December part of "ours" in reference to a tricycle I described in the "E. M." about 1868 or 1869, I would like to say a word or two from this far-off land. At the time I made that vehicle I was very closely confined to business, and I thought the exercise would be conducive to health. I, therefore, about 1865 or 1866, planned and produced the tricycle spoken of, and with your permission I will describe it, as, if it had been fitted with rubber tires in the modern style, I think it would have equalled many later machines. The two driving-wheels, formed of 1¼in. by ¼in. half-round iron bar, with 5-16in. round spokes, 12 in number, screwed into cast-iron hubs, were 36in., on a crank shaft with 5½in. cranks, one wheel loose. The seat was cushioned, placed slightly in rear of cranks, with the steering-wheel (afterwards altered to two) about 24in. diam., was carried about 4ft. astern of the driving-wheels, and a connection made with a lever on the right hand; against this lever I put a segment on the frame, $\frac{3}{4}$in. by $\frac{1}{4}$in., and a small blade spring held the lever to the segment, with sufficient grip to enable the hand to be released from the steering during the greater part of a journey—in fact, it could be set to any angle required. I remember setting it to run round a circle, on its trial trip, in the Mile End-road, London, which it did in about half the width of the road without a hand on the lever.

It was also made to unship for doorways. The frame (of T-iron), seat, and steerage, was narrow enough to enter an ordinary street-door, the lower half of the crank-shaft was hinged at one end, and a clutch at the other, while the wheels were held to the crank-shaft by feather and nuts. I could separate it and take it indoors in four minutes. I had also a mile indicator on the frame, working from the driving-wheel. I would like to say that I think this was about the first attempt to place the feet direct on the cranks; at least I had never seen or heard of it before, and I certainly had a power over it that could not be had with any treadle. I did not run far from London at any time, about 10 or 12 miles in the morning before breakfast, or in the evening. One snowy, frosty morning, mounting Muswell-hill, the wheels slipped very much in the snow: but I did it, and returned by Highgate-hill. Brakes were not thought of then, and I came down to Holloway at a splendid pace. Although I was mounted rather high, I remember one spill only, and that was in the Mile End-road, through running carelessly in the gutter.

Perhaps you would like to know something about these things here. A few months ago, a few young men met, and formed the A. B. C. (Auckland Bicycle Club). There are two or three machines here, and others have been ordered. Two of my sons sent home for the parts of two bicycles to fit up themselves; and here is an instance of the way in which English manufacturers get a bad name. They were to be hollow steel forks, with Stanley heads. Now, would you credit it, that the sockets on the heads were so loose in the forks that a lap of 18 gauge iron scarcely made them tight? I suppose it was, "Oh, let them go: they are too far off to send them back"; but things like these don't improve England's foreign trade. The roads around here are somewhat hilly, and not in such good condition as near London; but the Great South-road, extending about 70 miles, has very good gradients. It was made as a military road; but it remains to be seen how the rubber tires will be affected by the road metal, it being scoria from the many extinct volcanoes—very hard and sharp.

If this somewhat discursive letter is deemed worthy of a place in the English Mechanic, I may report progress another time. I am a subscriber from the first number.

SUPPOSED PHENOMENON WITH REGARD TO THE FLOW OF WATER FROM A PIPE.

[20148.]—Perhaps some of your readers can give me an explanation of the following phenomenon—or what appears to me to be such—which I observed whilst watching the flow of water from the mouth of the main drain-pipe here. The diameter of the pipe is about 2ft. 5in., and on the occasion in question the pipe was full of water to the depth of 7in. My attention was drawn to it by the circumstance that the flap of the pipe — which is capable of moving freely on its hinges—projected from the mouth of the pipe by about half an inch more than was absolutely necessary for the water to flow—7·8in. at water level, and 1·22in. at the bottom of the pipe. With the view of finding an explanation of the phenomenon I made the following observations:—(1) When the flap was moved to a certain small extent from the position above indicated, either by pushing back or pulling in, on the pressure being removed, it always returned to its original position. (2) When the flap was pushed in to such an extent that the opening between it and the pipe at water-level was just one half its original distance, or 7-16in. (the flap thereby coming into contact with the water), the pressure then being removed, the flap remained open to that extent. (3) When it was pushed close to the mouth of the pipe so that no water flowed, on the pressure being removed, though not quite instantaneously so to speak, the flap returned to the same position as in case (2), 7-16in. (4) Finally, when it was pulled back so that the distance between it and the pipe exceeded 7-16in., then it did not return to this position on the pressure being removed, but took up its original position 7·8in. at water-level.

The only explanation I could arrive at to account for the above phenomenon, was that of atmospheric pressure on the portion of the flap which is opposite the wetted part of the pipe; and this moment of atmospheric pressure may be estimated at about 5·70lb. **C. H. Romanes.**

THE CONTINUOUS BRAKES BILL, 1882.

[20149.]—The Continuous Brakes Bill was presented to the House of Lords by the Right Hon. Earl De-la-Warr, on the 24th of February, and read a "first time"; and on the 20th of March it was read a "second time" without a division.

The object of the measure was to compel the companies to fit their trains with brakes which fulfil the Board of Trade conditions; hence, it followed that all persons who have spent large sums of money in trying to "push" brakes which are inefficient, tried to the utmost to prevent a Bill becoming law which would require really good brakes to be used. A combination among the railway representatives in the House of Lords was formed, and two modes of attack decided upon. 1st. To move the "previous question" and thus quietly smother the subject. 2nd. To eliminate in committee the second or "automatic section," by which the Bill would be rendered perfectly useless.

On Monday, May 22nd, Lord De-la-Warr moved that the House go into committee on the Bill, upon which Lord Colville (chairman of the Great Northern) moved the "previous question."

Lord Sudeley, on behalf of the Board of Trade, expressed a hope that the House would go into Committee with the view to having it considered by a Select Committee; and after quoting the data given in the last return, he remarked:—

"The Board of Trade had up to the present time been in hope that the force of public opinion, and the moral pressure which they were able to bring to bear upon the companies, with these returns before them, would have induced them voluntarily to take up and deal thoroughly with this important question. Such a course was in every way far more desirable than to compel them by legislation to do so; but after the experience of the last five or six years it was difficult to maintain that anything short of legislative enactments would induce the companies thoroughly to grapple with it. In these circumstances, and while the Board of Trade would not, perhaps, have initiated a measure of the kind which was now before the House, they could not help thinking that the time had arrived, in the interests of the travelling public, when some pressure should be put on the companies."

Lord De-la-Warr said it was rather an unusual course to move the previous question on a motion to go into Committee on a Bill which had been read a second time without opposition. The only inference he could deduce was that the noble lord (Colville) did not wish that the Bill should be considered on its merits, as it might be in committee.

The previous question was carried without a division, and the matter is therefore delayed for the present. The *first* mode of attack having succeeded, the *second* was not required, but it will nevertheless be advantageous to consider the subject. Had the measure reached the committee stage, an amendment would have been moved "to throw out the automatic clause on the ground that automatic action is wrong because it is not used in other appliances on railways." This latter assertion has been so often made that some persons may begin to think it true: it will therefore be well to point out that an automatic brake which will not allow a train to proceed unless it is in safe condition, simply carries out the principle applied to all railway signals and the block system. When a signal-wire breaks, the signal flies automatically to "danger," and stops the traffic.

In working the block system, it is a rule that "in the event of any failure of the instruments or bells, no train must be allowed to pass a signal-box on that section of the line where the failure exists, without having been previously brought to a stand, and the driver and guard advised of the circumstance." Years ago all railway signals in their normal position were "off," and only put "on" to protect or stop a train when required; but at the present time every signal stands at "danger," and is only taken "off" for a train to pass when necessary. Now this is exactly the principle which applies to continuous brakes. A non-automatic brake is always "off," and requires to be put "on," and there is always the fear that this cannot be done when necessary.

An automatic brake may be considered as always "on," and requires to be taken "off," therefore it is certain to act when wanted; but like the signals and block system, when it fails it will cause slight delay to the traffic; but this is indeed a small matter compared with the very great safety obtained.

Clement E. Stretton.

Saxe Coburg-street, Leicester, June 3rd.

In Bulgaria a post-office has, on an average, to deal with about 16,000 letters annually, an English one has 107,000, a German one 85,000.

REPLIES TO QUERIES.

⁂ *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[20079.]—**Cheap Bunsen Battery.**—Will "H. T. B." kindly give necessary instructions for depositing the copper upon the carbons of battery, as offered?—Geo. Neville.

[45505.]—**Watch Jewels.**—In a former number a correspondent made a statement to the effect that watches with jewels for the pivots to work in required no oil; such is not the case. Such a watch would, in a few months, stop through the wear of the pivots or of the jewels.—Parkinson and Frodsham.

[46124.]—**Telegraphists' Paralysis.**—Speaking from experience, I would advise "M. G. N." and others who are troubled with a similar complaint, to try rubbing well with camphorated oil every night over the joints and tendons affected Of course, change of employment, as suggested by our valued friend, Dr. Edmunds, would be preferable, but, for many, very inconvenient.—Colleague, Monte Video.

[46427.]—**Electric Engine.**—There is no difficulty in making a large engine to drive a lathe-overhead motion; but the cost of battery power for an 8-horse engine would be too much to suit any amateur, and a description of one would be no use. I do not think such an engine could be worked with satisfaction unless by a secondary battery charged by a dynamo, in which case the first cost would be very great. The power of an electromotor to work by a common galvanic battery should not be over 600lb.—1ft. per minute. This would be big and heavy enough, if properly made, to be called a $\frac{1}{4}$-horse engine, and could do three or four times more work by increased battery and cost when required. I will describe an engine that will do this if the Editor thinks it worth while.—J. Sutcliffe.

[46598.] — **Half-Chronometer.** — Although your correspondent, "T. M.," is not altogether wrong in stating that the above term is a misleading one, as it frequently induces the purchaser to believe that a watch so named partakes of the character of the chronometer as a timekeeper, still the word has a value and a definite use, as when not used to palm off inferior timekeepers, it designates, and that without possible error of description, a watch that is so far a chronometer that it keeps time without any greater variation from Mean Time than one minute per month. To describe such a watch as a "best lever," or even "compensated lever," only, would not be giving a sufficiently correct idea of its value and quality. —Parkinson and Frodsham, 4, Change-alley, London.

[46598.] — **Half-Chronometer.**—"T. M." would do well to study Saunier's work, and particularly the detent escapement, described on p. 515, and drawn on plate 10, Fig. 11, of that work. "T. M." is wrong in stating this to be a drawing of the escapement known as Morton's patent; he will see his mistake if he refers to my description (in my reply to "Chronos") of the last-named escapement, which has *two* locking pallets, and are unlocked by every vibration of the balance, whereas the one he refers to in Saunier is a single-beat escapement with only one locking pallet, and unlocked by one vibration of the balance, the return vibration being dumb; in fact, the only difference between this escapement and an ordinary pivoted detent chronometer, is that instead of it having a coiled spring for the recovery of the detent, it has a supplementary pallet known as the recovering pallet, and quite a different thing to what Morton's patent lever chronometer is. "T. M." also says Morton's escapement is never used. I have had some very fine watches through my hands for repairs, fitted with this escapement, and the term "half-chronometer" is as often used in speaking of it as any other name, and I must disagree with "T. M." when he says "half-chronometer" is shopkeepers' "clap-trap" to hoodwink customers, and is only a lever watch with a compensation balance. I admit that a "cheap-jack," or some dishonest shopkeeper, might try to palm off such a watch as a half-chronometer; but that is not the question.—G. K., Stockton.

[46598.] — **Half-Chronometer.** — I have not seen any answer that properly explains this question. "G. K." is quite in error in putting forward Morton's patent 14, which, by the way, is an unknown affair, comparatively speaking, to the practical watchmaker. The principle is very old, and "Saunier" says that "escapements of this class have always been unsatisfactory, and for evident reasons," which reasons he gives. Again, "T. M." does not help inquirers at all out of the difficulty, and certainly uses the "claptrap" with which he saddles the shopkeeper by trying to "hoodwink" the reader. This he does when he leads the reader astray by saying that "a verge watch or a Yankee clock is as much a chronometer as any kind of timekeeper; but, as a trade term, it is only applied to a watch with a detent escapement and a compensation balance." And that is all the explanation we get about the "half-chronometer," out of some five-and-forty lines of real, spread-eagle scribbling!. All the rest that he says the "trade" already know, and have long known; whilst for those who move outside of the horological orbit it need never have been said, for the good and sufficient reason that they cannot comprehend it. But we are not going to be "clap-trapped" and "hoodwinked" in that way, and "T. M." deserves to be cauterised for attempting to pass off upon the ENGLISH MECHANIC such pitiful, logical cheap-jackery. I make bold to affirm that there is not a sentient human being anywhere, who has anything whatever to do with a watch, but is perfectly aware that a chronometer is a distinct form of instrument standing by itself alone; and that it has no more connection with a verge watch or Yankee clock than "T. M." seems to have with the common-sense of the argument; and that is saying a good deal. And now about the half-chronometer. The term "half-chronometer," in its clearly-understood meaning, is the expression for the highest possible development of the lever watch. It consists of a chronometer-balance and an isochronal-spring, whether flat, breguet, or cylindric; in other words, of two-thirds of the movement of a full chronometer, the only difference between it and the chronometer proper being in the lever-escapement instead of the detent. Take the lever out, and put the detent into the movement, and then the "half" becomes the "whole," and *vice versâ*, if you choose. Of course, the "half" is "adjusted" and "timed," as well as the "whole." If "T. M." is in the trade, and happens to send his verge watch or Yankee clock to a customer who has ordered a chronometer, I am very strongly of opinion that a judge and jury will soon "scarify" him out of his foolery. Let "T. M." repent forthwith, and determine not to so insult the readers of the ENGLISH MECHANIC again. One word more. The name "half-chronometer" is very much abused by "pushing tradesmen," just as many things are abused; but the respectable maker will always, at once, explain to you in what it consists. Trust in no other.—C. S. M.

[46642.]—**Drilling Fluid.**—Bateman, East Greenwich, sells some salt which, dissolved in water, is the best stuff I ever saw for lubrication of drills and turning-tools. I have not any idea of what it is composed.—J. K. P.

[46694.]—**Brick Kiln with Down-draught.**—This should be about 12ft. wide, 7ft. to spring of arch, and 21ft. or 22ft. is plenty long enough for a kiln of this sort: fire-holes 11in. wide, lined with fire-brick and slake a little towards bottom of kiln, same as bars, 2ft. 9in. between holes, flue down the centre from one end to the other, 2ft. wide by 2ft. deep, to be covered over with strong fireclay slabs set apart for draught. I should suggest a stack at each end of kiln, as it allows the steam to escape better, to stand about 10ft. or 12ft. above top of kiln, not too narrow to throttle steam, as this is a great matter in these sort of kilns. Should be able to tell you more about it if I knew the clay. Entrance at each end suitable for a brick barrow to enter easily; should be three strong baulks each side, set in the ground and pinned together at top; also a screw cramp at each end to be screwed up when it is ready for burning. Further information if desired.—BRICK-BURNER.

[46702.]—**Drills.**—I think "A. F. W." might have let "Beetle Crusher" alone with the answer he gave to 46702 query. Any experienced mechanic will corroborate "Beetle Crusher's" statement "that a drill for cutting brass ought to be ground to a sharper angle than a drill for iron," and I may add, a drill for brass ought to be made a little harder and driven a good deal faster than one for iron. It is quite the reverse with a turning tool: for brass it ought to have a more obtuse angle.—D. D. M. L.

[46709.]—**Mildew on Composition Statues.**—If "Blackwater" gave some idea of the composition of his statues, and also of what he means by mildew, he might obtain a useful reply. As his query stands, it is doubtful if anyone can do more than guess at an answer.—NUN. DOR.

[46710.]—**Depositing-Trough.**—The best thing to line troughs with is pure sheet-lead, in which the joints have been burned, not soldered; but perhaps you will find pitch answer, if applied as a paint in turpentine. For copper solutions the trough can be lined with a cement made of six parts Burgundy pitch and one part guttapercha, or the latter can be used alone; but when silver solutions are in question, guttapercha will not do, as the cyanide of potassium acts on the joints. The tanks used in large silver-plating works are now made of iron, sometimes with a thin lining of wood or a coat of cement. I have not tried the experiment, but I think, if you soaked your wood trough inside with melted paraffin, it would answer well, provided you do not work with hot solutions.—W. E. G. M.

[46711.]—**Terra-Cotta.**—Do not the replies given pp. 73, 141, of the last volume answer this query?—T. P.

[46719.]—**Reading-Lamp.**—If the oil, wick, and especially the "&c.," are always precisely the same, it follows that someone must cause the oil to overflow. It is probable that the conditions are not always precisely the same; but I do not see how the action can be explained without examining the lamp.—E. P. B.

[46720.]—**Pitch of Cogs.**—This query has been answered many times in back volumes. Let "Jeff" look on p. 539, No. 437, and refer to the indices since then.—T. P.

[46728.]—**Ferrules.**—They are coloured either with lacquers or with stains. A bronze can be produced by brushing over a mixture of sal-ammoniac, common salt, and strong vinegar, or by exposing the metal to fumes of hydrochloric acid or chloride of lime. In fact, there are many ways of doing them which you will find described in back volumes.—ESSAR.

[46729.]—**Vegetable Ivory.**—What is it querist wishes to know? I don't understand what he means by preparing vegetable ivory, which is known as Coquilla nuts in commerce. If he wishes to make a pigment of them, I suppose that would be done by burning them in air-tight boxes and grinding.—NUN. DOR.

[46730.]—**Cheap Oils.**—Anyone who knows how to make a "good lubricating oil" at twopence per gallon, must be in possession of a secret of some commercial importance, and will scarcely be likely to impart it to others, except for a consideration.—NUN. DOR.

[46745.]—**Stopping Decayed Teeth.**—Many thanks to all. I was afraid a mass of metal pressing against a nerve would cause much trouble. A druggist told me that there were several qualities of carbolic acid (nine or ten I think), and that the pure was 9d. per ounce, and was in the form of a white crystal like oxalic acid. It appears to me that a really perfect stopping for teeth is still unknown. It ought to be white, as hard as ivory, not easily friable, placeable in the cavity of the tooth, in the form of a paste, not poisonous, and strongly adhesive to bone. It has often occurred to me (and it may not be a new idea), that a small cavity left in the stopping (internal) over a nerve, would preserve the latter, and prevent pain being caused by the plug. Like Mr. Ollard, I am a vegetarian, and have been for ten years. I do not smoke, except three or four times a year, as a cure for the toothache, and I seldom find it fail to do so in half an hour or so, but if it does fail, camphorated spirits of wine generally succeeds.—MURANO.

[46758.]—**Bicycle Varnish.**—There are some special preparations advertised, but probably ordinary pale lacquer will answer as well. Make the wheel as hot as you can bear it, and apply with rapid strokes.—T. P.

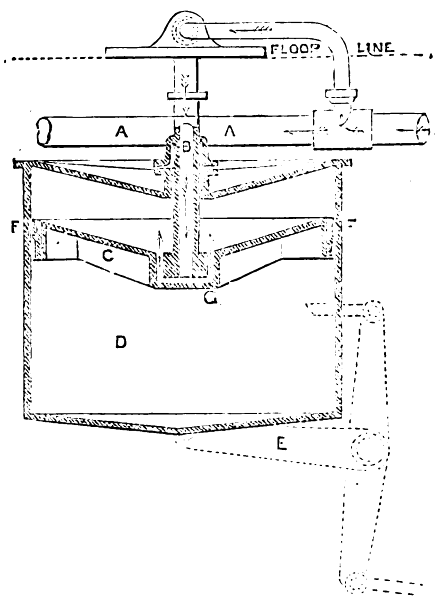
[46761.]—**Compensated Watch.**—I may tell "M. F." that finding my watch sometimes gaining and sometimes losing, I had it "adjusted" through a local watchmaker. It was sent to London, and examined by one who makes it a part of his business, and a contract was given that it should be done for 50s. It was declared to be a good watch and worth adjusting. I had it done, and it is vastly improved.—GIMEL.

[46761.]—**Compensated Watch.**—"M. F.," before buying his watch, should have exacted a written guarantee from the seller as to the amount of time that his watch should be allowed to vary in different temperatures. Some watchmakers are so conscientious that they will only use the term "compensation balance" when speaking of watches that are sufficiently well compensated to be spoken of as watches having "compensated balances"; but they reserve this term for their pet watches of a superior standard of timekeeping.—PARKINSON and FRODSHAM, 4, Change-alley, London.

[46767.]—**Repolishing Ebonised Pianos.**—It requires re-polishing with clear French polish, and if you have never tried your hand at the work it would be advisable to get a polisher to do it. There is nothing better than the polish, unless you have it varnished like a carriage, and that would cost rather too much.—T. P.

[46793.]—**Glueing Belt-Splicings.**—Get some good glue, melt it in the ordinary way, and then add tannin, leaving it to digest until the whole becomes what is called "ropy." Clean by skiving the ends of the belt to be spliced, and anoint both with the glue; place between two iron plates and clamp up until dry. Properly done, a very few stitches will suffice to keep the splice firm.—E. G. M.

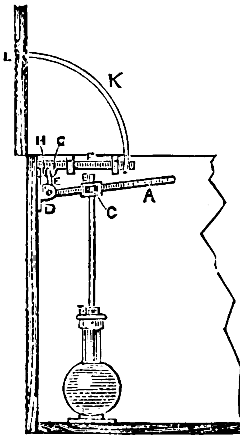
[46828.]—**G.W.R. Vacuum-Brake.**—The inclosed sketch of the cylinder of this brake will no doubt be acceptable, showing the brake on. A, continuous brake; B, hollow piston-rod connected by branch pipe to continuous pipe; C, piston; D, cylinder capable of moving freely up and down on the fixed piston, and connected at the bottom with brake-levers E. The piston is packed with an indiarubber packing-ring F, so arranged that air can pass freely from the bottom to the top of the cylinder; but not from the top to the bottom. The piston-rod is also packed with an indiarubber ring. Brake on.—Air is admitted into the continuous pipe and down the hollow piston-rod into the upper part of the cylinder, which pressing the indiarubber packing-ring against the sides of the cylinder, seals the vacuum on the under side of the piston, so that the pressure of air in the upper part of the cylinder, having nothing to balance it on the other side of the piston, thrusts up the cylinder and presses the brake-blocks against the wheels. The air then slowly leaks through a small hole G, into the lower part of the cylinder, and gradually releases the brake. The driver can take off the brake by creating a vacuum with the ejector, the air is then exhausted from the pipes and cylinder, and the vacuum being equal on both sides of the piston, the cylinder falls of its own weight, and holds the brake off the wheels.—NORTH STAR.



[46847.]—**Equation.**—A decisive proof that Mr. Lane Davies' solution (p. 226) is founded on a fallacy, as pointed out by "M.I.C.E." (p. 289), is the fact that the *three* unknowns are determined entirely from the *two* equations (3) and (a), the equations (1) and (2) being not used except in deducing (a). The fallacy is an old one, and it may be shortly expressed thus: if $a = b$, then $a^2 = b^2$, whence, on taking square roots, $-a = b$, so that $a = -a$. As "M.I.C.E." suggests, there is absolutely no reason for expecting a quadratic solution; there is, on the contrary, every reason for expecting the solution to be biquadratic, i.e., giving *four* values for each unknown, as *two* of the given equations are of the *second* degree. "A Medical Student's" artifice (p. 267) is perfectly legitimate; since, however, β is found by equating (A) and (B), x must be determined from either (A) or (B), and not from (V), which, being derived only from (a) and (b), can be satisfied by values that will not satisfy (c). Thus the second values given for the unknowns—independently of those for y and z being accidentally interchanged—are wrong. A direct solution is as follows:—Mr. Lane Davies' equations (b) and (1) give $2z - y = 18x^{-1}$ and $z + y = 11 - x$ respectively, whence $y = \frac{1}{3}(22 - 2x - 18x^{-1})$ and $z = \frac{1}{3}(11 - x + 18x^{-1})$, and these values, substituted in either (2) or (3), give on reduction $7x^4 - 55x^3 + 100x^2 - 198x + 324 = 0$, the four roots of which must be determined in the usual way. Of these one is a 2, second 6·062640 very nearly, and the others imaginary. The corresponding real values of y, z are 3, 6 and 2·301905, 2·635455 very nearly respectively.—R. E. B.

[46847.]—**Equation.**—The spirit in which "M.I.C.E." criticises my solution is quite refreshing after the style which "A Medical Student" thought proper to indulge in. Neither of them, however, has proved a fallacy in my solution. I do not see how it can be correctly said that the terms which I multiplied together to form a quadratic are identical simply because they can be reduced to an identity, any more than it can be said that equations (C) and (d) are identical, which manifestly are not; but they are the same equations in another form as those multiplied together, and not, as your correspondents say—$xy/2 - 3 = -xy/3 - 6$, a form into which they can be reduced. I quite agree with "M.I.C.E." that casting out a factor, found by trial, as "A Medical Student" has done, is not a quadratic solution. This can, and has been done, in various ways, better and shorter than the cumbrous process given by "A Medical Student." "M.I.C.E." asks—"Why should we expect to be able to solve the equation as a quadratic?" It is simply because it was given to be solved as such. Herein lies the difficulty. It is easily enough solved as a bi-quadratic.—J. LANE DAVIES.

[46854.]—**Mechanical Action.**—In the hope that I have understood your query, I venture to suggest the following mechanism:—The zinc rods are raised and lowered by means of the handle A, which having a slot B, acts at the centre of a horizontal bar C, connecting the zinc-rods of the cells. The object of the slot is to give to the ends of the rods play, so as not to interfere with their vertical motion. The whole lever is a bell-crank lever, turning on pivots D D¹. When A is depressed the rods will be lowered; at the same time the short lever E will move to the right, and together with it, for a short distance, the "belt" F, with the projections G and H. When A is raised, the zincs are raised, and as soon as they are lifted to the top, H is pushed to the left. Every time that F moves to the right it enters a hole in the quadrant K, which is fixed to the lid; L thus fixing it. H may be made as long as you like; G only long enough to be acted upon by E, till K is properly locked. If required, you could also easily arrange matters so that the handle A is outside the chest.—R. KANTHACK.



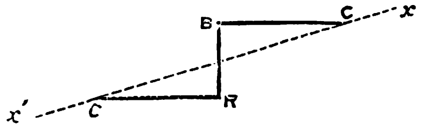
[46874.]—**Australian Railway Prospects.**—The prospects for any competent railway men in Australia are good in either New South Wales or Victoria; but, if possible, it would be advisable to get an appointment before starting, unless you can land with a little spare cash. The wages are good, but clothes and house-rent are dear.—S. M.

[46879.]—**Telephone Transmitter.**—To MR. TOLMAN.—Will you kindly send description of coil and how to make it, also should the carbon be plunged into mercury or not, and whether the primary wire should be wound next to core or not? Should the core be a solid rod, or composed of wires? A sketch of the connections, &c., will greatly oblige.—BEGINNER.

[46883.]—**Bleaching Straw Hats.**—These can be bleached by exposing them to the vapour of burning sulphur, which is about the best and cheapest method. It is usual to steam them first, and then put them into a chamber filled with sulphur vapour.—E. G. M.

[46884.]—**Varnishing.**—The best varnish for the purpose is, I think, the best hard copal, but, as a rule, it is a spirit varnish that is generally used, such as brown hard. If the chairs are painted it is cheaper to mix the final coat with some varnish such as copal.—T. P.

[46901.]—**Watt's Parallel Motion.**—I have to thank Mr. Fred. Walker for his reply to my query relative to the above. I think, however, that on consideration, he will see that he has not really met the point of my query. I assumed that the beam and the radius bar were equal and of given length, that their centres of motion were at a fixed distance apart, and that the point of attachment of the piston-rod was the middle point of the link; and what I wanted was the length of the link to make the motion most nearly rectilinear. To put the thing in a more mathematical form—Let b = length of beam C B, or of radius-bar C′ R; $2c$ = distance between centres of motion C C′; $2a$ = lengths of link B R. Then the locus of the middle point of the link (when C C′ is taken as axis of x, and its middle point as origin), is $x^2 (x^2 + y^2 + a^2 - b^2 - c^2)^2 + y^2 (x^2 + y^2 + a^2 - b^2 + c^2)^2 = 4a^2 c^2 y^2$. Now b and c being given, what must a be that this equation may represent most nearly a straight line? Will $a^2 = c^2 - b^2$ suffice? This relation would permit of the following position being taken up:—Where C B R and C′ R B are right angles.—A. J. SMITH.



[46954.]—**Dividing Apparatus.**—In my reply on p. 290, line 16, strike out the words "in order."—J. K. P.

[46956.]—**Chronometer and Watch-Rating.**—The rating of instruments to tenths of seconds is entirely a "faculty" of practice with both eye and ear; indeed, hardly any two raters can tenth the time alike. A ship, or box, chronometer beats half-seconds; and in rating it, the eye must be on the seconds-hand, whilst the ear must be on the tick of the regulator. But a good deal must be approximate guess-work until long practice has educated both ear and eye. An electric arrangement is possible to make the pendulum record the tenths of itself.—C. S. M.

[46963.]—**Astronomical.**—I am much obliged to "F.R.A.S." for his lucid explanation of my difficulties, and to the Editor for engraving wood blocks for the same. I hope it has been useful to others besides myself. May I further ask if the principle involved in the second question holds good in all pairs of bodies; for instance, between the earth and the sun, does the sun "in a sense" revolve round the earth—that is, round the centre of gravity between the two? And if so, would the sun be similarly affected by each and all the planets?—GIMEL.

[46975.]—**Gravel.**—A few days sea-voyage is an excellent cure. Sickness stirs up the acids in the body, and they reform healthily.—N.O.

[46983.]—**Cost of Concrete.**—There is evidently some error in the calculations of "W. S.," given in your last number. The mass of concrete is given as 38ft. by 14ft. by 5ft., or 2,660 cubic feet = 98·5 cubic yards. The cost for cement is £17 4s. = 2s. 10d., and not 3s. 4d. as given. The cost of slag, £14 = 3s. 6d., and not 4s. as given. Assuming the labour to be 1s. 8d. a yard, as stated, the total cost per yard would be 8s., instead of 9s., as given by "W. S." I also notice an error in the statement that "ashlar, at 2s. 6d. per cubic foot = £1 2s. 6d. per yard." As there are 27 cubic feet in a cube yard, 2s. 6d. per foot = £3 7s. 6d. a yard. I wish to add that the estimate for concrete is extremely low, and is to be accounted for by the very small quantity of cement used. Taking the weight of cement at 107lb. per bushel (the usual specification is 112lb.), and the ton is equal to 1 cube yard, as only 8 tons of cement were used to 98·5 cubic yards, the cement was less than one-twelfth of the mass instead of one-sixth, as is generally specified. The cost, then, on the prices given by "W. S." would be per yard.

	s.	d.
Slag	2	10
Cement	7	0
Labour	1	8
	11	6 per yard concrete.

Even this is a very low cost. A friend of mine, a harbour engineer, who has great experience in concrete work, estimates the cost at about 15s. a yard.—DENNY LANE.

[47004.]—**Bread.**—"Disgusted Foreigner" begs the question. Less than six hours ago, I remarked to some friends with whom I am staying that during the past two years I have never tasted any bread in the United States equal to that on their table. There is much bad bread in this country as well as elsewhere; but in my opinion the highest perfection is reached here. English bread that is really "semi-dried dough" may owe its faultiness to badness of flour, or ignorance of the proper method of making, or lack of proper oven-heat in the baking. The bread that pleases me so much is undoubtedly made of good material, is well manipulated, and well baked. To abuse English bread is what a Yankee would call "too thin."—R. M. TUTTLE, Haddenham, Ely.

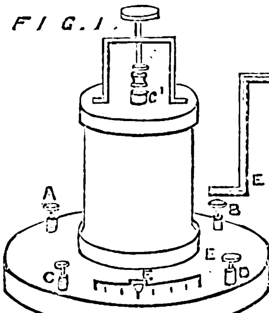
[47022.]—**Shafting.**—If "J. A." would strip the brasses both of the footstep and the top of the shaft, it would make it all right. It is the shaft having too much play, and therefore, although it gets ever so much oil, it does not retain it.—D. D. M. L.

[47022.]—**Vertical Shaft.**—The screaming noise you refer to is probably caused by the fact that when you oil your upper bearing the oil passes from between your bearings by gravity. I should recommend you to shrink a collar on the shaft immediately below the bearing, and make a circular grease-cup of tin to go on top of bearing. I may say that I had once a vertical shaft that screamed perpetually, but the fault lay in the step. I kept putting in new brasses, to no good effect, till I put a hard wood bearing in, and filled it up with powdered plumbago; that is eighteen months ago, and it has not screamed nor cut since.—FRED. WALKER.

[47023.]—**Sea-Sickness.**—Having crossed the Atlantic twice (my second voyage ending four days ago), let me give "A Rechabite" some practical advice. The sea-sick passenger meets with a variety of advice when on shipboard. The passenger who is never sick, and who eats a good deal, will urge the sufferer to eat freely, if even he vomits directly afterwards. Others will tell him to eat little or nothing. My plan is to eat nothing whatever during the first three days of the voyage. I am always very sick for two days; but if I were to eat at such times, the food would only serve to irritate the stomach, and keep me ill for a longer period. It is well while the *mal de mer* prevails to drink plain soda or Appollinaris water, avoiding all drinks that are sweet. Dr. Beard, of New York, who is thought by some to be an authority on such matters, advocates the use of bromides; but in my opinion the remedy is worse than the disease. Brandy, which is recommended by some persons, always makes me worse. Sea-sickness makes one feel very miserable; but the philosopher accepts it as the inevitable penalty of the traveller.—R. M. TUTTLE, Haddenham, Ely.

[47025.]—**Medical Coil.**—To MR. FRED. WALKER.—I have a reel, $2\frac{3}{4}$in. in diameter and 3in. high, and a stand 8in. in diameter, standing upon three wooden feet. In the centre of the reel I have a $\frac{1}{2}$in. clearing hole, not reaching the bottom by a $\frac{1}{4}$in.; into this is dropped a piece of $\frac{1}{2}$in. iron, softened in the fire and allowed to cool gradually. This is long enough to project $\frac{3}{4}$in. above the top. I have a small upright A in Fig. 2, of brass, screwed at both ends, one end to screw through the top of the reel and project a little below to allow of attachment, the other to fit a brass milled nut D. B is a slip of thin copper sheet, $\frac{1}{2}$in. by 2in., to which is riveted a small soft iron cone C, and a hole at b has a small piece of platinum riveted through it. E is a slip of brass sheet $\frac{1}{8}$ thick and $\frac{1}{4}$ wide, bent in form shown, with two wood screw holes in feet to fix by. A milled-headed screw F passes through this, to which a piece of platinum wire has been soldered. This fitting is placed athwart the contact-breaker, so that the platinum point of F is immediately over the platinum at b; when fixed up, the iron cone C should be 3-16in. above the soft iron core. Now as to wire, I had $\frac{1}{2}$lb. of No. 22 at 3s. the pound, cotton covered, and commenced to wind from the top of the cylinder, first boring a hole so as to pass the end down and connect to binding-screw A, Fig. 1. I then wound right-handed, and at each third coil soaked with melted paraffin, first baring the wire alternately at top and bottom of each third helix, soldering thereunto a short wire to each, which passes down under the stand and comes up in front of the coil. To each short wire is soldered a piece of brass wire $\frac{1}{8}$in. diameter, standing in a semicircle, and $\frac{1}{4}$in. high; the end of the wire itself, when all is wound on, is fixed to the last of these wire uprights, and called the strongest power. This power is also connected by a short wire to upright A, Fig. 2. The bent brass

FIG. 1.



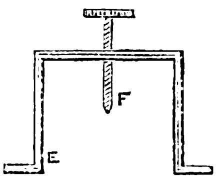


FIG. 2.

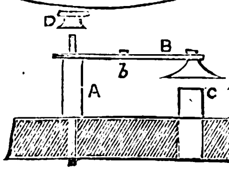

FIG. 2.

E is connected to binding-screw B, which, with A, is for battery connections. The wire which is connected with E and B is also connected with binding-screw D. Between the reel and the brass powers there is a brass wire bent, as shown at E, Fig. 1, having on it a slip of brass long enough to rest on the powers, and moving easily enough to rest on any at pleasure. This brass wire is connected to binding-screw C, which, with D, is for patients. Two brass tubes, 1¼in. by 6in., should have ends and binding-screws soldered to them for handles; also there should be a circular piece of brass sheet, hammered concave, and soldered to wire for a spine attachment. This completes the coil. Its cost is about 6s., and one Daniell cell will give a fair shock; two will render the manipulation of the powers necessary, It should be remembered that what renders medical galvanism futile in many cases is that the application of the current is not understood. The positive and negative binding-screws are those opposite the corresponding battery connections. For rheumatism the positive pole should be placed on the spine, and the negative on the hands or part affected; indigestion the reverse; and so on.—Fred. Walker.

[47027.]—**Electric Current.**—The current is produced from all the coils at once, though in a less degree from some than others (see Fig. 1).

FIG. 1.

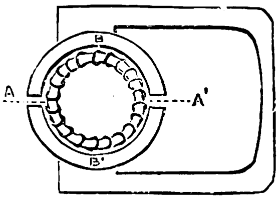

FIG. 2.

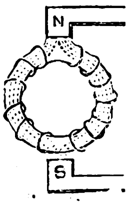
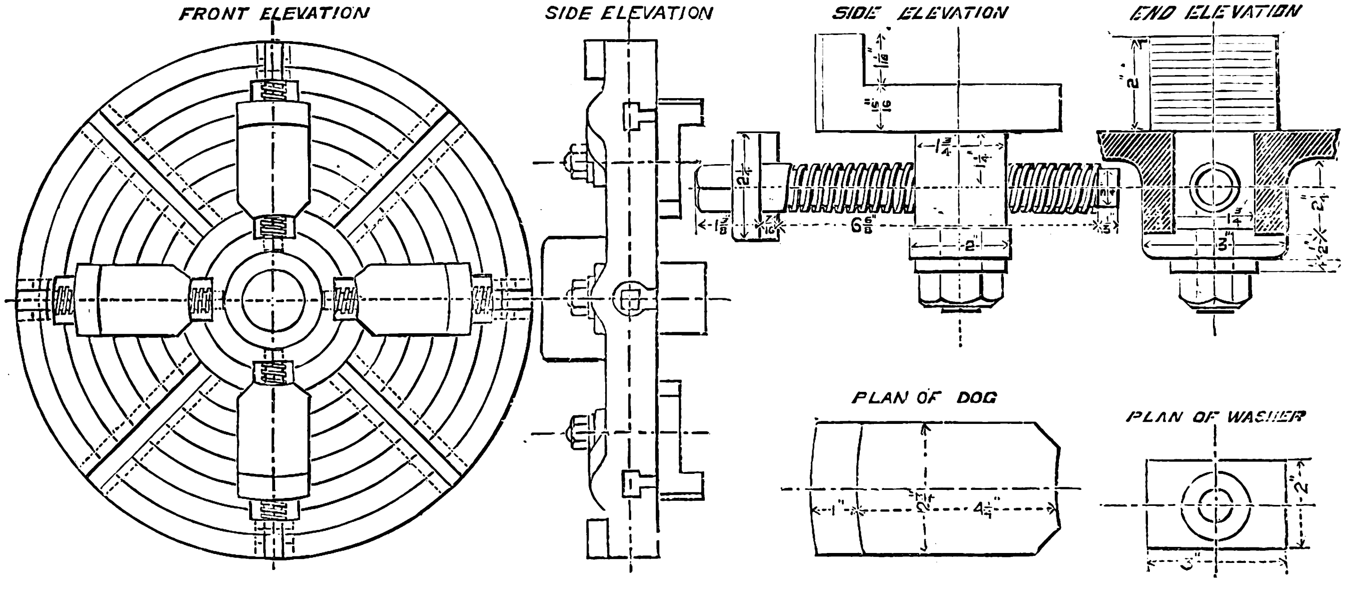


The greatest current is produced from coils at A and A'—the least, in those at B and B'. If there were no iron ring the current would be very small. The ring has the effect of so placing the lines of force that they are in the best condition for being cut by the coils in their rotation. If ring were not there, lines of force would go straight from pole to pole, and no coils would cut them. I do not think there is any other better than the Gramme.—W. H. L. H.

[47034.]—**Dog Chuck for Lathe.**—I beg to hand "E. D." a tracing of a 4-screw dog-chuck, which is self-explanatory and fully dimensioned. Front and side elevations are 1½in. to the foot; details ¼ size.—H. L. Crate.



[47032.]—**Stonehenge and Sun-Worship.**—It is stated there are two gnomons and stations at Stonehenge for observing sunrise 21st June and sunset 21st Dec., but there are none existing for sunrise at the winter solstice or for sunset at the summer solstice, unless the same gnomons were used.—W. B. P.

[47032.]—**Stonehenge.**—As "Neo" is so very interested in Stonehenge, he could not do better than read the chapter which is devoted to the subject in "English Traits," by the American philosopher who has so recently passed away, Ralph Waldo Emerson.—W. Henly Richmond.

[47032.]—**Stonehenge.**—I have to thank "Diamond" and "F.R.A.S." for assistance given and promise of further. The reputed cromlech I refer to is situate at Clun, in the S.W. corner of Shropshire, 52° 25′ N. latitude. If any correction is necessary for the fraction of a degree difference in latitude between Beaumaris and Clun, I should be obliged if "F.R.A.S." would give it at once. The plantation is not a complete circle. There would appear to have been two angles, and the boulder (10ft. long) lies opposite the southernmost one, and pointing towards latest sun rising. Is there anything unusual in this? I am extremely interested in the matter, and hope to report further to the English Mechanic.—Neo.

[47033.]—**Mining Questions.**—The way to proceed to rebar an oblong shaft depends a great deal upon the circumstances. If the size of the shaft must be kept at 14ft. by 6ft., it will necessitate the removal of some of the old wood; to do which, it would be best to commence at the top, and secure the sides by temporary supports, the number of which and the way of fixing will altogether depend upon circumstances. If there is room for the bars to be fixed inside the old casing, there will be no difficulty whatever in re-barring the shaft. Column pipes for pumping should be fixed perfectly plumb, by means of a line and stays, put in every 6ft. at least. Wooden guides for cages should also be put in perpendicular and secure. In most cases two will suffice, one at each end of cage, with four receiving guides at top and bottom. The two guides should be in a right line with the winding rope.—G. Worland.

[47035.]—**Safety-Valve for Kitchen Boiler.**—In my opinion, and most of the plumbing trade, the best valve for kitchen boilers is the one manufactured by Messrs. John Warner and Sons, and sold by all plumbers—the Randall's Patent Safety-Valve.—Chas. Hosken.

[47037.]—**Watchmakers and Jewellers.**—Yes, there is. Kelly's people publish "The Watch and Clock, Goldsmiths' and Jewellers' Directory." Price 20s.—C. S. M.

[47053.]—**Conservatory.—A Question for Spectrum Analysis.**—Using ground-glass for a conservatory is certainly a drawback. Ordinary plain glass transmits only the luminous rays of the sun, and is opaque to the non-luminous heat rays. The only heat-giving power of the sun's rays in a conservatory made of plain glass is therefore due to the luminous rays of the sun. Now, in the case of ground-glass, owing to repeated reflection and the dispersion of light, the number of luminous rays entering the conservatery is reduced, and therefore also the amount of heat. Anyone may notice these differences of light and heat by going into a room with plain glass windows, and then into one with windows of ground-glass. But it is just possible that the flowers would thrive better by a more careful attention to the conservatory. The latter should be so constructed as to admit abundance of air; and, in summer-time, the roof (and better still, the glazed sides as well, except the north side), should be removed, as the rain, dew, and the *direct* rays of the sun produce a richness of foliage and vividness of colour in plants that cannot be brought about by any artificial means. Without this, the plants in a few years become long-stemmed, naked, and almost, or quite, destitute of colour, except white, and are anything but beautiful.—J. Jones.

[47056.]—**Bacteria.**—It seems to me, who pass much of my life studying and fighting these beings, that "Cygnet's" difficulty is due to not boiling the wort after straining from the rye and malt meal. Unless this is done it is not possible to keep the barm free from the germs of bacteria—lactic, acetic, butyric—because, in spite of scientific theory to the contrary, practical men who have only observation and experience as their guides irresistibly conclude that these germs have their origin in the albuminoids of the cereals employed in brewing. The albuminous matter or endosperm of cereals, such as barley and rye, is composed of a mass of cells united into a tissue, and it is the contents of these tissue cells that are called endosperm and carbo-hydrates. This endosperm consists of three, if not four, distinct albuminoids or proteids—soluble albumen, soluble casein, fibrine (organised nuclei), and aleurone—which there is reason to believe are of different chemical or molecular constitution; judged to be so not from chemical analysis, but because they are coagulated and rendered inert in water at different temperatures. The lactic ferments which "Cygnet" encourages, by leaving aside the mash or wort for twenty-four hours before the alcoholic torulæ are added, is, as was pointed out by M. Mège-Mouries, transformed soluble vegetable casein. This lactic ferment, which I have no difficulty in controlling in flour barm at temperatures below 80° Fahr., has a decomposing action on vegetable fibrine cells; their normal development in a fermentable fluid into torulæ by endogenous division is arrested; they dissolve, and the granular protoplasm, in the presence of excess of acid, develops into butyric and acetic germs. The practical brewer and baker, with knowledge born of experience, while they may not reason as above, act on the assumption that it is true, and the brewer will not linger in bringing the wort to a boil after straining, boiling briskly and thoroughly, till he sees the albuminous matter coagulated and in flocks. The lactic producing soluble casein is not killed by merely raising the heat of the wort to 212° Fahr. That is why milk boiled at that temperature will not keep, even although atmospheric germs are excluded; but, prolonged boiling of the wort, aided by the astringent tannin of the hop, will coagulate the casein, and that, I believe, is the reason for the almost total absence of lactic organisms from British beers. And that is also why "Cygnet" finds skimmings from a back attenuated with pure yeast contain few bacteria. The brewer coagulates the casein and fibrine from which they arise, and renders these substances soluble and assimilable to the alcoholic torulæ. "Cygnet's" difficulty to coax the "old mother" to send her offsprings to the surface as skimmings after the first broust is doubtless due, not so much to the presence of bacteria, but to the not boiling of the wort. If pure malt, and not more pure sound rye is used than the malt diastase can invert, and the wort resulting from their proper mashing is thoroughly boiled, cooled rapidly, and fermentation started (according to quantity), between 51° Fahr. and 70° Fahr., and the proper saline elements are present necessary for healthy cell-life, then no power in nature, that I know of, except an atmosphere chemically altered by electricity, will prevent the yeast rising to the surface. But "Cygnet" would, there can be no doubt, produce a purer and stronger yeast with a bottom rather than a surface fermentation, whether the wort is boiled or unboiled; his aim being yeast rather than a high alcoholic and rapidly fermented beer. And it is advisable to start each new fermentation with a "store" or "mother" from malt beer skimmings. I find, in my experiments with yeast, the best and purest food for the cells is the ash of carbonised figs, raisins, and malt grains. Unfortunately the ash is black, and the fluid is a porter-colour in proportion to quantity of ash. The ferment tubs should be covered till fermentation is in full force, and carbonic acid is being rapidly evolved. As to keeping the yeast covered or uncovered, it is of more consequence to keep it cool, but, if covered, it should be in a barrel, full, and made air-tight; if kept in open tubs, leave them open and uncovered, so as to allow the cells free oxygen for respiration, instead of compelling them to obtain this necessary oxygen from any unaltered sugar, or from the protoplasm and cellulose of weak cells, which the stronger cells kill by excreting an acid inversive ferment.—W. A. THOMS, F.R.M.S.

[47061.]—**Mixing Brass for Melting.**—Put 5oz. copper into a small crucible, melt it, and then throw in 2oz. melted zinc; stir it with a stick of wood, and pour it out into a hole in your moulding sand. When cold, try the metal with a file for colour. Then remelt, and when melted add ½oz. lead, and, if the colour is too deep, ½oz. to 1oz. zinc, according to judgment, as experience is the only guide. Do not use any tin, solder, antimony, or gunmetal to mix with the brass, or it will be hard. The lead used should be quite pure. For larger quantity use proportionate weights; but judgment is required, as copper is very variable.—J. SUTCLIFFE.

[47064.]—**Flight of Rifle-Bullet.**—The problems proposed by "A Rifleman" are indeterminate for want of sufficient data. The following equation will show this and may interest him. If d be the lateral deviation of the bullet in feet, caused by the wind; t the time of flight in seconds; v the velocity of the wind in ft. per sec.; a the lateral acceleration of the bullet in ft. per sec. for unit velocity of wind (1ft. per sec.); then we have this equation—viz., $d = t\,v - 1/a \log (t\,a\,v + 1)$. The constants v and a must be given or ascertained by experiment. The datum of "A Rifleman" that $d = \cdot 5$ft. for the first 100 yards, combined with the others, would enable us to find t for the first 100 yards; but mathematics will not enable us to deduce thence the time of describing the next 100 yards, which time must be known in order to get the lateral deviation at 200 yards. For the high velocity of a projectile, the relation between it and the resistance of the air can only be given by an empirical and but approximate formula. The above equation depends on the fact that, for a low velocity, such as that of a moderate breeze, the pressure of the air is sensibly proportional to the square of that velocity. The equation enables us to see this much, that for a gentle breeze in which v is small, the deviation is nearly proportional to v and to the time of flight; also that as the time of describing each successive 100 yards increases very rapidly from the resistance of the air, the deviation increases very much more rapidly than the distance traversed by the ball. For further information it is necessary to consult empirically-constructed tables.—DUBLINIENSIS.

[47068.]—**Swelling and Pain about the Knees.**—Homœopathic remedy for young gent.: Aconite, two pilules every four hours for two or three days. For young lady, arnica pilules two every three hours for two days; at first arnica lotion for the knees, every day kept moist with soft linen.—A SYMPATHISER.

[47069.]—**Fruit-Growing.**—Books on this subject seem to be rather scarce. There is a work entitled "Our Common Fruits," by Mrs. Bayle Bernard, which will most probably give "Highlander" all the information he requires.—W. HENLY RICHMOND.

[47077.]—**Casehardening.**—The most simple method by which "Cycle" can caseharden his collars is to take a small cast-iron box, close at one end, fill it with coal-dust, the collars being in the midst of the dust, cement up the open end of box with clay to exclude all air, heat the box in a bright fire for four hours. Quench them in water containing a small quantity of salt. A small quantity of yellow prussiate of potash will greatly facilitate the hardening.—K. PAXTON.

[47079.]—**Regulator.**—The index-plate at the bottom of the pendulum of a regulator is for the purpose of showing through how many degrees of a circle the pendulum is swinging. This is useful to the clockmaker when adjusting the amount of weight necessary to drive the clock. It is also useful as giving an indication by the diminished arc of vibration of the pendulum of the effect of cold on the oil of the clock, as also to indicate when it is positively necessary that the clock should be cleaned.—PARKINSON and FRODSHAM, 4, Change-alley, London.

[47079.]—**Regulator.** — The index-plate over which the regulator pendulum swings, is to indicate the degrees of arc on each side of zero. Its proper name is "degree-plate," and its use is to show, or point, by means of the pointer at the end of the pendulum, whether the same arc of the swing—to use a home-made expression—is being kept, whether it varies, and in what sum the variation consists. The degree-plate is marked 1°, 2°, 3°, 4° on each side of zero, or the line which the pendulum covers when hanging in a state of rest. It may be interesting to mention that the first clock with a pendulum that was made in England was by a horologist named Richard Harris, in 1641, and was set going in St. Paul's Church, Covent-garden.—C. S. M.

[47080.]—**Fits.**—I believe all fits are caused by worms. Take cina, three pilules, night and morning for a week or two: then china for a week, &c.—HOMŒOPATHY.

[47083.]—**Diabetes.**—Consult a good homœopathic doctor. Common unsweetened gin with cold water, taken night and morning, might be tried first.—A SYMPATHISER.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

USEFUL AND SCIENTIFIC NOTES.

Fossils uniting the Characters of Pigs and of Monkeys.—Some time ago M. P. Gervais discovered in Upper Eocene strata, near Apt, in France, a portion of an upper jaw with teeth which exhibited an analogy to those of certain omnivorous pachyderms allied to the *Suidæ*, and yet resembled in other respects those of the monkeys. For this fossil (*singe-cochon*) he suggested the appropriate name of *Cebocherus*. In studying the mammalian remains found in the phosphorite deposits of Quercy, M. H. Filhol detected several specimens of *Cebocherus*, which enabled him more fully to describe the dentition, our knowledge of which was previously very imperfect. But he also discovered other somewhat similar remains, which approached yet more nearly to the monkeys, and to these he gave the generic name of *Doliocherus*. Quite lately he has obtained an almost complete head, with lower jaw in place. This unique fossil he described before the Académie des Sciences at their meeting on May 1. It is, therefore, now proved beyond all doubt that there existed during the late Eocene period a group of mammals (*Pachysimians*) which united many of the characteristics of the pigs on the one hand with those of the monkeys on the other—an association of characters which naturally gives to these fossils a peculiar interest to the student of evolution.

OF the 400,000 tons of Bessemer ingots which were used for other purposes than rails in 1881, a large part took the form of blooms for export to the United States. The production of blooms in 1881 was about 100,000 tons in excess of that of any former year. About 50,000 tons of ingots were manufactured into tires, axles, and general forgings; and 15,000 tons were made into angles for shipbuilding purposes, and so forth.

THE Census Bureau revised report of the United States population statistics shows an area of 2,900,170 square miles. The population is 50,155,783, the number of families 9,945,916, and of dwellings 895,512, being an average of 17¼ persons to each square mile.

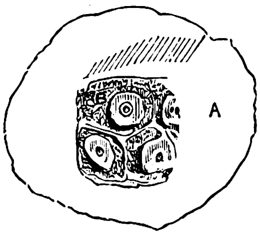
QUERIES.

[47086.]—**Picture Frames.**—Are there any rules of the material, colour, breadth, depth, and section of these? I am a perfect novice in this matter, and picture-frame makers I find cannot help one in it. They can only say such and such a kind of frame usually goes with water-colours, engravings, or photographs, as the case may be; which, being interpreted, means that such and such is the present fashion. I have been led into asking these questions through endeavouring to find a substitute for gilt mouldings for framing—a detail in household decoration not surpassed by any other, in my opinion, for vulgarity and pretentiousness; and I have thought the various woods offer a desirable field for the necessary variety required, and where their natural colour is not suitable it might be treated in some unobjectionable manner to make it so. I should esteem it a favour if any of your readers (and I should think there are many who could) give me a few hints or refer me to any published information on the subject. I do not want expensive frames.—SALT.

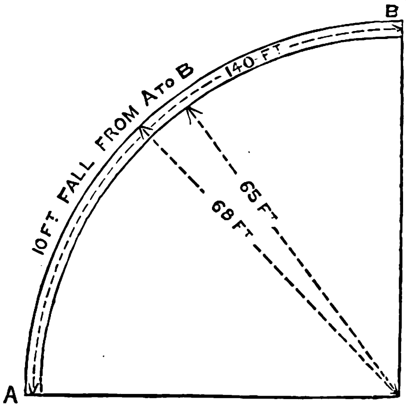
[47087.]—**Small Launch.**—I am thinking of building a small launch. Will some practical reader of the "E. M." kindly give me the benefit of his advice on a few points? It is to be 18ft. long and 5ft. beam—at least, so far as at present decided. I want to get a good speed, and light draught of water; the lines will be tolerably fine for the sake of speed. I want to know whether a steam cylinder 3in. by 5in. will be sufficient to give a good speed, worked at, say, 80lb. pressure, what kind of boiler to get—whether vertical or horizontal—and dimensions of it? What would be the best kind of screw, what size must it be, where could I get it from, and approximate cost? I suppose, for a river launch, that twin screws would really be the best. But I am afraid that in a small boat the machinery would be too complicated;—I should be glad of advice on this point. I am of course, aware that it will be impossible to get all my requirements in a small boat. If great speed is required, a great deal of space must be given up to machinery. But I shall be extremely obliged if some reader will kindly proportion all the principal parts for me, so as to get the best effect. One naturally does not like to be passed by every small tug on a river, and, therefore, wants some degree of speed. I shall be glad, therefore, if anyone, in giving me advice, will also estimate the speed.—MARINER.

[47088.]—**To Dr. Edmunds.**—I have a child 16 months old very backward in every respect; has not yet a single tooth through, no strength in her legs to make any attempt at walking, and is very small. It seems to me she does not assimilate all the food she takes (milk and bread, sago pudding, oatmeal, &c.), as, notwithstanding her being tolerably hearty for so small a child, she does not make flesh, and is really very poorly. Born a little prematurely, owing to a fall a fortnight before birth.—J. N. W.

[47089.]—**Fossil.**—Can anyone tell me the name of the fossil of which I send a sketch? It is in a depression in a stone which my dog brought me out of a hedge. The sketch is natural size, the part a being light brown, b very small cellular formation, and the rest of the stone apparently flint.—W. E. K.



[47090.]—**Tramway into Gravel-pit.**—I am now about laying down the metals. How much higher the outer rail ought to be than the inner one, the outer one laid to a 68ft. radius, the inner one about 65ft. radius; the incline of the line is 10ft. in 140ft. Note.—The horse will only walk with truck-load of gravel.—H. BOOKER, Sidcup, Kent.



[47091.]—**Inhabited House Duty.** — To MR. FRED WETHERFIELD.—I have built a house and shop, the domestic apartments of which are not completed, and the shop is occupied only in the daytime for business, no one sleeping on the premises at night; but I find I have to pay inhabited house duty, rates, and income tax. Will you tell me what rates and taxes can legally be demanded? and oblige—JIMBO.

[47092.]—**Optical Illusion.**—To DR. EDMUNDS.—I have for some time, when looking at a bright light backed with a dark ground, observed a halo strongly tinged with prismatic colours, the red rays outside the circle, the violet inside, the inclosed space filled with radial lines or rays. Please say to what cause this optical illusion is due, and whether it could be got rid of? I may add that I am well up in years, but enjoy a good state of health.—P. M.

[47093.]—**Double Steam-chest.**—I have a model steam-engine of two cylinders, each 1¾in. by 2¼in., worked of course, on the same shaft, and the two "throws" or cranks of the latter are only 2in. apart (inside), thus making the faces of the cylinders (against which the slides work) 1⅝in. apart. Now, I want some of your kind correspondents or readers to say if I can introduce a slide-valve of such dimensions and shape as can be conveniently fixed between the two cylinders. The engine has hitherto been worked by the slide-valves being outside the cylinder; but as this necessitated two steam-pipes and two exhausts, I am anxious to change. How can I manage to get the two eccentrics on the inside of the crank-shaft, also?—J. M. L.

[47094.]—**Combustion of Coal.**—Will any of your numerous chemical experts tell me how to work out in plain figures the quantity of atmospheric air required to form CO^2? or, in other words, suppose the analysis of coal was—

Carbon	88·42
Hydrogen	5·61
Oxygen	5·97

Calculate the weight of air required to burn 20cwt.—ATMOSPHERIC AIR.

[47095.]—**Paint for Loco. Engines.**—Will anyone inform me what ingredients to use in mixing paint for loco. engine, so as to stand heat, the finishing coats to be green and brown? Also, what varnish to use?—CYMRY.

[47096.]—**Legal.**—To MR. FRED. WETHERFIELD, Solicitor.—Last January I fell out of work, and my wife, instead of stopping with me and earning what she could as a tailoress, went home to her father, and now she will not come back, though I have sent repeatedly and asked her. I sent her money when I got in work again, but have now discontinued sending money, as she will not come back. Now she has put it into a solicitor's hands, and he has sent me a letter to say unless I maintain my wife, he is instructed to issue proceedings against me. My wife and her mother came to my place when I was out, and removed several articles of furniture which have been bought with my money, as well as a sewing-machine which I bought for her. Will you kindly tell me whether she was acting right in doing this, and whether they can compel me to keep her while she is away against my wish?—AN UNFORTUNATE BENEDICT.

[47097.]—**Loss of Smell.**—To DR. EDMUNDS.—I should feel very grateful for advice on the following case:—I have been subject to a cold in the head, more or less, for the last seven years, and for the last four years my sense of smell has almost gone. Sometimes in the morning I can smell a little, but towards the afternoon or evening I cannot smell at all. Otherwise, I enjoy very good health. I am engaged out of doors; age 25. Any doctors I have consulted, say that the affection of the nose has become chronic, but that a change of air might do me good—which I have tried, but without success.—T. H.

[47098.]—**Engine Queries.**—Will any reader give me information on the following questions?—1. To find the angular advance of an engine? 2. To find the angle of the crank, and position of the piston at any part of the stroke? 3. How I may find the pressure of water in a tank when full, which has an incline base?—PHENIX.

[47099.]—**Sunrise and Sunset.**—Would "F.R.A.S." kindly state at what point of the horizon the sun rises and sets 21 June and 21 Dec., respectively, in latitude 51° 2′ 45″ N.?—W. B. P.

[47100.]—**Loco.-valve Setting.**—Will someone kindly inform me how to try over a pair of valves to get correct length of eccentric rods, &c., and the use of the circles that I have seen valve-setters make on a piece of brass when getting length of rods?—DOME-JOINT.

[47101.]—**Polypus.**—To DR. EDMUNDS.—I suffer from this ailment, and have it cut every few months, but there seems no prospect of a cure. I see in No. 326 of "ours," replies 7763, p. 340, two correspondents give remedies. One advises a few drops of "Dutch drops" to be put in a spoon and applied with a camel-hair brush as far up the nostril as possible every few hours, when the polypus will wither away in a few weeks at most. Another states that "after paying numerous guineas to the doctors to no purpose, he was cured of polypus by taking tannin as a snuff." On p. 416, No. 329, another writer says: "Use fox-glove leaves dried and powdered, and take it as snuff." On p. 516, reply 10496, No. 358, another writer gives the following, taken from "Dr. Skelton's Science and Practice of Medicine": Gallic acid, two drachms; male fern root powdered, two drachms; sanguinaria, one drachm; triturate finely and use freely as snuff. Said to be an excellent remedy if the nasal bones are not affected. Does Dr. Edmunds think either of these remedies likely to be of use, and if he has not much opinion of them, would their application be injurious in any way?—D. L.

[47102.]—**Astronomy.**—Prof. R. S. Ball, in his lecture "A Glimpse through the Corridors of Time" (*vide* "E. M.," Nov. 4, 1881, pp. 204), affirms that the day is becoming longer and longer as the moon becomes more remote, and at some period of the moon's proximity the duration of the day was not more than three hours, with a tide flowing over the whole of England. With diminishing tide, the friction, surely, will diminish also—the day, therefore, diminishing too, as the moon is more remote—as, admitting the likelihood or truth of this almost uncommon "beautiful" tidal hypothesis, with the loss of friction, the earth's velocity will gain. Oppositely, then, the day will be longer in proportion to flow of tide, or three days, possibly, might be more like the globe's rotation period with the tide so mighty as described. Thinking it a little odd the professor should so seem to transpose the conditions, some astronomer might kindly throw light on the question, and oblige—INTEREST.

[47103.]—**Explosions in Collieries.**—Possibly some one of the erudite chemical contributors to the columns of the "E. M.," &c., would kindly inform me if conceivably is to be entertained the admission of a flow of non-explosive or neutralising gas into the coal-pit, either with the air-current or otherwise, for the object of destroying the explosive properties of the igniting hydrogen or carburetted gas; and either by combining with it or diluting it, carry it off, innocuous, or materially modify its risks and repetitions of fatalities. Such, say, nitrogenic gas, if not in itself too seriously injurious to life in the pit, to be contained in gas-holders below in the workings, or at the pit mouth, for service if occasion required, for purifying or, if possible, rendering more secure the mine.—ANTI-RISK.

[47104.]—**Light Punt.**—Will someone who knows all about it, kindly give me full instructions, with measurements, prices, &c., for making a miniature punt, having canvas sides and ends, very light, narrow, and swift, but capable of carrying two persons? Also, instructions for an amateur to make a pair of oars or paddles for the above, to be used when necessary.—MEDWAY.

[47105.]—**Enamel for Silver Prints.**—Will someone kindly give me instructions for making and using an enamel for photographs? Is there any kind of varnish ever used to give them a bright and even surface? If so, what is the formula? I have a small bottle of Newman's enamel-paste, which is very thick and stiff. Ought it to be so, or ought I to dilute it with anything? It is so thick that I can hardly wipe it off the print, as the directions say it should be done.—JOHN HALE.

[47106.]—**Dry-plate Photography.**—Will any reader please answer the following queries?—1. In "Easy Lessons in Dry-plate Photography," a few numbers back, is mentioned a "simple lens" among the lenses used in photography. Am I to understand that this is simply an ordinary meniscus, with the convex side towards the prepared plate. I have used such a lens but did not get the picture properly distinct, from the plate being out of focus. I assign this to one of two causes, either that the ground-glass and plate were not in the same position, or that the luminous and actinic foci of the lens did not coincide. Can anyone tell me is the latter the most likely? 2. What does "emulsify" mean, and what changes does the gelatine undergo in the process? 3. Will soaking a gelatine film in alum solution render it hard, so that it cannot be washed away by running water?—F. J. N., Liverpool.

[47107.]—**Bleaching Oats.**—Can any of your readers inform me of any other means of bleaching oats, except by drying on kiln and using sulphur?—NOVICE.

[47108.]—**Spring Blind.**—I want to make some outside blinds for room-windows. Will some reader of the "E. M." tell me how to make the spring to fit on the roller, so when a cord is pulled the blind will go up? A sketch will greatly assist.—ONE IN A FIX.

[47109.]—**Gymnastics.**—Could any of the readers of this paper inform me what are the best movements with dumb-bells to cure a high shoulder caused by working the hammer with the right hand?—D. D. M. L.

[47110.]—**Template.**—Will some reader describe the process of straightening a buckled template with a hand hammer?—D. D. M. L.

[47111.]—**To Mr. Lancaster.**—I wish to store up enough energy in a Sutton's secondary battery to work a small Swan incandescent lamp of about 3 or 4-candle power to light a small room with. Can you inform me as to the necessary size and number of copper and lead plates to be able to depend upon its working the lamp for about three hours or so every day? Can you give me particulars as to the making of a small dynamo to be able to charge it in about five hours or so by working it from the lathe when the lathe is in ordinary use? Or if you are not able, can you tell me where I shall be able to get a description of the general construction of dynamos? and oblige—ATELIER.

[47112.]—**Welding Cast Steel.**—Can any reader kindly tell me what I could use to weld cast-steel?—VULCAN.

[47113.]—**Bronzing Moderator Lamp.**—I have a bronzed brass moderator lamp which has worn bright. How can I rebronze it? How can I get at the interior? The oil seems to be supplied too fast to the wick. In fact, the pump requires to be wound up every four or five hours. Is this as it should be?—MURANO.

[47114.]—**Wood-chopping Machine.**—Will any reader of the "E. M." kindly oblige by giving me instructions and sketch for making the above for chopping cord or hard wood—to work by hand or steam-power?—FIREWOOD CHOPPER.

[47115.]—**Boiler.**—I have a boiler 32ft. long by 7ft., two furnaces 2½ft. each, six Galloway tubes in each flue. I have considerably improved it from reading the valuable information so freely given by *practical* correspondents in this paper; but I doubt my having arrived at perfection yet. I would feel much obliged if anyone who understands the subject would inform me the approximate number of horse-power it is capable of supplying steam for to a single high-pressure engine expanding from about one-third of stroke? Also, how many pounds of coal should be consumed per horse per hour? I am aware there is a difference in coal. We use Newcastle steam coal.—MANUFACTURER.

[47116.]—"**Livadia.**"—Can any reader kindly say what has become of the Czar's yacht, *Livadia*? Having gone on her trial trip, I would like to know what has become of her. I heard she was to be incased in wood, and then sheathed with copper.—ERIN-GO-BRAGH.

[47117.]—**Tinning Steel Wires.**—I should be glad if some of your readers would tell me the most ready means of tinning a number of steel wires about ⅛in. thick—especially the means of preparation previous to dipping.—G. C. T.

[47118.]—**Medical.**—Will Dr. Edmunds kindly tell "J. W." what to do, and what liniment to use to alleviate a most distressing pain in the forehead over the right eye, which now comes on, and continues for the night after a day's sick-headache, to which he has been subject all his life; but now, very often and very prostrating—the head, stomach, and back causing great suffering. I am in my 66th year. I think my case would be well-described by the word "megrims," and, without doubt, derived from my mother, who was a great sufferer for years before she died.—J. W.

[47119.]—**Speeds.**—I am fitting up a lathe for myself, and have driving-wheel for crank-shaft with four speeds; smallest is 14½in. in diam.; each of the other three is 1⅛in. larger. I want four-speed pulley for headstock to match, not to alter the strap, when I want to use the other speeds. Will "Sunlight," or some kind reader, give the size of the four speeds I require on coned pulley strap?—BICYCLE MAKER.

[47120.]—**Enamelled Bowls.**—Will anyone kindly tell me how to enamel iron bowls? and oblige—ENAMEL.

[47121.]—**Indian Locomotives.**—Can Mr. Gobert, or any correspondent of the "E. M.," give me a sketch of the engines on the Indian, Australian, and New Zealand lines, with dimensions and details? Also, those of the North and South American Railroads. Please show tenders, if possible.—RUSSELL.

[47122.]—**Size of Battery.**—I am desirous of changing the motive-power of a pump by which water is supplied to the fountain (pipe ⅜in. diam.) of an aquarium, and raised 3ft. by using a battery in place of a small steam-engine. Would you inquire for me what kind of battery would be best, and what size necessary, and if I could use a Leclanché or bichromate, and if I could, what size would be best? I wish it to work about an hour a day.—THOS. LEES.

[47123.]—**Electro-plating.**—Will someone kindly inform me if it is proper for the silver anode to become coated with a dark substance when plating? Also, what is the cause of gold solution yielding its gold very tardily after being in use a few weeks? I should mention that there is plenty of gold in solution, and that I have tried adding fresh cyanide, different battery powers, and temperatures.—ELECTRO-PLATER.

[47124.]—**Medical.**—I have about every five weeks a swelling in the right side of my nose, swells for about three days, and then breaks out into whitish-yellow scabs, and is very painful. I should be thankful to any reader who would point out the cause and remedy.—SUFFERER.

[47125.]—**Transmitter.**—I have a Blake's transmitter with switch, all in one case, on which the royalty has been paid. Can I alter the same by putting the transmitter in one box and the switch in another, like the instruments now used by the Telephone Co., without infringing on the patent?—E. T. C.

[47126.]—**Electrical.**—I intend to fit up a galvanic battery for medical purposes, and the only available space for cells (Leclanché) is an old outhouse. Will the frost in winter affect working, or in any way damage cells?—MEDICUS.

[47127.]—**Legal.**—About four years ago I lent some models to a tradesman on the verbal condition that if they were not returned when I sent for them they should be paid for. The said tradesman has not yet returned them, though I have sent for them two or three times. Can I legally send him a bill for them, and if he does not notice that, can I send him a County Court summons? I must remark, however, that no price was agreed upon between us, only what they cost working.—EPSILON.

[47128.]—**Chinese Cement**—Can anyone give me any information, or tell me where I can get information, as to the composition of a Chinese cement? I think that it is partly composed of quicklime and blood. Some time ago there was something about it in one of the scientific journals, but I cannot remember which.—T. D. HOLLICK.

[47129.]—**Organ Pedals to Piano.**—Wishing to connect a set of pedals to a piano, I should be glad if any correspondent will show me the easiest way to do so, and also describe the proper action, so as not to injure the piano-case.—J. E. B.

[47130.]—**Decorating Organ-Pipes.**—My show-pipes having become very dirty, I am anxious to recolour them. Before painting, must I remove all the old gilt and colour, or can I colour over? Can anyone give me a design for a small front—mahogany case? Pipes being small makes it difficult to stencil. Any suggestions will oblige—J. E. B.

[47131.]—**Pedal Pipes.**—Scales, lengths, &c., wanted for an octave of 16ft. bourdons CCC. to CC., smallest size possible. Will anyone oblige?—J. E. B.

[47132.]—**Hæmorrhoids.**—To DR. EDMUNDS.—Will Dr. Edmunds kindly give his advice in the following?—For some months past I have been troubled with blind piles. I have been recommended vegetable charcoal, and taken a good deal of it, but find little or no benefit from it. The piles do not inconvenience me much, as it is only occasionally I feel any pain from them; but I am afraid they may get worse, and so be harder to cure than they would be now. I fancied they were better when I had a good deal of sea-bathing. I should feel extremely obliged for any advice as to their treatment both from Dr. Edmunds or any others who may have received benefit from any particular remedy.—GRATEFUL.

[47133.]—**Gold.**—Would some of your metallurgical correspondents kindly inform me as to whether the gold in an auriferous iron ore passes into the slag or metal when the ore is smelted, and whether gold is ever found in refining slag, as I am unable to find the information in our ordinary textbooks?—K. A. G.

[47134.]—**Bicycle-making.**—Cannot we get some able correspondent to give us some practical articles on bicycle-making, with dimensions and sketches of any tools or parts where required to be understood? I think it would be conferring a great boon on many amateurs who, not going into ornamental turning, wish to make something useful.—A. B. R.

[47135.]—**Compressed Gas.**—I think of making in my spare time this summer a pair of condensed gas bottles for the limelight; but as I have never seen any of them, I would like some information how to proceed, the size they would need to be to hold about 8ft., and the construction of the valve. I was thinking of making them out of good Lowmoor boiler-plate ¼in. thick, making the tube first, and then welding in the ends. I am a blacksmith by trade, and I can get the use of a forge and a lathe in the evenings. I should like to have them ready by the coming winter season. Also, what like a thing is the pump for pressing the gas? We have in the works where I am employed, a hydraulic pump, used for testing boilers. It is used with water, but I think it would pump air or gas quite as well. I took this pump all to pieces to see how it was constructed. Would a pump of this kind do? If not, please to say of what style it would need to be, as the above would, I am sure, interest many other readers besides myself who take pleasure in exhibiting the magic-lantern, and would be willing to try their hand in making the above—the best and most portable of all forms of the limelight. I hope that someone who can give the information will do so.—Limelight.

CHESS.

All Communications for this department must be addressed to the Chess Editor, at the office of the English Mechanic, 31, Tavistock-street, Covent-garden, W.C.

PROBLEM DCCLIII.—By H. E. Kidson.

NOTICES TO CORRESPONDENTS.

F. C. Collins.—Many thanks for the problem. No doubt it will prove sound.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, June 7, and unacknowledged elsewhere:—

Westinghouse Brake Co.—H. H. Holt.—J. Bateman.—C. W. Wilson.—Bausch and Lomb Optical Co.—C. J. Stock.—J. Devey and Co.—T. Dockray.—Quod Dixi Dixi.—Tyro.—Enquirer.—M. H. C.—W. H., Hoyland.—H. A. Wassell.—J. C., Liverpool.—Spot Lens.—Electric.—A. Hallett.—G. J. H.—F. C.—Zelia Naien.—Brickwall.—Novice.—Mc—One who Wants to Excel.—Musical.—A Constant Reader.—Everton.—Core Boy.—W. M. Gardner.—J. H. Huxley.—Russell.—E. Gobert.—E. Martin.

A Defendant. (No; the defence would fail.)—Thomas Jones. (No.)—C. H. Domaille. (Yes, if not too long.)—W. Mayer. (If you can tell our readers anything that "Foundry" did not, or if you can usefully criticise the methods of working he described, do so by all means; but we can't waste two columns in discussing the relative importance of green sand and loam moulders.)—Chemistiana. (The last instalment appeared on p. 212, No. 895. We have received nothing from you since.)—Isle of Wight. (Yes, and most properly.)—Success. (Your best plan would be to read up some of the lectures on the subject, and utilise the papers we have given in back volumes.)—John Hale. (There is one on p. 269, and another on p. 424, No. 876.)—Festina Lente. (See p. 504, No. 879, for the solution, or p. 268, May 26.)—M. J. (Ivory black 1 cwt., treacle 28lb., rape oil 1 gal Mix to a paste. Dilute 21lb. of oil of vitriol with 2 gals. of water. Add to the paste by stirring forcibly. Cover up whilst still fuming, and it will be ready for picking up next day.)—Thos. Lees. (Yes, many; but you must refer to the indices, unless you specify what kind of motor you require.)—Alpha. (The Bunsen battery is the best for the electric light when it is required for more than a few minutes; but any battery is very expensive. Read what has been said in recent vols. and numbers.)—W. Henly Richmond. (There is nothing but emery and oil; but it would probably be advantageous to wet all parts thoroughly with paraffin oil some hours before starting. Use rather fine emery.)—Diet. (By referring to p. 451, No. 877, we find that one of the letters mentioned appeared in the *Echo* of Jan. 7 last, so that if you consult the file of that paper for the month of January you will probably find what you require.)—Nemo. (The preparation is a secret, but it is understood that they are compounded of hops, buchu, mandrake, and dandelion.)—Star Light. (Directions for making small air-pumps have been given many times. See p. 516, No. 775, for illustrations of two; p. 521, No. 802; and Nos. 818, 819, and 824 for details of parts.)—Humanity. (They eat only during the summer months; lettuce is a favourite food and bread soaked in milk. See p. 619, No. 467.)—Electrician. (The incandescent lamp mentioned is in all probability supplied by a bichromate battery.)—S. Williams. (Try vegetable charcoal in the shape of powder or biscuits; but it would be advisable to consult a medical man.)—Stain. (The cause is evidently constitutional, and no one can advise without personal examination.)—Ploughman. (See the indices of the last two volumes. The cost of the lenses can be ascertained by consulting the catalogues of the opticians.)—Gasalier. (Directions for constructing Leclanché batteries have been given over and over again. You will find the new form described on p. 541, No. 803. Two quart cells; line wire No. 18 or 20. 2. We know of no process of taking copies from pencil drawings; but if you draw them with violet aniline ink you can obtain 50 copies by means of the "graph" process.)—Steward. (If you are acquainted with the duties, you stand as much chance as others. Make application at some of the steamship offices, or to the masters on board the vessels.)—A Workman. (It is the scurf from the retorts at the gasworks, and is cut with much labour by means of iron blades and sand, or with good hard saws.)—Signed Tinsmith. (Full instructions on p. 238, No. 868. See also No. 860, p. 36, "Japans and Japanning.")—Mc. (Are we to understand that the engine is actually at work? There is nothing novel in the two pistons; but your explanation is wanting in clearness. If the explosion takes place inside chamber, it is not clear what prevents the gas being driven through the valve without the ram being brought down. We are afraid you are not likely to get the information asked for, because the data can only be ascertained by experiment. 2. If you get one of Messrs. Barnett and Foster's catalogues you will find illustrations of bottle-washing machines.)—Yoshi. (In the specifications of the patent, and also, we think, in some of the technical papers.)—Pimlico, S.W. (Use one of the cements advertised, or marine glue. To repair the cuts, fill up with rubber solution.)—Landscape View. (Cannot you try whether it makes any difference? As to the stand, see p. 445, No. 877.)—A. J. F. (It is constitutional, and if it continually recurs you should consult a medical man. 2. Do you mean a bicycle or tricycle? Any of the makers who advertise in our columns can supply you with one, and if you read up the discussion in the last volume you will be able to make up your mind. 3. This query must be put in some other form. What is it you wish to know?)—Electrician. (Make up your cell as directed on p. 5, using caustic soda as cheaper than caustic potash, or make up a cell like the Leclanché. See recent back numbers.)—Charles Davies. (Your battery is a modification, but not an improvement, of the Daniell.)—An Amateur Electrician. (About 30 Bunsen cells.)—Clayton. (See p. 284, last week, and many other places in recent back numbers. You could use lead jars if you prefer them, but not in lieu of porous pots.)—Amateur Photographer. (Have you read the papers on dry-plate photography, now appearing, and many replies in recent volumes?)—Otter. (Rough the tube, and glue the leather on.)—S. Murray. (There are two works on "Dyeing and Calico Printing," one by Crace Calvert, the other by Crookes. Perhaps the latter will suit; but we are afraid you require too much technical information. Get Calvert's catalogue of books, Great Jackson-street, Hulme, Manchester.)—Beginner. (Hunter's "Manual of Beekeeping," D. Bogue. See for an answer to your question p. 517, No. 488, and pp. 171, 195, 244, Vol. XVI. If you can look through Vols. XV. to XX., you will find a great deal of useful information about beekeeping.)—A Would-be Astronomer. (Your question was answered on p. 8, March 10. A 4in. telescope is needed.)—Theo. Mechan. (Mere examination questions, for which we can only occasionally find room.)—Malleable. (See p. 559, No. 777. The castings are packed in red hæmatite, and subjected to a red heat for a long time.)—C. A. (Has been fully explained many times, the last so recently as p. 156.)—North Pole. (The principle is not patented, but the methods of carrying it out are in the shape of the machines. It consists in supplying intensely cold dry air to the room, and is applicable to such a space as you mention, but in that case would be rather expensive. See p. 240, No. 264.)—W. Styles. (See the indices.)—Sunshine. (There are two kinds—summer freckles, produced by the action of the sun and heat, and cold freckles, due to some disordered condition of the system. A good lotion is said to be sal-ammoniac 1 drachm, spring water a pint; but most druggists make up suitable applications.)

Every Workman connected with the Building Trades requiring a situation should advertise in "THE BUILDING NEWS," published every FRIDAY, price Fourpence, at 31, Tavistock-street, Covent-garden London, W.C.

"THE BUILDING NEWS" is the Principal Journal, representing Architects and Builders, and has the largest circulation of any Professional Journal in the kingdom.

Every Workman should insist on seeing "THE BUILDING NEWS" every week at his Club or Coffee House. He will find more "Lists of Tenders" for new work in it every week than in any similar paper, and can thus judge where work is likely to be had. He is also specially invited to make use of "Intercommunication" if he wants to know anything about his trade; to write to the Editor if he has any suggestions to make and to advertise in the paper when wants work.

The charge for Advertisements for Situations is One Shilling for Twenty Words, and Sixpence for every Eight Words after.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

6s. 6d. for Six Months and 11s. for Twelve Months, Post-free to any part of the United Kingdom. For the United States, 13s., or 3 dols. 25c. gold, to France or Belgium 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 3d. each to cover extra postage.

Messrs. James W. Queen and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post-free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. XXIV., XXVI., XXVII., XXVIII., XXIX., XXX., XXXI., XXXII., and XXXIII., bound in cloth, 7s. each.
[Vol. XXXIV. Now ready.]

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in March and September, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d each, through any bookseller or newsagent, or 2½d. each, post-free from the office (except index numbers, which are 3d. each, or post-free, 3½d.)

Indexes for each half-yearly volume up to Vol. X. (except Vols. II., III., IV., V., and X.) inclusive, 2d. each. Post free 2½d. each. Indexes to subsequent vols., 3d. each or post-free, 3½d. Cases for binding, 1s. 6d. each.

*** Subscribers are requested to order Cases and Vols. through their booksellers, and not to send direct. The regulations of the post-office prevent their transmission through the Post.

CHARGES FOR ADVERTISING.

	s.	d.
Thirty Words	2	6
Every additional eight words..	0	6

Front Page Advertisements Five Shillings for the first 40 words afterwards 9d. per line. Paragraph Advertisements One Shilling per line. No front page or paragraph advertisement inserted for less than Five Shillings. Reduced terms for series of more than 6 insertions may be ascertained on application to the Publisher.

ADVERTISEMENTS in EXCHANGE COLUMN—for

	s.	d
Twenty-four words	0	3
For every succeeding Eight words..	0	3

ADVERTISEMENTS in the SIXPENNY SALE COLUMN:

	s.	d.
Sixteen Words	0	6
For every succeeding Eight Words	0	6

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions; and in cases where the amount sent exceeds One Shilling the publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement and charged for.

Advertisements must reach the office by 3 p.m on Wednesday to insure insertion in the following Friday's number.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a Pink Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

Holloway's Ointment can be applied to the most sensitive skin with the certainty of its removing pimples, eruptions, and roughness without producing any inflammation or unsightly blemishes. The balsamic nature of this ointment recommends it strongly to the young and delicate. It will cure scrofulous complaints which have resisted every other treatment.

OUR EXCHANGE COLUMN.

The charge for Exchange Notices is 8d. for the first 24 words, and 3d. for every succeeding 8 words.

A pair of well-finished **Needle Instruments** in good order, platinum contacts, new coils, thoroughly reliable. Offers.—Logan, St. Cross P. O., Winchester.

Parallel Vice, three inches, in good condition. Will exchange for Foot Blower or Stock and Dies, with taps, of equal value, or offers.—R. Parkes, 4, Frederick-street, Caledonian-road.

"**English Mechanic**" and "Design and Work" from commencement to present date, complete, clean, and strongly bound, half-calf. Exchange for Piano, American Organ, or Harmonium.—J. Wood, 189, West-terrace, Burley-Wharfedale, near Leeds.

I will exchange the first 24 numbers of "**Knowledge**" for "Photographic News," from first number of present volume to No. 1,231 inclusive.—F. J. Bratt, Post Office, Homerton, E.

Will exchange my beautiful collection of **Conjuring Tricks** cost 15 guineas, for good Flutina or portable Harmonium. Anything in music.—A. Spreadborough, West street, Farnham.

"**English Mechanic**" 20 odd back numbers, and last volume, with indexes. Exchange.—H. George Hewlett, Aubrey Villa, Old Church-road, Clevedon, Somerset.

Lathes.—A 9ft. 8in. centre gear and a 4in., with 3ft. bed, very cheap, to clear at once; or will exchange for useful offers.—37, Northcross-road, E. Dulwich.

Watch, 18-carat, English Lever, cost £16 16s. First-class timekeeper. Will sell a bargain or exchange.—37, Northcross-road, E. Dulwich.

Landscape Cameras, 8½ Square and half-plate, with dry-plate backs. Exchange for a good perambulator. Stamp for reply.—Wills, 116, Rotherfield-street, N.

Leading Screw, Saddle, Slide rest, Changewheels, &c., &c., for 5in. Screw-cutting Lathe. Would exchange for Tricycle or anything useful.—A. Hughes, Engineer, Ross, Hereford.

4ft. 6in. **Gap Bed,** planed, 4¾in. back-gear heads, halfbright, rest socket, two tee pieces, boring rest, and tools. Exchange small bench lathe.—J. S., 69, Newton-street, Millom, Cumberland.

Horizontal Engine, cylinder 2½in. by 5in., bored and turned, crank shaft and eccentric finished. Offers wanted.—J. S., 69, Newton-street, Millom, Cumberland

Two sets of **Wringing Machine Castings** cheap. What offers? Also some Tools. Machine Needles wanted.—J. S., 69, Newton-street, Millom, Cumberland.

Exchange 9 by 7 folding **Camera,** two double dark slides, hardly used, cost £6 6s.; for Empress of India Sewing Machine, new.—Jeffrey, Cheltenham.

Small specimens **Minerals,** Fossils, Shells, &c., great quantity. Will give the lot for large Telescope, or offers.—H., 4, Pratt's-place, Brooksbys-walk, Homerton.

Unmounted Objects, and a lot of plain slips, lot of minerals and small shells. What offers? Large Telescope.—H., 4, Pratt's place, Brooksbys-walk, Homerton.

Surveyor's **Level and Chain,** cost £8 10s. What offers in exchange? No use to present owner.—Thomas, 172, Bilston-road, Wolverhampton. No cards.

Set of fine-toned **Hand Bells,** ten in number, to suspend. Exchange Diamond Ring.—J. Thompson, Lodge lane, Liverpool.

Iron Safe, single speed Drilling Machine, 8-horse Portable Engine and Boiler, for 12in. Cylinder Horizontal Engine.—Wm. Newsome, Sowerby Bridge.

Stereoscopic Lenses and Views, second-hand. Offers.—Thos. Canning, Post Office, Eden, near Carrickfergus, county Antrim.

Books, &c., wanted in exchange for Photographs. Lists sent.—Collodion, Box 15, Post-office, Retford.

Engine cylinder 8½ by 3½, metallic piston, slide-valve and rod. Splendid stop valve, all fitted; cost £6. What offers?—F. Houghton, Dogget's-square, Strood, near Rochester.

Will exchange Soloman's **Enlarging Lantern,** 6in. condenser, lamp, lens, &c., for 10 by 8 double lens by Ross, or good maker.—W. B. Allison, N.S. Infirmary, Stoke-on-Trent.

Nice **Launch Engine.** 3in. by 4in. stroke. I want good back-geared lathe and bench drilling machine. Cash to balance.—John Middleton, Hope-street, Glasgow.

THE SIXPENNY SALE COLUMN.

Advertisements are inserted in this column at the rate of 6d. for the first 16 words, and 6d. for every succeeding 8 words.

For Sale.

Lantern Photographs, 10,000, with readings, from 6d. plain, 1s. coloured.—A. Pumphrey, Emily-street, Birmingham.

Gelatine Films for photographs, reduce cost and labour of photography to minimum.—A. Pumphrey, Birmingham.

The **Filmograph** carries 100 films or 12 plates. Lightest Photo. Apparatus. Illustrated tests.—Pumphrey, Birmingham.

Filmographic Manual, free 6d., with photograph from Film Negative. Full instructions. Films, Filmograph.—A. Pumphrey, Birmingham.

100-Fold **Filmograph Slide,** can be used with ordinary camera. Plates changed anywhere.—A. Pumphrey, Birmingham.

Collographic **Photographs** for Machinery and Trade Patterns. Sample and list for 2d.—Pumphrey and Day, Birmingham.

"The **Night-light Clock.**" Illustrated and described on page 370, No. 848. Price, carriage free, 6s. 6d.—F Robertson, 13, Greek street, Soho, W.

Perambulator, bicycle wheels, hood, apron, porcelain handle, 36s.—G., 425, Edgeware-road.

Complete **Practical Instructions** for performing Experiments in Mesmerism, electro-biology, &c., free, 5s. Usual price £1 1s.—Hezmalhalch.

Bachelor's **Brace Buttons.** No coming off. No sewing. Last lifetime. Packet free, 14 stamps. Wholesale.

New "Eclipse" **Pipe.** No oil in mouth. No smoking wet tobacco, 2s. free.—J. Hezmalhalch, 1, Fellincliffe, Leeds.

Launch Engines, different sizes, single and double. State size required.—John Middleton, 15, Hope-street, Glasgow.

Lathe, 3½in., 3ft. bed, screw-cutting, slide-rest compound, set change wheels, chucks, &c., second-hand, good as new, £11.—Makin, Cupola, Sheffield.

Stocks and Dies, now in extensive use. List one stamp.—F. M. Rogers, 21, Finsbury-pavement.

Electric Lighting.—Inventors wishing to perfect, patent, or sell inventions connected with electric lighting should communicate with F. M. Rogers, 21, Finsbury-pavement, E.C.

Minerals, 100 good specimens, including sapphire, ruby, topaz, emerald, opal, all named, different, 10s. Apply for list. Also many finer, rarer specimens.—Collector, Richard's Library, 42, Tachbrook-street, Pimlico.

The best **Ebony Stain** for wood, sample bottle 6d.—R. M. Hands, Westbourne, Bournemouth.

Tourist ½ **Camera,** slides, lens, shutter, tripod, chemicals, &c., all perfect, £3 10s.—Photo, 51, Legh-street, Warrington.

Metallic "E" **Violin Strings.** Infinitely superior to gut. Four post free 1s.—Smith, 2, Bedford-street, Plymouth

Ward's **Deobstruent Pills,** choice vegetable extracts. No nausea or griping.—P. D. Ward, Registered Pharmaceutical Chemist, 61, Bland-street, Moss side, Manchester. 13½d. post free.

Engineer's Stock, new, containing Whitworth's 1⅛in. and 1¼in. dies, price 29s.—North, Loveday street, Birmingham.

Gas Stocks, Dies, and **Taps,** new, must be sold. Particulars on application.—North, Loveday-street, Birmingham.

Metallic "A" and "E" **Violin Strings,** acknowledged success. Six, post free, 1s.—John Elarco, 36, Kelvingrove, Liverpool.

Equatorial **Telescope,** 9¼in., With-Browning mirror, at Stevens' Auction Rooms, King-street, Covent Garden.

Equatorial **Telescope,** 9¼in., cost nearly £100, by Auction, June 16th (Friday).—Stevens, King street, Covent Garden.

Equatorial **Telescope,** Silver-on-Glass, with Browning 9¼in. mirror, to be Sold by Auction, as above.

Bicycles.—One 47in. best quality, with adjustable cone bearings, cost £11 10s., offered for £9. One 54in., cost £12 10s., offered at £9 10s. These are equal to new, and guaranteed our own make.—Britannia Company, Colchester.

Bicycles.—Britannia Company are appointing agents for the sale of their bicycles, which, quality and durability considered, are the cheapest in the trade.

Band Saw, cost £28, offered at £15. Moulding Machine, £10. These are worth attention of purchasers.—Britannia Company, Colchester.

Chucks for Lathes. The best is the self-centring Essex Chuck for holding drills, &c., up to ½in., 25s.; small size, 10s 6d., holds up to ¼in.—Britannia Company, Colchester.

Micro. Photos.—List of 350 one penny stamp.—E. and A. Dancer, 436, Stockport-road, Manchester.

New loud **Violins.** No back or soundpost, 15s., 20s., by "Fiddler," 19, Edward-street, Burdett-road, E.

Second-hand **Camera and Lens,** by Negretti and Zambra (stereoscopic) shuts in box 11 by 9 by 7, brass top for tripod. Also complete box of chemicals, £3 3s.—Mason, 38, Park-road, Clapham, London, S.W.

Electric Machines, Bells, Batteries, Silk and Cotton Covered Wires.—King and Co, Electricians, Bristol. List, twopence.

For Sale, 5¼in. equatorial reflecting **Telescope,** by Calver, with circles.—Fay, 172, Edmund-street, Birmingham.

Gents' **Oxford Shirts** at manufacturer's prices. Price lists post free.—J. Smith, No. 1, Hodson's square, Corporation-street, Manchester.

Gents' **White Shirts** at manufacturer's prices. Price lists post free.—J. Smith, No. 1, Hodson's-square, Corporation-street, Manchester.

Ladies' **Underclothing** at manufacturer's prices. Price lists post free.—J. Smith, No. 1, Hodson's-square, Corporation-street, Manchester.

Calicoes, Dress Goods, Smallwares at manufacturer's prices. Any length cut. Patterns post free. Carriage paid on £2 orders.—J. Smith, No. 1, Hodson's-square, Corporation-street Manchester.

6in. **Lathe,** iron bed, double wooden frame, overhead motion, 5 speed flywheel, crank, treadle, &c., complete, cylinder poppet, rest and two tees, compound slide-rest and tools, several metal and wooden chucks, small circular saw on spindle, fretsaw to fit on lathe, set of taps to rose, small drilling frame, quantity of turning tools. Cost over £20. What offers? May be seen by appointment.—C. Hofman, 24, Park-square, Regent's Park.

52in. Special Challenge **Bicycle,** perfect condition, £4. Photo. sent.—Burgess, Hatfield, Herts.

Nickel Anodes for Sale, about 9 pieces, 6in. by 3in. by ½in., at 3s. 6d. per lb.—A. Arrowsmith, 64, Wells-street, Oxford-street.

52in. Special Express **Bicycle,** ball bearings to both wheels, good strong roadster, quite new, a bargain, £6 10s.—E., 10, Trevor-street, Wrexham.

Lathes, Lathes, cheap good screw-cutting, from £10. Easy payments. Hire system. First-class tools.—Makin, Cupola, Sheffield.

Remington Type Writer, by Auction, Friday, June 16th.—Stevens, 38 King-street, Covent-garden.

Dry Plates. Perfectly instantaneous. Samples in wooden box, by post free, 1s. Satisfaction.—P. Mitchell, Sydenham, London.

Just introduced, the perfect **Sensitised Paper.** Keeps 6 months. Most brilliant pictures. 10d. sheet on roller.—As above.

Dry Plates.—Buy no others till you have tried our special make. Samples 1s.—P. Mitchell, Sydenham.

100 only left of our little book, "**Photographer's Friend,**" half cost, 3 stamps.—As above, P. Mitchell.

A solid oak **Tool Chest,** containing 114 first-class carpenter's tools. A splendid opportunity for a gentleman amateur. Cost over £16. Will accept £6 10s. Approval to any trustworthy person.—Mackley, 77, Chadwick-road, Peckham Rye.

Electrical Depot and Manufactory.—Millar's, 126, Chapel-street, Salford. Handiest shop in the trade for amateurs.

Electric Lamps, 5s.; Bells, 5s.; Batteries, 2s. None better or cheaper. Instruments repaired.—Millar, as above.

Fine Art **Photographs.** Popular Portraits, Actresses, Celebrated Paintings, Antique and Modern Sculpture, Classic, Comic, Views.—Williams.

Selections Sent. Samples 6d. Catalogues free. Copying, enlarging, painting in oils.—E. Williams, Photographic Publishers, Bridgnorth.

Photographic Printing, C.D.V. 1s. 6d. doz., including retouching. Negatives enlarged.—Davy, 18, Dennetts-road, Queen's-road, Peckham.

Gas-Engine Drawings, with descriptions. Every known make. 6d. each; six for 2s. 9d.; twelve for 5s.

Gas-Engine Drawings. Indispensable to engineers inventing or using gas-engines.—Neal, 48, Junction-road, London, N.

Slide-rest, 10in., 40s. Engine, about 1-horse, 45s.—234, Swan-road, West Bromwich.

Combined **Engine and Boiler,** cylinder 5in. dia. by 10in. stroke, £19.—234, Swan-road, West Bromwich.

Bromo-Gelatine for preparing Dry Plates, equal to any in the market, at one-half the cost. Sample packet 1s. post free.—W. Robinson, Junr., 40, Smithdown-road, Liverpool.

Model Engines, separate parts, Castings, very cheap. List stamp.—Williams, 15, Dalley-street, Broughton, Manchester.

To Amateur Photographers.—For Sale, cheap, a Camera for plate 9 by 9, a Camera for plate 3¼ by 5¼, a quantity of uses, and materials, also a new Bunsen Cell and a Rhumkorff Coil; very little used.—For price and particulars, J. E. Cook, 60, Cobden-street, Leicester.

Electro-Plating Apparatus, complete sets, 5s. 6d. to £10. List one stamp.—H. Mills, Eastern Counties Plating Work, Ipswich.

Clockmaker's Hand Lathe, flywheel turned, almost new, good tool, price 10s.—McCash, James's-place, Cupar-Fife,

Photography.—Dry Plate Backs and Bellows, all sizes, cheap. Stamp for reply.—Wills, 116, Rotherfield-street, N., London.

Diamond Ring, massive, 3 stones, cost £25. Sell a bargain.—37, Northcross-road, East Dulwich.

Planing Machine for metal, 4ft. 6in. by 18in. square; bargain.—37, Northcross-road, East Dulwich.

Launch Engine, double cylinders 4in. by 6in. stroke, link motion and pump.; £25.—John Middleton, Hope-street, Glasgow.

9in. centre 14ft. Gap-bed Slide **Lathe, Drilling,** Shaping, Slotting Machines.—Newsome, Sowerby Bridge.

9 by 7 bellows body **Camera,** two double dark slides hardly used. Cost £6 6s, price £3 3s.—Jeffrey, Cheltenham.

Lamplough's **Tricycle Saddle,** cost 15s.; tricycle seat fitted on pillar and springs. Cost 12s. 6d.; price for both, 12s. 6d.—Jeffrey, Cheltenham.

Living Objects for microscopes. Ephemeridæ larvæ Hydra, Melicerta, &c.—S., care of Hunt, Barton Arcade, Manchester.

Burglar Alarms (for door or window), 1s. each.—J. Ogden and Co.

Fire Alarms (go off at 100° F.), 2s. 6d. each.—J. Ogden and Co.

Electric Switches, 1s. 6d.—J. Ogden and Co., 17, Montrose-street, Leeds

Waterlow's **Stylographic Pen,** splendid condition, cost 12s. 6d., price 3s. 6d.—H. Fisk, 20, Old Foundry-road, Ipswich.

Luminous Paint. A few bottles for Sale, price 1s. 6d. each.—H. Fisk, 20, Old Foundry-road, Ipswich.

Glazing and Enamelling Bricks, &c., white or coloured; also making Blue Bricks. Full instructions by a Practical Man, with 22 different genuine recipes. Price 5s. All particulars, price, and where ingredients can be obtained. Process simple and inexpensive.—W. Wakefield, 21, Brunel-street, Armley-road, Leeds.

Salt Glazing, full instructions by a practical man, price 2s.—W. Wakefield, 21, Brunel-street, Armley-road, Leeds

52in. **Extraordinary,** good condition, £8. Particulars from Henry Price, Hawthorns, Kingswinford, Dudley.

A. François' List of Aneroid Barometers, Field-glasses, Model Engines, Steam Boats, etc., will be forwarded free.

Readers of the "**Mechanic**" will do well to send for François' list and compare with others.

A. François, while thanking those who have honoured him with their patronage, beg to say he will forward list to them.

François, Devonshire-place, Ryland-road, Birmingham, has articles on his list at half usual price. Fact!

Boilers, one new vertical tubular, 9ft. 6in. high and 3ft. 9in. diameter. Cheap.—Dickinson, Osborne, and Shaw.

One new **Vertical Tubular,** 4ft. 6in. by 2ft. diameter, highly finished and cheap.

One new **Vertical Tubular,** 4ft. high and 1ft. 9in. diameter, with or without fittings. Cheap.

One second-hand **Launch Boiler,** 3ft. 9in. high and 2ft. diameter. All fittings complete. A bargain.

Launch Boilers of every description are manufactured by Dickinson, Osborne, and Shaw, 219, West Ferry-road, Millwall, E.

Hardy Irish **Ferns,** 10 varieties, good strong plants, 1s. 2d., doz., free.—M. Collins, Inishannon, Co. Cork.

Superior 4½in. **Slide-Rest,** good design, quite new, remarkably cheap.—F. Hodges, 186, St. James-crescent, Gloucester.

Handy Bench Vertical **Drilling Machine** (to ⅜in.), hand or power.—F. Hodges, 186, St. James-crescent, Gloucester.

6in. single **Headstock and Poppet,** superior make, new. Cheap.—F. Hodges, 186, St. James-crescent, Gloucester.

Tinman's **Jenny,** very little used, equal to new, 20s.—F. Hodges, 186, St. James-crescent, Gloucester.

Bicycle, 52in. Challenge, by Singer, in good order, front wheel brake, sale, cheap.—Sydney Evershed.

Horizontal Engine, 1-3rd horse-power, complete, in working order; quite new, cheap.—Sydney Evershed, Wonersh, Guildford.

The English Mechanic

AND

WORLD OF SCIENCE AND ART.

FRIDAY, JUNE 16, 1882.

SCREW PROPULSION.

THE somewhat heterodox views of Mr. J. B. Root on the problem of the screw-propeller, a notice of which we gave on p. 294 of our last volume, attracted some attention in this country, as they did in the United States; but, so far, no really practical result has followed the expression of the various opinions enunciated. Lately, we have had a lecture from no less orthodox a propeller-man than Mr. Griffiths, the inventor of the screw that bears his name, who, at the commencement of his remarks, made the statement that, although nearly half a century has elapsed since the introduction of the propeller, very little real improvement has been effected, notwithstanding the attention the subject has received. Such a statement, made, as it was, in the lecture-room of the Naval and Submarine Exhibition, might have taken the visitor by surprise; but it is nevertheless a fact that we are still a very long way off even that approach to perfection which alone can satisfy the engineer. The problem is acknowledged to be a difficult one, and there can be no doubt that to a certain extent progress has been delayed, as Mr. Griffiths suggested, by the prevalence of erroneous ideas respecting the loss of power which appertains to the propeller—one of the greatest difficulties in the path of improvement being the uncertainty as to the cause of the loss, many believing that it is due to the form of the screw, whereas Mr. Griffiths and others hold that the position of the screw as regards the hull of the vessel is by far the more important factor. The actual power required to force a vessel through the water is less than one-third of that which must be applied through the propeller to obtain the same speed, so that if we could but approach to the minimum by means of the screw, a great reduction in the weight and strength of the machinery would be possible. It is some years ago since Mr. Griffiths determined that the slip of the screw was by no means a measure of the loss of power; but although many experiments have been made since, it is not yet clear what becomes of the wasted power. In 1875 Mr. Griffiths made some tests on one of the steam launches in the Navy, which was towed at the speed her own engines would have given her, with the view of ascertaining the velocity of the water through the screw's disc. It was found that while the velocity through the bottom-half of the disc, and at the outside for some distance above the shaft was approximately that at which the launch was being towed, the speed of the water at the upper part of the disc was only about half. Therefore, as the screw propels the vessel by pushing the water back, there must be an unequal distribution of power, the blades as they approach the top of the disc meeting with greatly increased resistance, and giving rise to a series of jerks, which are recognised in the shape of vibration. Dynamometer diagrams show clearly the great increase of resistance met with by the blades when vertical, and this increase must fall entirely to the share of the upper blade. At those parts of the screw's disc where the water is being dragged with the ship, the greater part of the power is exerted, and as the tendency of the propeller is to force water away from the ship, much less pressure is given to the stern by the closing in of the water behind the vessel. To avoid this drawback Mr. Griffiths placed the propeller further away from the wedge of the run, and found an increase of speed until the screw was more than two-thirds of its diameter from the end of the wedge formed by the immersed lines of the stern. Beyond that distance a decrease of speed was experienced, for then the propeller was behind the meeting line of the water coming from each side of the stern, and the flowing together of those two streams offers, as may be readily imagined, considerable resistance to the screw. In carrying his plan out in practice, either a different form of rudder is used, or the old form is placed on a new frame, the object being to put the propeller in such a position that it is so far clear of the run as not to retard the progress of the vessel. The increase of speed claimed for so comparatively simple an operation is about 12 per cent.—in some cases as much as 15 per cent.—to attain which, by engine power, would involve an increase of somewhere about 40 per cent., an enormous augmentation in the money value of the machinery of a vessel. Several ships have been fitted with propellers on the plan proposed with satisfactory results—in two cases where measured mile trials were made, the gain was a knot and a knot and a half respectively. If the greater portion of the power is expended at the upper part of the screw's disc, it follows that a reduction in the diameter should within limits lead to some improvement, and in the case of three Atlantic steamers a slight increase of speed (about half a knot) was effected by reducing the diameter in two by as much as 30in., and in the other by 16in. The experiments with the *Iris*, which was fitted with four-bladed screws of 18ft. 6in. diameter, and subsequently with Griffiths' screws—four-bladed, 16ft. 3in., and two-bladed, 18ft. 1½in. in diameter, which, owing to their narrower points, meet with less resistance at the upper part of the disc—conclusively proved the advantage, as a gain of nearly two knots was the result.

The dragging back of the water at the upper part of the disc increases the resistance of the ship very considerably; but Mr. Griffiths proposes to remedy that by fitting plates in such a manner as to increase the current of water through the upper part of the disc formed by the screw. At present the plan has been tried only in model, but it seems that it is sufficiently successful to warrant experiments on the scale of 12in. to the foot. The idea of placing cylindrical covers over screw-propellers is not by any means a new one, but whenever it has been tried, a loss of speed resulted. Mr. Griffiths came to the conclusion that the loss was occasioned by the propeller not having sufficient water to act upon, and from some experiments he made he was induced to give the cylindrical casing a sort of funnel mouth, with the view of gathering in water into the casing. About seven years ago this casing was tried on the *Bruiser*, a gunboat having a propeller 6ft. in diameter. The casing was 6ft. 1in. over the propeller, and 7ft. at the funnel-mouth. When tried at the measured mile the gunboat showed an increased speed of about a quarter of a knot, and also answered the helm more quickly, while vibration was much reduced. There is another reason why a casing over the propeller is advantageous, which is especially applicable in the case of men-of-war, and that is the protection afforded against the fouling of the screw by ropes or wreckage. Consequently, if an increase of speed can be obtained, and at the same time the propeller can be protected, there will be every inducement to adopt the invention, especially in its latest form. The casing, as fitted to the *Bruiser*, though perfectly successful so far as it went, did not altogether satisfy Mr. Griffiths, and further experiments led him to adopt a casing in two pieces of different diameters. One of these, just large enough for the propeller to work in, extends from the rudder-post to the middle line of the screw, where it is overlapped by a ring of greater diameter (about one-eighth), which extends forward, and is supported by bars reaching from the "run" of the vessel to the outer rim of the casing. These bars, it will be understood, serve to prevent the entrance of substances which might foul the screw, while the annular space left between the two rings forming the casing provides an escape if more water is taken in than the screw requires. The arrangement is based on the theory that the screw draws in water opposite the forward part of the periphery for about half the width of the points of the blades, and opposite the after half drives it out. By fixing a ring case over that part of the propeller, this latter action is prevented, and more thrust is obtained; but it is necessary to increase the size of the ring forward, in order that the drawing-in action of the forward part of the periphery may have full play. A practical demonstration of the value of the device will be given shortly, as some steam-trawlers which are being constructed for one of the fishing companies, are being fitted with these propeller casings. The plates above mentioned represent casings cut away in parts, and are certainly simple and inexpensive additions. The upper one, which covers about two-thirds of the diameter of the propeller, extends from the rudder-post to some distance in front of the screw, and is kept at a distance from it of one inch for every foot of the screw's diameter; the lower one extends from the rudder-post to the middle-line of the blades, and while covering as large a diameter as the upper, is placed as close as possible to the points of the blades. In the case of twin screws, the position is altered, the upper plates being fixed more to one side rather than directly over the top of the screw's disc. It is stated that a simple addition such as we have here briefly described, promises, according to the experiments with models, to give an increase of speed of 7 per cent., while the cost can be only a few pounds in the largest vessel.

THE RHEOLYSER.

THIS name has been given by Prof. Wartmann to an apparatus (described by him to a scientific society in Geneva) which enables one to make the intensity of a derived current vary rapidly from zero to a maximum, and which indicates, in an exact way, the relations of these variations (see *Archives des Sciences*, May).

On a tripod, adjustable with screws, rises a column, to which six radii—all in the same horizontal plane—connect a graduated metallic ring rising above the plane. Each of the quadrants is numbered to 90° right and left of a diameter which is the line of zero. This ring surrounds a thick disc of glass or ebonite, resting on the radii, and having a circular canal, filled with mercury, near its outer border. At the top of the column is a diametral bar, terminated by two verniers, which acts like a movable Wheatstone-bridge, turning about the common centre of the canal and the ring. It carries two copper screws with amalgamated points, fixed near the ends of the diameter which form the line of zero of the verniers. These screws dip in the mercury at an interval of 180° from each other. Insulated electrically, they communicate with two binding-screws, placed near the centre of rotation, to which are

VOL. XXXV.—NO. 899.

joined the circuit ends of a mirror-galvanometer. Two orifices made in the bottom of the canal, at the interval of a half-circumference, admit copper conductors into the mercury. These latter are connected with binding-screws, in which are fixed the electrodes of the battery, and which are isolated on the tripod.

To use the rheolyser, one commences by making the zeros of the verniers coincide with those of the graduated circle. A tangent-screw regulates the small displacements of the bridge, and enables one to appreciate them easily with an exactness exceeding a minute of arc. The battery circuit is closed; and if the galvanometer shows a deflection, this is counteracted by the play of a second tangent-screw, which turns the disc in its place. Then the diameter which joins the points of bifurcation of the circuit is exactly perpendicular to that which passes through the dipping screws. When the bridge traverses equal arcs right and left of the line of zeros, the deflections of the galvanometer needle are equal and of opposite sign. Two of the mercurial arcs gain precisely what the supplementary ones lose—a circumstance which increases the sensibility of the apparatus.

Mercury has an electric resistance at once superior to that of the other usual methods, and less affected by variations of temperature. No more perfect or uniform contact is known than that which it gives with amalgamated copper. When it is pure, its liquidity insures complete homogeneity. These properties justify its use in the present case.

But it is indispensable that the conductivity of the mercurial ring should be and remain the same throughout. Local capillary influences, or a possible imperfection in the support of the disc, might prevent this condition being fulfilled. To obviate this, the author covers the canal with a plate of glass which is held by springs, and turns with the bridge. The mercury, whose convex surface is flattened by this plate, fills the whole annular cavity; moreover, it is sheltered from dust and other impurities.

That the apparatus may be transportable, one of the small orifices in the bottom of the canal allows the mercury to flow into a glass cylinder under the disc. This reservoir is closed below by an iron piston moved by a screw. Thus the canal may be easily emptied, or a liquid ring of desired section introduced. One of the electrodes is then in communication with a plate of copper inserted between the disc and the metallic top of the reservoir. This plate is pierced with a central hole at that part of the canal.

The rheolyser may be used:—

1. To obtain a current of a given intensity.

2. To maintain this intensity with rigorous constancy.

3. To verify, by an operation similar to that of a commutator, the construction and installation of apparatuses based on electromagnetic reactions, such as sine and tangent compasses, electrodynamometers, galvanometers, &c. The mobile system is in its true position of equilibrium, and free from perturbating causes, when it deflects through equal arcs, under the action of currents equal and successively opposite, produced by displacements of the bridge on either side of zero.

4. To determine directly the value of the co-efficient of reduction which renders comparable evaluations made with two of these apparatuses not identical. This coefficient is equal to the ratio of the lengths of the mercurial arcs, reckoned from the zero of compensation, for which the deflection of the mobile system is the same in both instruments.

5. To form a table of correspondence between the intensities of different currents and the galvanometric deflections measuring them.

6. To form a table of corrections necessary for indications of ordinary tangent compasses.

7. To find the relations of intensity of electro-motive forces obtained from different sources. These intensities are to each other in the inverse ratio of arcs of the rheolyser which produce the same deflection in the galvanometer.

8. To estimate the ratios of the resistances of various conductors, as also variations of resistance in the same conductor.

9. To assure oneself of the good construction of shunts, resistance-coils, and other apparatus of the kind.

10. To express, in absolute measure, the intensity of derived currents, when one knows the value of I, as also that of the resistances R and ρ.

IMPROVEMENTS IN SAFETY-LAMPS.

THE proposal to employ electric lamps in coal-mines does not appear to meet with much attention from practical miners, although the safety-lamps at present used are confessedly not everything that could be wished. It is tolerably well-known that numerous as are the devices already seeking for patronage, there is no real safety-lamp amongst them, and it is difficult to conceive a design which in all circumstances could be fairly regarded as safe. There is a natural reluctance to adopt a comparatively untried system like the electric lamps, which, moreover, may introduce an element of danger from which the existing devices are free, for miners prefer the risks with which they are acquainted to others of which they know practically nothing. The question of the safe-lighting of coal-mines has been recently debated at some length by the Manchester Geological Society; but, although many practical workers have taken part in it, none of them have even suggested the electric lamp—perhaps because they are unacquainted with it, but more probably because they are not inclined to trust it, from a vague but not ill-grounded fear that it would introduce elements of danger from which the present lamps are free. It is certain that sparking between severed connections would inevitably fire an explosive atmosphere, and there might be some risk from lightning flashes if a system of electric "leads" were carried through a mine. At a recent meeting of the Manchester Geological Society, Mr. Jas. Cunliffe, of the Bridgewater collieries, submitted an improvement of the Davy, the principal object of which is apparently to secure a better light. He urged that as it was impossible to construct useful lamps which would not be liable to be broken by ordinary accidents in the mine, it would be better to seek for improved lighting power, which would diminish the risk of injury to the lamp, and trust to the indication supplied by the flame for the detection of dangerous atmospheres. Lately, several ingenious devices for ascertaining the dangerous character of the gases have been devised; but as they must needs be under the control of overmen, they would scarcely meet all the accidental conditions which sometimes arise in fiery mines. What the miner requires is a lamp that will give the best possible light, indicate unmistakably the presence of foul-air, be proof against tampering, and while resisting the effects of "shots," be strong enough to resist any accidental blows it may receive. It is not very difficult to devise a lamp which shall be so inclosed that a sudden blast of air, such as may be given by the firing of a shot, shall have no effect on it, in the shape of driving the air through or sucking the flame out; but it is not so easy to give sufficient light and avoid all danger from the accidental blow of a pick. The members of the Society above named do not appear to have been able to arrive at any conclusion, although many experienced mining engineers were present at the meeting; the discussion in the end being adjourned to a special meeting to be held at Wigan at the end of this month. Mr. J. Ashworth, of Derby, exhibited his modification of the Museler lamp, the principal improvement being the addition of a light copper or tin shield above the gauze, which touches the chimney at six equidistant points and prevents any current passing through the gauze on one side of the chimney and out again on the other, as it may do in the ordinary Museler. An appendage called a "chimney pot," consisting of a cylinder containing three wings which commence a little above the top of the chimney, and extending to a little below the bottom of the cylinder, divide the pot into three compartments, is another improvement. With these additions it is claimed that a continuous and steady current is maintained in the lamp with no more air entering than is required to supply the flame, whilst the air so entering is highly heated by direct contact with the chimney, and thus assists in producing perfect combustion. Mr. Ashworth prefers mineral oil, and so far as his own experience goes, he considers it safer than any other. He admits that it is useless expecting Government to make the use of any particular lamp compulsory, but thinks they might insist on the employment of lamps of standard types only, and that all new lamps introduced from time to time should receive the authorisation of the Home Office before they could be used in any mine. Mr. J. S. Martin, Inspector of Mines, said there could be no doubt that the lamp which was required was one which would go out when it came in contact with an explosive mixture, because so long as the flame continued inside the lamp when in the midst of an explosive mixture something must ultimately give way, and the result in all probability would be an explosion. The chief use of a safety-lamp should be considered as an indicator for detecting the presence of gas, and not for working in the midst of an explosive mixture.

IMPROVEMENTS IN VELOCIPEDES.

AMONGST recent "improvements" in velocipedes, whether bicycles or tricycles, are several devices to obviate the rotary action of the feet, and to replace it by an up and down motion in which the length of the stroke is at the rider's pleasure. Those who visited the Stanley Exhibition at the Agricultural Hall did not fail to note as one of the novelties the Merlin bicycle and tricycle, which we briefly described on p. 558 of the last volume. In that machine, it will be remembered, the pedals are at the ends of two levers pivoted to forward extensions of the framing, and connected, about the centre of their length, to loose pulleys carried on the axle. The connection is a leather band, and inside each pulley is a spring, which reverses the motion of the pulley, coils up the leather band, and so raises the pedal lever for the next down stroke. Motion is imparted to the axle through a pawl carried by the crank arm, which engages with the ratchet teeth on the side of the loose pulley. A somewhat similar method of imparting motion to the driving wheel has been recently patented in this country on behalf of S. N. Silver and C. E. Page, of Maine, in the United States. Their invention consists in a tricycle having two pivoted foot levers connected with arms loosely mounted on the driving axle, and provided at their outer ends with pivoted pawls engaging in notches in discs loosely mounted on the axle, the discs being provided with friction clutch dogs catching on the inner surface of the circumferential flange of a disc fast on the axle, whereby when the foot levers are depressed springs on the axle connected with the loose discs, and other springs, also connected with these discs, will be brought in tension, and when the pawls are released from the discs the springs revolve the loose discs which catch on the fast disc, thereby rotating the axle and propelling the vehicle forward. The tricycle is provided with a brake operated by means of a handle sliding on a squared rod surrounded by a spiral spring, and the front guide or steering wheel is connected with a like square rod, provided with a handle and spring, these handles and springs being also used to increase the power for propelling the vehicle. The frame is in form of a right-angled triangle, and is bent upwards at its rear end to form bearings for the axle. The driving wheels may either be fast on the axle or provided with boxes having internal ratchet teeth with which pawls on the axle engage only when the axle turns in the one direction and not in the other. The foot levers are pivoted at their front ends to the frame in front of the axle, and their rear ends extend behind the axle, and are respectively connected by links with arms loose on the axle and carrying pawls engaging with notches in the edges of discs also loose on the axle. Between the loose discs is another disc fast on the axle and having a broad rim, against the internal periphery of which bear two opposite friction clutch dogs pivoted to the inner face of each loose disc, and resting against and connected by springs to a diametral rib on the inner face. The arms and loose discs are held close up to the fast disc by a coiled spring. Powerful springs are coiled upon the axle at either side of this double friction clutch box, and are attached to the loose discs thereof, and strong springs are also attached to the frame and to the loose discs. Either or both of these springs may be used. By depressing the treadle levers alternately the arm and pawl are drawn down and the corresponding loose disc is turned backwards a portion of a revolution (its movement being limited by a stop), and the springs connected to it are thereby put in tension. When the pawl reaches the end of its stroke it strikes a fixed cam block and is thrown off, thereby releasing the loose disc, which is thereupon turned by the springs in the forward direction. In this forward movement the friction clutch dogs engage with the rim of the fast disc on the axle, which will then be rotated, the vehicle being propelled forward by the power of the springs. The treadles have a socket at the underside resting on a ball on the treadle lever and held thereon by a stirrup embracing the lever. A steering wheel is loosely mounted on a short shaft in the front forked end of the frame in line with one of the driving wheels, and an arm on this short shaft is connected by a rod with a crank arm at the lower end of an upright rod, turning at its upper and lower ends in the frame. This rod is of square section, and upon it slides the lower bent end of a guided rod, having a handle at its upper end by which the square rod can be turned at the same time that the handle is free to slide up and down thereon. The handle is pressed down by a strong spring on the square rod, but may be locked in the raised position when the action of the springs is not required. A similar arrangement at the opposite side of the vehicle is connected with a cross bar carrying brake shoes to be applied to the driving wheels. The action of the springs applied to these two handles is by drawing the handles downward against the upward pull of the rider's hands, to draw the rider's body downwards, and so increase the power applied to the treadle levers. It is not necessary to give illustrations of this device (the specification is No. 4434, 1881), as the application of the principle will be readily understood; nor are diagrams necessary in the case of another invention patented here on behalf of M. A. Mange, of Lonchamp, France. This patent, which is No. 650, 1882, is for devices by which the weight of the rider's body is utilised as motive power. The rider sits on a saddle about midway between the driving and the steering wheel, so that the former carries only such part of the weight as is transmitted through the frame. The saddle is connected to a rocking bar in the frame, and the pedals are also attached to the ends of the bar by links. The driving wheel has one crank only, which is attached to the rocking bar by a connecting rod, and the weight of the parts of the mechanism is "equilibrated" by a flywheel at the other end of the driving axle. The inventor has provided an ingenious arrangement of bevel wheels and a pinion by which the throw of the crank can be altered without dismounting. The rider can, if he so desires, touch the ground with his feet—that is, if anyone cares to ride such a machine when made. It is a good problem for young mechanics to find out how much of the weight of the body is utilised when the saddle and one of the pedals rise and fall together.

PRACTICAL NOTES ON PLUMBING.—XXXVI.*

By P. J. Davies, H.M.A.S.P., &c.

(*Continued from page* 299.)

FIG. 211a, referred to in the last line, last week, but not shown, is here given. I.J.H. illustrates the pull, and G the fly-nut; Fig. 212 illustrates the lavatory basin-waste, and which will also work for the supply valve as fixed upon a bracket, also illustrated, but fixed at M L (Fig. 203). In Fig. 212 the adjusting holes can be seen at S W H R; the rocking standard G, and the stopping-box on the top, are also plainly shown. To take this valve to pieces, first take out the cotter-pin from the spindle at X, then the rocking standard cotter-pin at G; if you take out the cotter-pin at G first, you will most likely bend the spindle, and so cause the valve to jump or work irregularly when closing, &c.

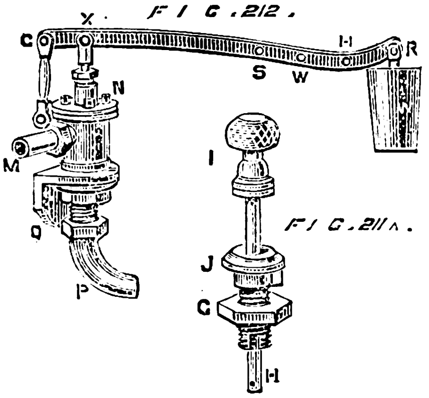

FIG. 212.

FIG. 211A.

Pillar Lavatories.

Fig. 213 illustrates a pillar lavatory, suitable for schools, &c. The inlet supply-pipe A may be brought up within a length of cast iron or up the inside of the column B, with the waste-pipe W; D is the lever to work the outlet valve; E the overflow; F the basin; this may be of cast iron, as also the top G. Of course the basin and top may be had in one casting, enamelled or galvanised, or in one piece of porcelain. For school-work I cannot recommend the washer and plug being fitted to the bottom of the basin, because the plugs get lost, and corks used in their places, that not unfrequently are found pushed down the waste-pipe; but with the lever arrangement D, all this nuisance is obviated.

FIG. 213

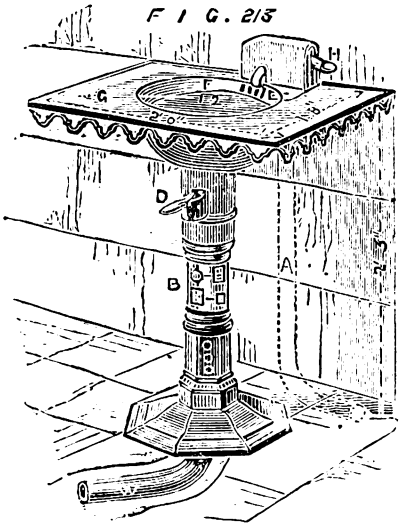

FIG. 214.

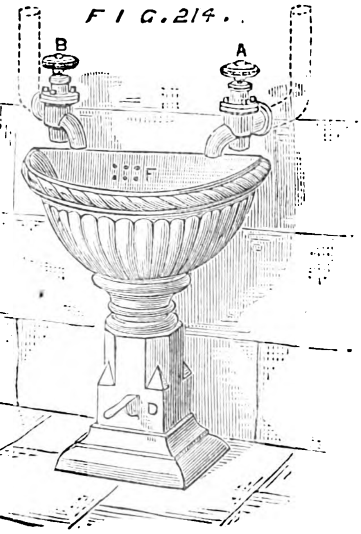

Fig. 214 is a similar pillar lavatory arrangement, but fitted with hot and cold water cocks for giving a constant stream whilst washing. I like the outlet of the two cocks to be branched into one pipe, then the temperature of the water can be regulated; the lever D for the outlet valve may be worked by the foot. One of the best kinds of inlet-cocks for this lavatory basin is illustrated at Fig. 215. A is a long screw to go through a wall, or to screw to a skirting, and makes a thoroughly good fixing; Fig. 216 illustrates a suitable horizontal cock for such work and such places where an ordinary bib-cock cannot be used, of course the bend C can be fitted to the cock (Fig. 215).

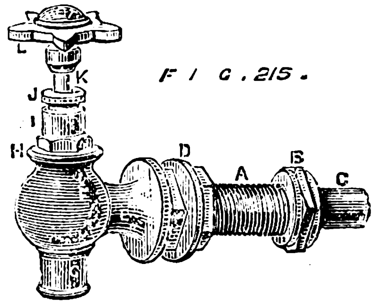

FIG. 215.

FIG. 216.

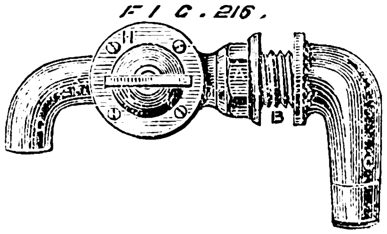

Fig. 217 illustrates a section of an upright basin valve-cock for fixing through the lavatory top: D is the fly-nut for screwing the valve to the top or slab. This may be had with plain brass or porcelain knob.

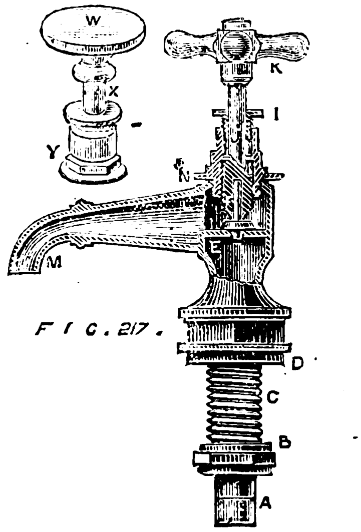

FIG. 217.

Fig. 218 illustrates a very useful kind of lavatory basin valve-cock, embracing all the good qualities of an ordinary Chrimes' screw-down valve-cock, with the additional valve J to shut off the water, whilst the ordinary shut-off valve E is taken out for releathering, &c., this addition valve being closed from the pressure of water from behind, or it may be had with

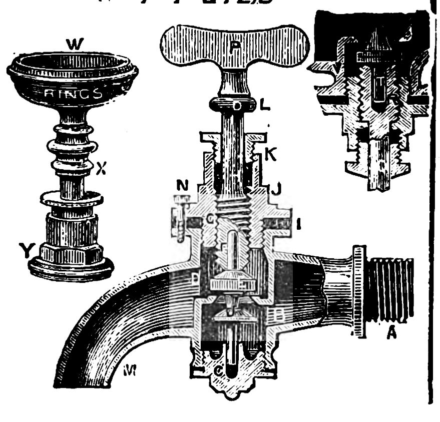
FIG. 218



the extra screwed spindle with stuffing-box Q R T V fixed at the bottom of the shed at C; but in this case the bottom of the cock should be let through the slab, or otherwise kept high enough to turn. This cock may be fitted with the ring-cup W, or with any kind of fancy knob.

Fig. 219 illustrates an upright basin valve, for fixing flush with the top of the slab. The

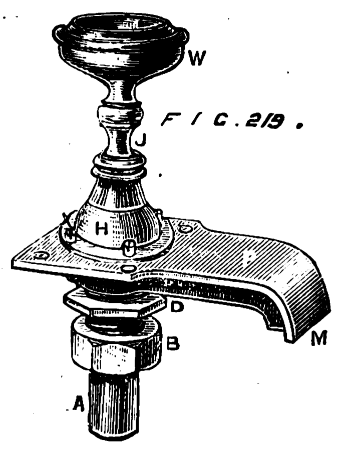


FIG. 219.

snout of this cock is made flat to give a good water-way, which will take off the pressure from the rubber diaphragm, which does not stand long together in these small valve-cocks.

MEAT TRANSPORT FROM THE ANTIPODES.*

WHAT may be regarded as a "new departure" of a very important character has just been made in the importation of refrigerated fresh meat from the antipodean colony of New Zealand. In the particular case of which we are about to give some details, there is involved a very great deal of scientific interest, for the consignment of the meat itself is the first cargo that has yet been brought to this country from New Zealand in a sailing ship. The vessel in question is the iron ship Dunedin, 1,250 tons register, built by Messrs. Robert Duncan and Co., Port-Glasgow, in the year 1874, and owned by the Albion Shipping Company, of which Mr. Peter Denny, of Dumbarton, is the chairman.

The enterprise in which that vessel has just been engaged, and is likely to be further engaged, has arisen in some measure out of the disastrous failure of the City of Glasgow Bank, one of the assets of which is a great extent of land held in the name of the New Zealand and Australian Land Company of Edinburgh and Glasgow. Being desirous of turning that property to the best account, the directors of the Land Company about a twelvemonth ago consulted Mr. J. J. Coleman, of the Bell-Coleman Mechanical Refrigeration Company, Glasgow, in reference to the possibility of bringing home a cargo of fresh meat from New Zealand by sailing ship, on the supposition that it would be necessary to have a refrigerating machine on shore for freezing the meat and one on board the vessel for maintaining it in the frozen condition during the voyage. Considering the fact that in New Zealand alone there are somewhere about 13,000,000 or 14,000,000 sheep, such an experiment was certainly one of far-reaching importance, alike to the colonists and to the people at home, who are dependent on other countries for at least 33 per cent. of the meat which they consume.

It was feared by the directors of the Land Company that if the experiment required two refrigerating machines, one at the port of shipment and the other on board the vessel, the cost would be too great to admit of the enterprise being made a successful one from a pecuniary point of view. Mr. Coleman found, however, that he was able eventually to suggest to them that under certain conditions one machine might be made that would be sufficient to overtake all the refrigerating work. The suggestion was that all previous practice in meat refrigeration should in a measure be set aside, and that a very powerful machine should be fitted into the vessel, one capable of producing refrigerated dry air at the rate of 70,000 cubic feet per hour. He argued thus: As the freezing of fresh meat involves the abstraction of about 145 deg. of latent heat in addition to the 40 deg. required to reduce the meat from a temperature of, say, 72 deg. (that of the meat cooled naturally) to 32 deg., a machine of the power just mentioned would, theoretically, be required for freezing meat at the rate of 20 tons per day. It was assumed that, in actual practice, about 10 tons of dead meat per day could easily be obtained by the facilities on shore for killing, dressing, &c.; and in order to avoid having to go to the expense of purchasing and fitting up two machines, the Albion Shipping Company agreed to allow their vessel to remain in port during the time necessary for the meat to be put on board in small daily instalments of 10 tons or so, assuming, of course, that the cargo of wool would be stowed away before the meat could all be got on board in a satisfactory manner.

In carrying out this interesting and important experiment, the principle adopted was in the first place to freeze each day's supply of carcases while hanging in the 'tween decks space, and then, after each of the carcases had been sewn in a coarse calico bag, to take them into the hold amidships, where they were packed, "head and tail," as closely as they could be stowed. The depth of the hold was nearly 18ft. Eventually the cold chamber in the hold was completely filled with frozen carcases in the way mentioned, and then the 'tween decks space was packed in a similar manner, until at last nearly 5,000 sheep and some 400 lambs were aboard in the refrigerating chambers.

The principle observed in providing for the distribution of the cold air was to bring it first into contact with the carcases that were already frozen, and then to bring under its influence those requiring to be frozen in the 'tween decks chamber. In adopting this mode of distributing the cold dry air, the object aimed at was not to maintain a uniform temperature throughout the meat chambers, but rather to make it absolutely certain that the air passing through the mass of meat in the 'tween decks was always at a temperature somewhat under 32 deg. Fahr., under which circumstances the lower hold, which first received the air from the refrigerating apparatus. must necessarily have been very much colder. That was most desirable, so as to insure the perfect rigidity of the carcases; for had the meat not been thoroughly frozen before being packed away in the lower chamber and still kept in that condition, the mere dead-weight of the superincumbent portion would have crushed the carcases forming the lower layers into a shapeless mass. As it was, however, the carcases of mutton and lamb forming this experimental shipment arrived in the Thames, after a passage of ninety-eight days, in their naturally rounded condition, and as faultless in shape as those that may be seen hanging in any butcher's shop. In the case of shipments of fresh mutton from Australia it has not unfrequently happened that the carcases have arrived quite misshapened, evidently in consequence of the ineffectual freezing power applied to the carcases before stowing them away even in the comparatively shallow space of the 'tween decks.

This shipment by the *Dunedin* is highly important from the fact that it has afforded accurate scientific data in regard to the refrigerating power really required, as the operations both of freezing and carrying have been entirely under one control. Hitherto the shipments of fresh meat from Australia have only been partially successful, owing in some measure, doubtless, to the fact that the carcases have not been frozen on shore by the same sort of machine as that used in the ship carrying the meat; and there is good reason to suppose that the freezing power employed on shore has not been at all adequate for the work to be done.

The Bell-Coleman machine on board the *Dunedin* occupies, together with the ship's linings and the upper and lower meat chambers, about 600 tons gross of carrying capacity, calculated at the rate of 40 cubic feet per ton; and the total internal capacity of the meat chambers was about 400 tons, calculated at the same rate. In that amount of space there were packed about 175 tons of meat; but as the refrigerating machine was only worked to about half its power during the voyage it is proposed to increase the internal capacity of the meat chambers about 50 per cent. for the next voyage, The machine is provided with a surface condenser, and it has a pair of compressing cylinders each of 21in. diameter, with a piston stroke of 24in. in length. Steam was generated by a pair of vertical and multitubular boilers, each having about 400 square feet of heating surface. The average number of revolutions was 60 per minute, and the average air pressure was 34lb per square inch, while the daily average number of hours that the steaming was maintained during the voyage was 15, and the consumption an average of 3lb per indicated horse-power. While the refrigerating air was delivered from the apparatus at a temperature of about 80deg. below zero, the average temperature of the lower hold was 5deg Fahr., and that of the upper hold, or 'tween deck space, was about 22deg.

[*] Condensed from *Engineering*.

IMPROVEMENTS IN ICE-MACHINES.

THE so-called binary absorption system, the device of Tessié Du Motay and August J. Rossi, obviated some of the difficulties encountered in the manufacture of ice. This plan consisted in the use of two volatile liquids and substituting the chemical affinity of absorption for the mechanical efforts of compression generally used in returning a gas to a liquid state. In this method, sulphurous acid was absorbed in ether, forming a binary liquid. This, by the action of a gas-pump, was vaporised, producing cold, and, on passing into a condenser, the ether became condensed and absorbed the sulphurous acid, thus re-forming the binary liquid ready for revaporisation. The chief advantage of the use of this binary liquid, which was called ethylo-sulphurous-dioxide, was, that cold was energetically produced at a low pressure of not more than 15 to 25 pounds. This system has been successfully used in this country, Cuba, Mexico, Hayti, China, and Japan.

After the death of M. Du Motay, Mr. Leonard F. Beckwith became interested with Mr. Rossi in a further study of the binary system, and their investigations have resulted in the discovery of a method of liquefying ammonia through its absorption in gaseous form in glycerine, and the consequent production of cold at a low pressure. This method of producing cold utilising the best known agent, and overcomes the chief obstacle to its use, the necessity of high pressure. The non volatile liquid glycerine was found to absorb about 600 times its own volume of ammonia, producing a binary liquid containing a volatile agent absorbed in a non-volatile one. After being placed in the refrigerating machine, a vacuum is mechanically created, the ammonia separates from the glycerine, and an intense cold is produced. The ammonia is then reabsorbed in a condenser by the glycerine, and then passes again into the refrigerator tank ready to be again used. This method of producing cold is constantly carried on while the machine is in operation, and the waste is comparatively small. Practical tests of this new system of producing cold artificially were recently made before Prof. Charles A. Seeley, an expert in such matters, and other gentlemen. The result showed that, in fifteen minutes after the machine was put in operation, the temperature of the refrigerator was lowered from 68° Fahr. to 18°, and ice was formed in twenty minutes from the time the machine was put in operation. The vacuum under which the ammonia was volatilised in the refrigerator where the binary liquid was placed was twenty-five inches. and the pressure under which the ammonia was reabsorbed in the condenser into the fresh glycerine was an average of twenty-five pounds, never exceeding fifty pounds. There is, it will be seen, a remarkable difference between this and previous methods employed when ammonia has been used, and when the pressure has averaged 125 pounds when at rest, and from 225 to 300 pounds when at work. The mechanical pressure heretofore required in the use of ammonia is done away with, and the much easier method of chemical affinity substituted. The new plan, if wholly successful, will do away with the necessity of the use of heavy machinery that has been an absolute necessity when ammonia was used as the cold-producing agent. Another advantage claimed for the use of this new binary liquid is, that the machinery used, like all low-pressure machinery, is easy to manage. Under the old conditions, when ammonia was used, the services of an educated, careful, and skilful engineer were an absolute necessity, or a destruction of the machines would follow. Under the low-pressure system, now made possible, an ordinary engineer would be able to manage the machine, and the danger of an explosion and destruction of the machinery is lessened. Leaks in the pipes or at valves are less apt to occur, and the expense of production is materially lessened.—*Engineering and Mining Journal* (U.S.)

HOME-MADE DRILL-CHUCKS.*

HOME-MADE drill chucks, as usually found in the average machine shop, are "bores" for reasons not necessary to explain here. This is especially true of those things which have a hole drilled in the end and a set screw in the side to secure the drill. The sockets used for receiving taper-shank drills are good, but these drills are much more costly than those with straight shanks.

The qualities which drill chucks should possess may be stated as follows: 1. Drill chucks should be simple in their construction, so they can be easily and cheaply made. This is the first thing the "practical man" generally looks for, and it is an excessive demand for this quality that often leads to anything but economy "in the long run," by the use of such things as above referred to. 2. Drill chucks should be so constructed as to hold the drill always concentric with the spindle of the lathe, or drill press, wherever they be used. As straight-shank drills may be found in every machine shop, having all sizes of shanks, whether they be twist drills or the ordinary flat, home made drills, this valuable quality is not possessed by the chuck which secures the drill from one side by a set screw, or any similarly acting device, unless the shanks fill the hole—which is hardly ever the case. The writer has, in times past, found it most convenient and economical to use round steel for home-made drills, very near the size of drill wanted; flatten one end, leaving the point a little wider than the body.

3. Drill-chucks should be easy and quick in their operation, so as to consume the least possible time in setting and removing drills.

4. There should be no projections about the chuck, such as set screws, notches, or anything which would have a tendency to catch a man's clothes or "knock the bark off his fingers," just when he is engaged on a job which "is in a hurry," because this is just the time such phenomena generally take place, and is a time when it is least desirable to have a man stop for surgical operations or for oratorical exercises.

Figs. 1 and 2 of the accompanying drawings represent designs of drill-chucks, which possess all the above qualities to a greater or less degree. The collet part J, Fig. 2, may be fitted to the spindle of a lathe or drill press. There are three jaws, E, held in place by the shell nut D. It may be necessary to have more than one set of jaws, according to the range in the sizes of drills intended to be used. It is best to make these jaws of iron and case-harden them, as steel would be likely to spring more or less in hardening. Pieces of soft rubber, I, are placed between the jaws. These serve to open the jaws by their elasticity, when released by the nut D. F is a rubber band, which serves to hold the jaws together when they are taken out to be replaced by a set with a larger or smaller hole. Springs may be substituted for the rubbers, but the latter are cheaper than the former. The nut D has six holes H, drilled into it to receive a spanner-wrench in setting the larger-sized drills. A knurled band, G, on the nut, will admit of its being set by hand when small drills are used. In the chuck shown in Fig. 1 the nut D is fitted directly to the lathe-spindle C. The disc, K, serves to cover the hole in the spindle to form a backing for the drill. Otherwise the drawings explain themselves.

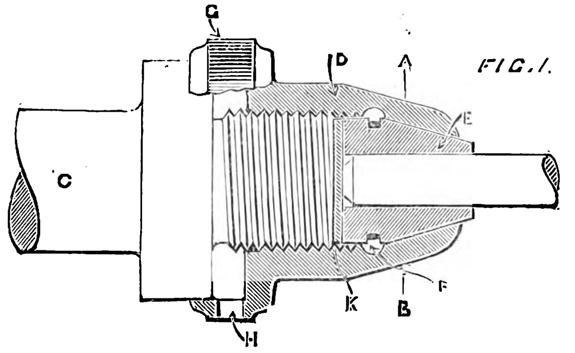
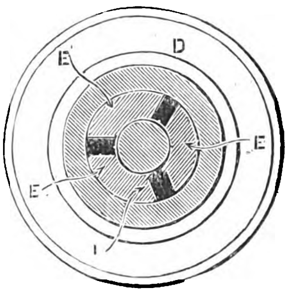
SECTION. L M.

FIG. 1.





SECTION. A.B

A NEW THERMOGRAPH.*

THE instrument under consideration is a thermograph for recording atmospheric temperature, the fluctuations of which are much less regular and more frequent than one who has not made a study of it would suppose. It records the temperature directly from the column of mercury in the tube of a thermometer by dots or perforations upon a sheet of paper previously ruled with degrees and hours.

Its principal parts are, as shown in Fig. 1. 1st. A thermometer in the form of an ordinary mercury thermometer, but open at the top of the tube, and having a wire entering the bulb and connected to one pole of a battery, the other pole of which is connected to the mechanism of the instrument. 2nd. An upright cylinder revolving by clockwork, covered with a paper which is divided vertically into 24 parts by lines representing the hours, and horizontally by lines representing the degrees. 3rd. A bar raised and lowered by mechanism driven by clockwork, furnished below with a needle entering the tube of the thermometer, and carrying a pencil—or preferably a point—driven forward by a small electro-magnet when the circuit is closed by the needle entering the mercury, and then making a mark at the proper place upon the paper and indicating the temperature. The bar carrying the needle rises about half an inch from the point at which the needle leaves the mercury and then descends until the needle again touches the mercury, whether that in the mean time shall have risen or fallen, when the point makes its mark upon the paper and the bar again commences to rise. This movement is accomplished by the mechanism shown in the drawing, of which only the wheel E, gearing into the rack upon the needle-bar, is shown in Fig. 1, but which is shown in full and upon an enlarged scale in Fig. 2, which is a top view. The two wheels A and B are moved by clockwork (not shown) and are constantly revolving in opposite directions, as indicated by the arrows. These wheels are not attached to the shaft upon which the wheel E is fixed, but are attached to sleeves which move without affecting that wheel except when they are joined to it by the clutches C or D. They are so geared that when the wheel E is joined to them its rim moves at the rate of half an inch per minute. Upon the shaft with the wheel E is also a loose sleeve F, which is free when the clutch C is not in action, but which moves with that wheel when that clutch is on. The levers actuating the two clutches unite and move upon a common pivot, from which point they extend as an arm, which is capable of a lateral movement between two stops, bringing one or the the other of the clutches into action. Opposite to the wheel E the needle-bar passes through a guide which is furnished on the back with a small wheel taking the thrust of the gear and reducing friction. For a lower guide the needle-bar is furnished on each side with a rod parallel to the needle, and of nearly the same length. These rods are at such distance apart that they pass clear of the thermometer tube. They are not shown in the drawing, as they would lie directly in front of and behind the needle and tube. The teeth of the clutches are partly V-shaped and partly square, or nearly so, as shown in Fig. 3; that is, they have slightly tapered sides but V-shaped points and bases, so that they enter freely, as entirely V-shaped teeth would do, and when in action they have no outward thrust. The V-shaped base strengthens the tooth and admits the point of the opposite tooth. A very small spring on each side of the sleeve F holds it out of gear while the clutch C is off. Beneath the clutch arm is a pressure spring, one end of which presses against the end of the arm and the other against a plate moving upon the same pivot with the arm, which plate also is capable of a lateral movement between its stops. If this spring-plate is moved in either direction to its stop, carrying with it the base of the spring, the clutch-arm will be moved in the other direction and the clutch on that side will be brought into action; and if the position of the spring-plate with the base of the spring be reversed, the position of the clutch-arm will be reversed—that clutch will be disengaged and the other will be engaged—the wheel E being moved and the needle-bar raised or lowered accordingly. To the sleeve F is attached an arm which is connected by a draft rod to the spring-plate. When the clutch C is in action—as shown in the drawing—connecting the wheel A with the wheel E and the sleeve F, raising the needle-bar, the arm of the sleeve F draws upon the spring-plate—moving to that side the base of the reversing-spring, which, when its base has passed the line, between the pivot and the end of the clutch-arm, presses that arm to the other side, disengaging that clutch, loosing the sleeve F, engaging the other clutch, and reversing the motion of the needle-bar, which now descends. The length of the arm on the sleeve F is such that when the needle-bar has risen half an inch the spring-plate is moved over, and the clutch-action is reversed. When, by descending, the needle is brought into contact with the mercury and a circuit is made, the large electro-

* By C. A. Smith, in the *American Machinist.*

* By G. Morgan Eldridge, in the *Journal* of the Franklin Institute.

magnet, thus vitalised, attracts its armature, which is attached to a lever connected with and drawing upon the spring-plate, and moves the base of the reversing spring to that side, changing the position of the clutch-arm and reversing the action of the clutches and the movement of the needle-bar, while at the same time the recording point upon the needle-bar is, by its electro-magnet, driven into the paper and the temperature is recorded upon the scale. The sleeve F, being loose, yields to the movement of the spring-plate, and is afterwards held by its clutch, and acts as before. The action of the large electro-magnet is supplemented by that of a spring drawing upon the same side of the spring-plate, whose strength is such that it is not quite sufficient of itself to overcome the thrust of the reversing spring, but whose force is greatest when that of the electro-magnet, by reason of its distance from its armature, is least, the greatest possible portion of the work being thus put upon the clockwork and the least upon the battery. This spring aids the electro-magnet, but does not in anywise reduce the effect of the reversing spring in holding the clutch to its work; so long as the base of that spring is unmoved its action is unimpaired. The resistance of these springs occurs only during the ascent of the needle-bar, which is, therefore, counterpoised to excess, and the resistance and the motion are thus rendered uniform. By reason of the form of the clutch-teeth before described there is no outward thrust upon the clutches while in action, and hence the reversing spring requires only to be strong enough to throw the arm over and to shift the clutches. The stop of the clutch-arm next the electro-magnet is an insulated plate to which the battery-wire leading from the magnet is connected, so that as soon as the arm has left the stop the circuit is again broken, although the needle may for a short time remain in contact with the mercury; the recording point is at once withdrawn, and thus makes upon the paper a single perforation which must be a true record of the position of the mercury in the tube, unaffected by friction or other disturbing cause, since this action must always take place at the moment of contact of the needle with the mercury, and these dots or perforations are repeated at the end of each interval of time required for the needle-bar to ascend and descend the required distance, which will be about two minutes with the wheel-motion designated.

The graduation of the scale upon the paper must correspond with the movement of the mercury in the tube of the thermometer as accurately as the graduation of the scale of an ordinary thermometer corresponds with the movement of the mercury in its tube. If but one instrument of this sort is to be made this is very easy; the rate of motion is ascertained, a scale is made to fit it, and the paper is ruled to that scale. In all thermometers heretofore made the scale has been made to fit the tube; but if more than one of these instruments is to be made it becomes necessary, or at least very convenient, to have one set of ruled papers that will fit all the instruments, and it then becomes necessary to reverse the practice and to make the tubes to fit the scale. The rise and fall of mercury in a thermometer depends upon the proportion between the diameter of the tube and the volume of mercury in the tube and bulb, and while it is possible to construct these parts in such proportion as to obtain proximately a given motion, it is not possible thus to obtain it exactly. The tube and bulb are made in separate parts, as shown in Fig. 1, of such size that when the tube is thrust half-way into the bulb the volume of mercury filling the tube half way at 32° Fahrenheit is as nearly as may be properly proportioned to the diameter of the tube. If, now, there be found too much motion, the capacity of the bulb is diminished by thrusting the tube further in, and *vice versâ*, and the proper height of mercury at 32° for that purpose is marked upon the tube. Mercury exposed to the air will slowly form a coating of oxide upon its surface. To prevent this a small quantity of glycerine, or of oil free from oxygen, is placed in the thermometer tube above the mercury. If, notwithstanding, the oxide shall accumulate to an inconvenient extent, the observer in charge of the instrument will remove the thermometer from its place, and will put the bulb in warm water until the oxide is floated off. He will then supply the loss with pure mercury, determining the proper quantity by immersing the bulb in broken ice, when the mercury column should stand at the mark for 32°. The whole apparatus, except the thermometer itself, can be inclosed and so protected from the weather and dust, while the thermometer is exposed to the air below. The system is equally applicable to a barometric record, in which case, on account of the small range of motion, the needle-bar is connected to a lever, thus increasing the range of the record.

THE boring of the Arlberg tunnel is proceeding rapidly, the rate of advance averaging ten metres daily, which exceeds the average made with the St. Gothard by six metres. At this rate boring is expected to be completed before the end of 1883.

SCIENTIFIC SOCIETIES.

ROYAL ASTRONOMICAL SOCIETY.

THE June meeting of this Society was held on the 9th inst., at Burlington House, Mr. E. J. Stone, President of the Society and Director of the Radcliffe Observatory, Oxford, occupying the chair.

Mr. Franklen George Evans, Tynant House, near Cardiff, was balloted for and duly elected a Fellow of the Society.

Mr. Knobel read a paper by Prof. Pickering, being a description, accompanied with photographs, of the photometer employed by him for observations of stars on or near the meridian. At the end of the instrument furthest from the eyepiece are two plane mirrors connected with tubes placed horizontally east and west, and capable of revolution in the plane of the meridian; the inclination of the mirrors to the axis of the tube can also be varied. One of the mirrors is directed to λ Ursæ Minoris, with which the stars to which the other mirror is directed are compared. The light is received by two object-glasses, both pencils of rays first passing through a double-image prism. The ordinary image from one mirror is compared, by means of a Nicol's prism, with the extraordinary image from the other; the prism is then reversed, and the comparison repeated with the other pair of images.

Mr. Knobel read a paper by Dr. Henry Draper "On Photographs of the Nebula in Orion." The negatives, of which enlarged photo-lithographs were exhibited, were taken on March 14th, 1882, with an 11in. refractor, the exposure being 137 minutes. The stars are much over-exposed, and are also somewhat elliptical, in consequence of the wind, which disturbed the mounting of the telescope during the long exposure. On the original negative, however, the stars of the Trapezium can be seen separate on careful examination. Most of the small stars, including some which are almost the *minimum visibile* of the telescope, appear in the photographs, so that it seems possible, by still further increasing the exposure, to photograph stars which are invisible to the eye. Photographs of the spectrum of the nebula, taken without a slit, show that two of the condensed masses preceding the Trapezium give a continuous spectrum, and therefore contain either gas under pressure, or liquid or solid matter.

Mr. Newall: I have procured from the Royal Society the loan for this evening of a drawing of the Nebula in Orion, by Mr. Lassell, which is now exhibited. It appears to me one of the most perfect drawings of the Nebula in existence, and as it has never been published, I should strongly recommend that it should be reproduced by photography, which could, I believe, be done at a small expense. With regard to Dr. Draper's photograph, I think the telescope must have moved considerably to have produced the nebulous masses around the brighter stars.

Capt. Abney: The great increase in the diameter of the stars in Dr. Draper's photograph is due to reflection from the back of the plate. This might have been prevented by backing the plate with asphaltum, which was the method adopted for the photographs of the recent eclipse.

Capt. Noble suggested that if Mr. Lassell's drawing were reproduced, the colours should be reversed, black being put for white, so that the Nebula might be given as it really appears.

Lord Rosse: There is much difficulty in reproducing by photography drawings containing faint detail. I have had experience of this lately in regard to photographs of drawings of Jupiter, which do not by any means give the delicate detail of the original; I believe that the old process of copper-plate engraving is the best, after all, though of course more expensive. There are practical difficulties in the way of reversing the colour, as suggested by Captain Noble.

Captain Abney: It is practically impossible to obtain a perfect photograph of a black and white subject. The only way to obtain a perfect gradation is to have a slightly *tinted* background, otherwise the delicate half-tints must inevitably suffer.

Mr. Maunder read a paper on the "Spectrum of Comet *Wells*," observed at the Royal Observatory, Greenwich. The most striking feature in the spectrum is the development of a bright line in the yellow, apparently corresponding to the D line of Sodium. On June 7th this was so brilliant that the comet might almost be said to shine by monochromatic light.

The President: I do not know whether I ought to mention that I have received a letter from Dr. Copeland, in which he tells me that he has distinctly seen the D-line in the spectrum of the comet *double*.

Mr. Hind gave a few practical directions to observers who desired to attempt the observation of the comet in daylight in close proximity to the Sun. Mr. Hind said: The comet has not quite kept pace with the theoretical law of increase of brightness; still, at noon to-morrow it should have the brightness of a first magnitude star, and be visible in a telescope of not less than 7in. aperture, though only 3° 3′ from the Sun. I may mention that after its perihelion passage the comet will be again visible in this country at the beginning of July.

Mr. Knott read a note on the variable star U Cephei. The minima of this star occur in sets, alternate minima at intervals of about five days, the intermediate minima being observed as each set comes round. There is reason for suspecting a difference of three-tenths of a magnitude between the minimum magnitude reached in the two sets. If this is confirmed, we must regard the period as a double one.

Captain Noble thought that Mr. Knott's observations threw doubt upon Prof. Pickering's hypothesis that the variability of stars was caused by the revolution of a large satellite round its primary.

Mr. Knott: I do not express any opinion as to the cause of the variability. If the variations in the light of U Cephei are caused by occultations, they would appear to be occultations by a nebulous body, as the star changes in *colour* as it changes in magnitude.

Mr. Christie: Captain Noble is, I think, under a misapprehension; the hypothesis of Prof Pickering's, which he mentions, is only offered in the case of stars of the *Algol* type. Prof. Pickering divides the variable stars into four or five classes, and has different hypotheses to explain the different peculiarities in their variability. There are two principal hypotheses which he has considered: the one is the occultation of a primary by its satellite, and the other the revolution round its axis of a body, different parts of which present different degrees of illumination.

The President then gave an account of some of the arrangements which have been made for the observations of the Transit of Venus on the 6th of December. He said:—As far as the British expeditions are concerned, no serious attempt will be made to apply photography, as the committee have not felt justified in recommending the Government to incur the large extra expense that would be involved. Confining ourselves to contact, however, I think the arrangements justify us in expecting a fair estimate of the Sun's distance. Arrangements have been made to have two observers at Bermuda, two at Jamaica, and two at Barbadoes. The Canadian Government have also well seconded our efforts, and have placed a sum of £1,000 at the disposal of observers working in harmony with our scheme. This will give us, if we have favourable weather, 11 or 12 contacts. To correspond with these, there will be six telescopes at the Cape of Good Hope, and another at Natal. There will be one at Madagascar and one at Mauritius, so that we shall probably have nine or ten contacts to correspond with those on the other side. The effect of parallax between these stations is about 11′ 30″ or 12′, so that, unless there is an error in the observations at all these stations of eight seconds of time, we should get the Sun's distance within a million of miles. If all observe the same kind of contact, we ought to get the observations correct within four seconds of time, which would give the distance within 500 000 miles. Besides these stations, however, we shall have observations made at Sydney and Melbourne, Brisbane, and New Zealand. With regard to other nations, a large number of observations will be made in America, though, unfortunately, these will not be balanced by a sufficient number made in the Southern hemisphere. The French will have a number of stations in South America and some in the West Indies. The Portuguese will send an expedition to the West Coast of Africa, and the Spanish to the West Indian Islands. Our own colonies have come forward with great alacrity, and are willingly assisting the Old Country in carrying out the work.

The following papers were also announced and partly read:—S. W. Burnham, "Measures of the Companion to Sirius," and "Double-Star Observations made in 1879 and 1880, with the 18½in. Refractor of the Dearborn Observatory"; Dr. Terby, "Remarques à propos des Recentes Observations de M. Schiaparelli sur la planète Mars"; Prof. C. W. Pritchett, "Transits of the Red Spot across the Central Meridian of Jupiter"; the Rev. S. J. Perry, "Observations of the Solar Eclipse, 1882, May 16th;" T. W. Backhouse, "Observations of Comet *b*, 1881"; N. C. Dunér, "On the Spectrum of Comet *Wells*"; Captain Parsons, "Sextant Observations of Comet *b*, 1881"; E. J. Stone, "Remarks on Prof. Newcomb's Paper on the Instructions for Observing the Transit of Venus"; A. Marth, "Note on M. Loewy's Communication referring to an Apparatus for Determining Flexure Errors," "On the Best Method of Determining the Errors of Division Circles and Scales," and "Ephemeris for Physical Observations of Jupiter"; E. J. Stone, "Curves Showing the Changes in the Diameter of the Moon, from the Greenwich Observations, 1750 to 1830"; and F. C. Penrose, "Elements of the Orbit of Comet *Wells*, obtained Graphically."

SCIENTIFIC NEWS.

THE death is announced of Mr. John Scott Russell, M.A., F.R.S., which took place last week, in his seventy-fifth year. The deceased gentleman will be best remembered, perhaps, by his achievements in shipbuilding, but he was also a distinguished engineer, the great dome of the Vienna Exhibition of 1873, 360ft. in clear span, being, perhaps, his most enduring monument.

At the meeting of the Royal Society last week, the fifteen selected candidates were elected Fellows:—Professor Valentine Ball, M.A., George Stewardson Brady, M.D., F.L.S., George Buchanan, M.D., Charles Baron Clarke, M.A., F.L.S., Francis Darwin, M.A., F.L.S., Professor William Dittmar, F.C.S., Walter Holbrook Gaskell, M.D., Richard Tetley Glazebrook, M.A., Frederic Ducane Godman, F.L.S., Professor Jonathan Hutchinson, F.R.C.S., Professor Archibald Liversidge, F.G.S., Professor John C. Malet, M.A., William Davidson Niven, M.A., Robert Henry Inglis Palgrave, F.S.S., Walter Weldon, F.C.S.

The Rolleston memorial has been established in the shape of a prize, to be awarded every two years, to the author of the best memoir embodying the results of original research in Animal and Vegetable Morphology, Physiology and Pathology, or Anthropology. The fund is vested in the University of Oxford as trustees, and the prize, which will amount to about £70, is open to all members of the Universities of Cambridge and Oxford within ten years of the date of their matriculation.

The general committee of the Royal Cornwall Polytechnic Society have determined to celebrate the jubilee of that excellent institution by making the annual exhibition doubly attractive, and by organising excursions to places of interest in the vicinity. The exhibition will be held in the Polytechnic and Volunteer Drill Halls, Falmouth, from the 5th to the 16th of September, dates which, it will be seen, follow close upon the meeting of the British Association at Southampton. In these circumstances a number of scientific visitors may be expected, and several men eminent in science have already promised to attend and deliver lectures. The committee estimate the expenditure at about £600, and they appeal to Cornishmen for help.

According to Prof. Blyth, who read a paper recently before the Royal Society of Edinburgh, the action of the microphone cannot depend on variation of resistance due to pressure altering the specific resistance of the material, as such resistance is unaffected by considerable variation of pressure. He thinks the effect is due to the sound-waves acting directly on the small arc between the microphone points and the tremor set up in the points themselves by transmitted vibrations. It may be remembered that other experimenters contend that pressure does affect the resistance of carbon.

At the June meeting of the Photographic Society of France, M. Janssen exhibited prints of the recent solar eclipse, and called attention to the fact that the moon's outline was very clear and distinct, proving that if the moon has an atmosphere it cannot be one of great density. The eclipse observers, or some of them, think that the moon has an atmosphere.

A so-called incandescent gaslight is about to be tried in Clerkenwell, in some of the thoroughfares leading to the Angel. It consists in a modification of the Bunsen burner, to which is adapted a cap of platinum gauze. Compressed air is supplied to the burner in a small stream, which induces an inflow of atmospheric air, and the mixture of gas and air being ignited within the gauze cap, the latter quickly glows with a brilliant incandescence, the hot platinum assisting in effecting perfect combustion.

A method of testing nitrate of silver for purity is to dissolve it in the smallest possible quantity of water, filter, and drop in hydrofluosilicic acid. If turbidity is produced, an alkaline salt is indicated. Should the solution remain clear after several drops of the acid, it is mixed with an equal bulk of alcohol, when any alkali is at once precipitated. To detect nitrous acid and nitrites, the liquid is evaporated as much as possible, and a solution of 1-100th per cent. of magenta in glacial acetic acid added. If nitrous acid or nitrites are present the liquid changes colour, running from violet to yellow. Free mineral acids also cause a similar change; but if water is added, the red colour is restored in that case.

Amongst recent patents we notice one that resembles the polysphenic ship. The bottom of the vessel is formed of a number of inclined planes connected to the atmosphere above the deck by means of pipes. When the vessel is propelled she is said to skim over the water. The No. is 4868, 1881.

Mr. Stretton has issued an appendix of three pages, which is to be attached to the third and fourth editions of his pamphlet on railway accidents. It contains the letter we published last week, with some additional matter.

Physiologists have tried to estimate the volume of blood in a living animal's body, but the methods used have not been very exact. An improved method recently adopted by MM. Gréhant and Quinquand is as follows:—The animal (a mammal) is made to breathe gas containing a known amount of carbonic oxide (CO). After a quarter of an hour, the volume of CO remaining is observed; and this shows how much has been fixed by the blood. On the other hand, by analysis of the blood, one ascertains the amount of CO fixed by a given volume (estimating the respiratory capacity of two samples, taken one before, the other after, the poisoning). From these data it appears that the total weight of the blood in mammalia is comprised between 1-12 and 1-13 of the weight of the body. In the normal condition there are no great variations in this relation.

The so-called "Electrotechnical experiments in the Royal Crystal Palace at Münich," from 16th Sept. to 15th Oct. this year, will, it is known, be an exhibition of quite special character, the chief object being to compare the action of various apparatus for practical application of electricity. The examining committee, where not awarding a medal, will give an official certificate as to the results of trial of apparatus to any exhibitor desiring it. Electric street-lighting, and its feasibility in Münich (where gas is very dear), will have special regard. The managers of the Royal Theatre have arranged for trial of various modes of lighting and other applications of electricity in theatres, and a temporary stage will be provided. The waters of the impetuous Isar will be utilised to drive the machines (a company has been formed for this purpose, in case the town authorities do not take the matter up). Among other apparatus to be exhibited will be Gentilli's Glossograph, an automatic quick-writer, based on the physiological laws of speech. A collection of journals and books relating to electricity will be furnished, with facilities for study; and the official catalogue will indicate, with regard to each apparatus, where an account of it may be found.

The annual consumption of dynamite in Saxony is now represented by a value of about £50,000. A project, by Herr Spinner and Dr. Schröder, is now on foot to establish a dynamite factory at Hartha, in the Ullersdorff Forest-district. It is proposed to make it in two divisions, about 443ft. apart; one for the safe operations, the other for the dangerous and for storage. There will be a pond of about 7½ acres between, and the dangerous part will be surrounded by a thick earth wall as high as the enclosed houses. Much objection was taken to the project, but sanction has been obtained from the local authorities on certain conditions. The storage of dynamite must not exceed 25 cwt. in each magazine. Conveyance of the masses within the works must be in spring-furnished waggons on rails. All ways must be kept smooth; stairs are to be avoided; passages are to be covered with peat-ash; the floors in buildings must be of asphalte; and after stoppage of work (which work is to be only by daylight) they must be washed clean. The magazines must be steam-heated, and all freezing of cartridges is carefully to be avoided. For acid gases a condensing-tower and regenerating apparatus is required. The water containing sulphates and nitrates must be fully neutralised with ammonia, and kept from entering the ground. A layer of earth must be formed over the powder-houses.

An important rectification is required, according to M. Guyot, in our ideas about the Shiré river, which has figured largely of late years in accounts of African travel. It has been supposed that the Shiré after entering Lake Lydia, resumes it course southward to the Zambesi. M. Guyot now maintain that the Zambesi really feeds this Lake Lydia through a canal called Zio-Zio, and to a larger extent than the Shiré does. The large lake in question is covered during a great part of the year with aquatic plants, making navigation and discovery of the entrance of the Shiré very difficult. The latter, at its entrance, is about 660ft. wide, shallow and sluggish; whereas the Zio-Zio canal is, in some cases, nearly a mile across, and some fathoms deep.

Measurements of the winter movement of a large glacier in North Greenland (the fjord of Jacobshavn), have been recently made by Herr Hammer, and the summer observations of Herr Helland on the same glacier in 1875 can be compared with them. The velocity is much the same, apparently, in summer and in winter; about 50ft. in twenty-four hours may be taken to represent the rate in the middle of the glacier (where it is greatest).

The company, Schäffe and Walcker, of Berlin, now supply ejectors or mouthpieces for fountains, made according to Böckmann's patent, and requiring, with equal effect, only one-fifth to one-half the water consumption of previous arrangements. The system is adopted in some of the squares in Berlin. The pressure of the issuing water is employed to force up a quantity of the water previously ejected; and at the same time this jet is rendered voluminous, white, and foaming by admixture of air. As shown by figures in the *Deutsche Industrie-Zeitung*, a vertical tapered jet enters, a little distance below the water-level, a piece of cylindrical tube open above and below, and having a number of side apertures at its lower part. This, which projects above the surface, gets filled with water from below. It is surrounded by a tube opening above to the air and fitting closely to the inner tube below; through this the air is sucked down and enters the water of the inner tube by the apertures just referred to. The price of these mouthpieces varies, according to size, from 10s. to £3 5s.

Luminous paint, as hitherto made, has a yellowish-white appearance in daylight. A Dresden firm, Schatte and Co., now produces various paints, pure white, blue, red, green, violet, and grey; so that the objects, which become luminous at night, may have a pleasing appearance by day.

A "burglar alarm platform" is a recent American invention. This is placed level with the floor, in front of a safe or vault, and is so constructed that when it is stepped upon, an electric circuit is closed, and an alarm given at a distant point. The platform is supported on spiral springs, and by day it is prevented from being depressed, when stood upon, by means of a sliding-frame and supporting pins.

Two noteworthy recent events in telegraphy may be here referred to. One is the opening of direct communication between Germany and America by means of a submarine cable between Greetsiel (near Emden), and Valentia on the west coast of Ireland. This, besides accelerating the traffic, has already lowered the cost of telegrams to New York; instead of 1·40 mark, they are now 1·05 mark (say, 1s.) a word. And the new line also benefits the traffic between Germany and England by setting free the Borkum-Lowestoft cable for it. The other event is the opening of telegraph traffic by cable between Trieste on the Austrian Coast, and Corfu, off the Albanian. By this line, forming the first direct connection of the Austrian telegraph lines with the international submarine cable system, a third path is afforded for telegrams to the East, which have hitherto gone *viâ* Italy or Marseilles.

Among processes recently submitted to the French Société d'Encouragement, is one by M. Lutz-Knechtle, a Swiss, for decoration of glass in the cold state. With solutions containing zinc-white or ultramarine, he prepares colours, which he applies to the glass with pads or rollers. Patterns cut from thick paper serve to form reserves by means of which the aspect of cut or ground muslin glass is imparted. By an ingenious method, he easily juxtaposes or superposes two or several colours on the same glasses, increasing the decorative effect. The colours, with silicate of soda base, dry very quickly (in an hour or two), give soft tints and very distinct contours, and resist washing well; and the glasses, so decorated, are much cheaper than those obtained by hydrofluoric acid or mechanical processes. The process can be carried out in glasses in position.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor *of the* English Mechanic, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made Payable to J. Passmore Edwards.

*** *In order to facilitate reference, Correspondents, when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."
—*Montaigne's Essays.*

SEVERAL MORE PUFFS — COMET WELLS—ζ HERCULIS AND δ CYGNI—CENTRE OF GRAVITY OF A REVOLVING SYSTEM—POINTS OF SUNRISE AND SUNSET ON THE LONGEST AND SHORTEST DAYS—IMPRESSION OF A FOSSIL SEA-URCHIN.

[20150.]—If "Paugul" (letter 20089, p. 281), reads the London morning newspapers, he must have noticed that the advertisements of the gentleman to whom he refers are by no means confined to the *Leeds Mercury*. I have been, I confess, most singularly amused, to note in one of your morning contemporaries that, after four or five telegrams enlightening the British people as to what the gentleman in question did (including the returning thanks for a toast to them in their collective capacity), another one came home actually telling us what he *didn't!* This ingenious method of keeping a man's name persistently before the public struck me as particularly fine. The Earl of Aldborough's testimonial to Holloway's pills was nothing to it; and it is enough to make the gentleman who sells the transparent soap die of envy.

"Paugul" (same letter and page) most pertinently invites attention to my omission of the words which he puts in a parenthesis. Of course, I meant to say that the comet would disappear from our night sky before attaining its predicted great brilliancy. As a matter of fact, at six o'clock next Sunday morning (I write this on June 8th) when it will be in, or close to, perihelion, it will only be some 2° 30′ south of the Sun; and at its meridian passage will be nearly 59° above our south horizon.

Mr. Simms (letter 20122, p. 305) is right in his surmise that the distance of the components of ζ Herculis has very slightly increased since 1880; in fact, I fancy that they cannot be now very far from their maximum of separation, which is roughly 1·5″; possibly 1·4″ or 1·45″ would fairly represent it. It happens oddly that the last time I examined this star was with a 3in. telescope, which, *ex necessitate*, wholly failed to divorce it. I am writing far away from my observatory, or I would look at ζ Herculis with my own instrument. With reference to δ Cygni, I may say that two conditions are absolutely necessary for the detection of its companion in a 4in. telescope. The first is the highest power that the objective will bear; and the next is twilight. It is useless to attempt to do anything with this very difficult object with a moderate object-glass after the sky has got dark. I have seen it beautifully immediately after sunset, but have invariably failed to do so two or three hours later.

In reply to "Gimel" (reply 46963, p. 313), every pair of revolving bodies must necessarily perform orbits about their common centre of gravity. In the case of the sun and earth, however (assuming them, for the moment, to exist alone in the universe), the sun weighs as much as 324,000 earths; and hence their common centre of gravity would be removed, comparatively, but a very little way from the sun's centre of figure. When, though, we come to consider the cases of Jupiter and Saturn, whose masses respectively are as great as 1-1046 and 1-3496 of that of the sun, we see that the centres of their orbits must approach nearer to the sun's surface; and, further, if we imagine all the known planets to be ranged in a line on one side of the sun, we should have him describing a very appreciable orbit about the common centre of gravity of himself and his attendant worlds.

I may answer the reiterated query of "Neo" contained in reply 47032 (p. 314) by saying that the Sun rises on the longest day in latitude 52° 25′ N. at a point 40° 43′ 40″ to the North of the East point of the horizon. If my querist employs a compass to determine this point, he must not forget that its needle does not point due north, but at Clun probably some 20° or so to the west of it. Allowance must, of course, be made for this.

And while on the subject, I may answer the cognate query, 47099 (p. 316), by telling "W. B. P." that in latitude 51° 2′ 45″ the Sun rises 39° 16′ 11″ to the North of East (setting as much to the N. of W.) on the longest day, while on the shortest day he rises 39° 16′ 11″ to the South of East, and sets to the South of West by the same quantity.

"W. E. K." (query 47089, p. 315) has found the impression of part of a cidaris (a highly-ornamental form of sea-urchin) in a chalk flint. They are very common. Illustrated descriptions of these organisms, of the fullest and most exhaustive character, will be found in the Volume of the Palæontographical Society for 1862.

A Fellow of the Royal Astronomical Society.

LUNAR PHENOMENA.

[20151.]—I am a recent subscriber to your valuable journal. I have been an amateur astronomer since boyhood—say, for 50 years. When I first read old Ferguson's "Astronomy," the sun's parallax was roughly estimated at about 10″, and distance of the sun (if memory serves) about 82 millions. It has been grand to have watched, through half a century, the growth of our noble science.

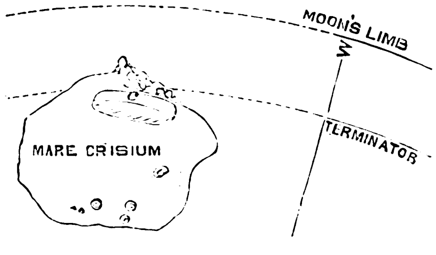
I am almost a worshipper of your old English worthies—your Newtons, Herschels, and others. I read the former's "Principia" when a student, and marvelled at his wonderful insight into the realms of nature. I calculated, in 1837, the Transit of December next, and have a projection of it then made hanging in my office.

Though such a lover of science, my way of life has not led much into practical work in that line, and I never owned a telescope until now; having been engaged during the leisure hours of the past winter in mounting a Calver reflector of moderate power. This much by way of introduction, which you may publish or not, as may seem best. Following is my first contribution to your paper, whose *tone* I like:—

Last evening (May 19th) on observing the moon's slender crescent, about two days old, I was struck with a very peculiar appearance on the westerly side of the Mare Crisium, just on, or immediately within, the dark of the "terminator."

It seemed a curved feathery mist or cloud lying just over the edge of the "Mare," and against the spur or range of mountains bounding the westerly side of the great valley. It seemed to be divided longitudinally by a faint dark line, and looked not unlike a feather. It must have been more than 100 miles long, by 40 or 50 miles wide.

The definition was excellent, and I watched it for nearly an hour, showing it to several friends. In colour and appearance it was so strikingly different from the other illuminated parts, and so different from anything else I have ever seen on the moon, that I scarcely think it possible to be mistaken in its vapoury character. I await with much interest the report of more experienced observers.



The accompanying sketch will give an idea of its whereabouts and appearance.

J. G. Jackson.

Sunset Cottage, Hockessin, Del., U.S.A.,
May 20.

P.S. of May 21.—Last evening I had most excellent definition, but the mist could not be seen, only the faint dark line at C. The question arises. Did the *fog* come from out that long crevice, and have the advancing rays of the lunar morning sun dispelled it?

CLOUD WEST OF MARE CRISIUM.

[20152.]—I hasten to send you the following, coming as it does just after the observations during the eclipse. Jno. G. Jackson, of Hockessin, Del., writes that on the eve of the 19 inst. while observing the moon with a six-inch reflector, he saw, just over the western edge of the Mare Crisium, a peculiar cloud, not less than 100 miles long by 40 or 50 wide, presenting a misty feathery appearance, unmistakably different from other portions of the surface. The cloud was seen by several friends in the observatory. On the following evening the cloud seemed to have been dissipated. He advises astronomers to examine the same spot about two days after the next new moon.

M. Herbert Bridle.

1018, Wood-st., Phila., Pa., May 26.

MERCURY.

[20153.]—Thanks to Mr. Fleming (20068, p. 259). I had a grand naked-eye view of Mercury from 9.30 to 10 o'clock, on the evening of 31st May, setting to the right and a little below Venus. As I could only see him from the front of the house to the street, I did not turn my larger instruments upon him, but my binoculars and a small hand-telescope (1¾) brought him up beautifully. He was, however, very conspicuous to the naked eye, much to my surprise, for, knowing how rarely he is seen, I long ago despaired of ever seeing him. He appeared to me to be about one-third the magnitude of Venus, but much less brilliant, though as conspicuous as any second-magnitude star seen so low. I had a great treat, and wish to record it to encourage others, and to thank Mr. Fleming.

R. W. I.

GRINDING AND POLISHING GLASS SPECULA.

[20154.]—This letter must be the gathering up of the fragments of practical information that could not well be introduced before.

The amateur will do well to finish the lower angle of the triangular hole in the brass chimney, by filing the end for about 1½in. of a piece of steel wire, which is between 1-16in. and ⅛in. in diameter, into a triangular form, with one of its angles slightly smaller than its other two angles; do this with a smooth file, and make the less angle to be sharp; now this will cut the brass, as much as is required, like a very smooth file; but if a little of the finest emery and oil be used with it, a very good angle will be produced in the brass, much better than with the smoothest file. Let the amateur be careful to keep the sides of the hole sloping towards the inside of the chimney, so as to have the sharp edge outside the chimney. I have carefully compared the shadings from a small round hole through a thin sheet of copper suspended before the triangular hole when open to its full extent, with the shadings from the small triangular hole of about the same area, and I can perceive no difference in the indications produced; but I have thought I have noticed this advantage in the triangular hole—that the light goes off more gradually at the last, and thus makes the test more manageable to the amateur. This is produced by the light being shut off along the nearly horizontal angle of the triangular hole, instead of against the nearly perpendicular side of the round hole that the shutter has suddenly to come up to at last. The rivet that is to hold the sheet-brass slide against the triangular hole, had better have a thick head, the head being put inside; then it will stand being rested on a bick iron while being riveted without being injured; this riveting must be so done that the sheet brass will stick anywhere without falling.

If the amateur wants to measure the diameters of any rings on his speculum, he can easily do so by taking a piece of cardboard, in length equal to the diameter of the speculum, and in breadth equal to half the diameter of the speculum; along one of the longer sides he must put notches ⅛in. wide and the same in depth, occurring every inch, beginning with the one in the centre; now, by leaning this cardboard against the speculum, with the notched side across the centre of the speculum, the rings will appear like rainbows on the notched edge, from which the amateur can judge to a ¼in. the diameter of his rings; then he may be able to trace them to his grinding-tool or polisher.

A short-sighted amateur will most likely see—and the more short-sighted he is, the more likely he will be to see, even with his spectacles on—a gauzy or mottled appearance over the face of the speculum, when the light is reduced by the hole being reduced to its proper size for severe testing. This gauzy or mottled appearance will move about as he moves his head; now, all this seems to be caused by the shortness of the focus of the eye, enabling the inequalities on the surface of the cornea of the eye to be perceived. The remedy is for the short-sighted amateur to constantly move his head from side to side about 1-16in. or ⅛in. while testing, when the gauzy or mottled appearance will disappear, being made into an average distribution of these inequalities, through which the shading on the speculum will be perfectly seen. To accustom the amateur to be on the look-out for these sources of mistakes and blame his speculum instead of his eye, let him, when testing, with the hole as small as possible, so as to give enough light to see the shadings by, partly close his eye till the upper or lower eyelid just covers half the speculum. Now let him suddenly open his eye wide, and he will see left on the speculum a dark line, marking where his eyelid has left a ridge or wave of tear, through which he has to a certain extent to see his speculum; if he keeps his eyelids open, he will see this wave fall by its own weight over the cornea, and gradually subside at the same time.

The amateur may perhaps some time see suddenly shoot across the face of the speculum shadings that look like flexure of an irregular character, and he will begin to blame himself for omitting some precaution, and thus getting his speculum bent; he perhaps will think to examine the edge of his shutter in the daylight with his unaided eye, but he sees nothing to account for his trouble there; but let him examine the edge again with care and a ¼in. lens, and he will probably discover that some floating fibres or bits of dust have attached themselves to the edge of the shutter, and thus have been the cause of his trouble. This will show him the importance of having the edge of his shutter smooth and clean. I occasionally rub a piece of the finest emery cloth on each side of the edge of the shutter at an angle of about 45°, then I rub my finger along the edge to clear off any bits of dust. In fact, I often pass my clean finger along the edge of the shutter to be sure that there is no dust there when I begin to test.

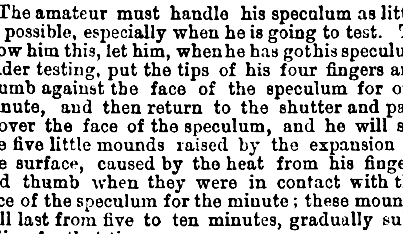
Of course, I take it for granted that the amateur knows that all his testings must be done in a dark room, and that no second person is walking about at the same time, who would be sure to cause currents of air by his movements, and if the air in all parts of the room be not perfectly of the same temperature, which is most unlikely to be the case, then these currents will be seen, and interfere with the shadings: in fact, they will produce shadings of their own in a most fantastic and tantalising way. Further, it is impossible to test satisfactorily on a boarded floor—it has so much spring in it, and every movement is seen when testing. This is specially detrimental when measuring the difference of the zonal foci. I find the solid cellar-floor the best.

The amateur must handle his speculum as little as possible, especially when he is going to test. To show him this, let him, when he has got his speculum under testing, put the tips of his four fingers and thumb against the face of the speculum for one minute, and then return to the shutter and pass it over the face of the speculum, and he will see the five little mounds raised by the expansion of the surface, caused by the heat from his fingers and thumb when they were in contact with the face of the speculum for the minute; these mounds will last from five to ten minutes, gradually subsiding for that time.

I will now give a practical illustration of the application of the zonal test to the testing of a speculum. I shall do this upon a speculum lent to me by a friend for testing, and with his permission. The speculum was made by a London maker over twenty years ago, and I give it the more readily as showing that there has been great progress made since then, for I believe that neither Mr. With nor Mr. Calver, nor any first-rate maker in London now, would turn out such a speculum; the fact being they have greatly improved methods of working now compared with twenty or thirty years ago, and I further introduce this speculum to show all who have to buy that they cannot be sure of getting a really good speculum unless they go to makers whose reputation is thoroughly established. I may further observe that I am not aware that the maker of the speculum I am about to remark upon is now in business. I believe he is not; I knew him personally over twenty years ago as in business, and my object is not to injure anyone now in business. I would rather help them if I could; at the same time I would urge all, both professional and amateur makers, to a greater degree of perfection.

Fig. 1 gives to the eye an ideal representation of the figure of the speculum, which is 6in. diameter. I divided it into ½in. zones, which are marked by dotted lines and numbered. Now the figure of the speculum I at once drew when I put it under testings, and before I took the foci of its zones, its figure was so manifest. The lengths of its zone foci are as follow:—

FIG 1.



1.	2.	3.	4.	5.
·063	·042	·025	·013	·0047
·16	·042	– ·04	– ·04	·01

The upper line is the zones, the second line the true parabolic aberration; the third line the actual aberration of the speculum. Now, it will be observed first, that the edge turns down fearfully, so much so, as to make it completely useless. I had, therefore, to set the index to start with the next zone, No. 2; I then measured the outside zone as best I could, taking its average length, and found it to be ·16, in other words, it was between two and three times longer than No. 2 than it ought to have been; this would make it impossible to attempt to get good definition by uniting the two outer zones; then again, the turn down towards the edge of this No. 1 zone was so rapid that the edge would have been much more out than ·16: this being the focus of the centre of this zone, there being a visible difference without measuring between the focus of the centre of this zone and the focus of its edge. This ought not to be in any zone; the shadings ought to come on evenly as far as we can see over each edge (outer and inner) and the centre of each zone; in fact, we ought to divide our speculum into such a number of zones that we can see no difference between the two edges; if we can, then our zones are too wide or the speculum is fearfully bad. Now, if we divide our speculum, whatever its diameter, into six zones (including the centre), we shall be right as to width of zones. No. 3 zone was – ·04; i.e., it was 4-100in. shorter than ·0; we must, therefore add this to ·025 to give its real departure from the true length of a corresponding zone of a parabola; in other words, it was over 6-100in. too short. It would be impossible to get good definition by attempting to combine it with No. 2 zone, much less with No. 1 zone. No. 4 zone was the same as No. 3 zone, so that it was part of the same spherical surface; these two acting together would have produced better definition than zones 1 and 2 or 2 and 3 together. No. 5 zone was slightly too long for the starting zone No. 2, being ·01 instead of ·0047. Now, these two would have worked best together, being nearest to the two corresponding zones of a parabola; but this No. 5 zone would not have worked well with No. 4, nor with No. 3, for here the proportion was reversed to what it ought to be, No. 4 and 3 being considerably shorter than No. 5, instead of slightly longer. From all this it will be seen that no three zones of this speculum could have been advantageously combined in actual observation; only two sets of two zones each could be formed, and these two sets could not be well used together, while the outside zone was utterly useless with any other zone. It will be observed that there is a fearful depression at the crosses; this is the pecking in I always get when I use a tool or polisher not cut away at the edge, and is caused by the outside of the tool or polisher not wearing away fast enough; it therefore wears away the speculum as far as it reaches inwards at the end of each stroke, and there the depression ends. Now, the centre of the speculum not having the advantage of the wear of the raised edge of the tool or polisher, is left above the general level as a mound, as seen in the figure, not that it is actually a mound, but it is not so short a focus as the rest of the surface, and appears, therefore, in comparison with the outside of the speculum to be raised, for as the spherical surface appears under testing at the centre of curvature as a plane, any departure from the sphere appears to be raised or depressed from this apparent plane, according as it is shorter or longer in focus, although every part of the speculum is concave as compared with an actual plane. The Foucault's testing, without the measuring, only shows any departure from the sphere, but it does not tell how much, the sphere being the only figure it can detect with certainty without measuring when used at the centre of curvature. The tool and polisher would always be concave as compared with the speculum —i.e., it would touch the speculum at the edge if rubbed on it; this concavity would go to produce the turning down of the edge of the speculum as seen in the figure; because the stroke, which would be from the edges to the crosses, being large in this case, about ⅓ the diameter would make the tool and polisher very concave as compared with the speculum, especially if the tool were top; consequently it would wear much on the edge of the speculum, and turn this edge down, all the more if the polisher were soft, such as cloth (and this I suspect was the case in this instance from other indications); but if the stroke had been ¼ or ⅓, then the turning down of the edge would have been almost counteracted by the general wear, and the depression would have been direct from the edge to the crosses (which mark the end of the stroke), which would, in this case, be the ⅙ to 1-6 the diameter from the edge; thus the figure which Mr. Calver says is most likely to be produced by amateurs would be formed. From all this it can be easily seen how difficult it is to produce a true spherical surface by grinding two tools together, just as Mr. Calver says in his "Hints," page 9 (1877). "It is generally supposed that the spherical curve is a very easy matter, so easy, indeed, that it is difficult to avoid. This is a great mistake—a spherical curve of undeviating truth is as difficult a problem as the true parabola. . . . The curve most liable to be obtained by the amateur is the spheroidal, a curve with its marginal rays shorter than the central, or half the radius of curvature." All this I can corroborate from my own past experience, and from amateur work I have examined. How difficult it is to get the speculum good up to the edge, and to avoid the turning down, is witnessed by Mr. Thornthwaite, F.R.A.S. In his "Hints," p. 82 (1880), he says: "As a rule specula are worked in discs of the required size, and therefore the extreme edge is often slightly defective. This is the reason why there are 6½, 8½, 10½, and 12½in. mirrors, it being supposed that the marginal ¼in. shall be covered with a stop." From this latter quotation it would appear that even professional opticians cannot always secure their specula good at the edge. The fact is the whole working of specula wants taking out of the region of haphazard production, where a good speculum is a happy accident, into the clear region of a perfect understanding of all the laws that govern the various processes. This is the region I am trying to find, and I am sure I have got nearer to it than I used to be.

In answer to "Prismatique's" letter (20110, p. 285), I would call the attention of all to the fact that he has most consistently kept to what he set out with—viz., the giving of the trade mode of working specula; that, if there be anything to be gleaned by the amateur from it, he might have the advantage of it. This is noble. I have, I hope, as consistently kept to what I set out with—viz., the giving of the amateur mode of working specula: thus any difference is only incidental to the different circumstances of the two modes; for instance, I hope to tell the amateur how he can make his specula without going to the trouble and labour of making and grinding two iron tools to a perfect fit—and this is a fearful job to the amateur (I know what it is); but my way would not be the best way for the trade, simply because the trade wants tools that will last a lifetime, and produce hundreds of specula from each tool; the amateur, only wants tools that will last for a short time, and at most do only a few specula, perhaps only one for each size. The fact here is, as in many other things, "circumstances alter cases"; thus each of us is right in his own sphere. I am very thankful to "Prismatique," for I have learned from him what I hope to use up for the amateur's benefit, and which I shall not be slow to acknowledge in its proper place. As to the quotation from Sir John Herschel, I may observe that he did not understand fully the Foucault's test—this he acknowledges; and then the measuring accurately of the zonal foci was not definitely adopted or brought to its present perfection. The fact is, we have advanced since Herschel's time, I believe very much in the last twenty years. We can now measure the figures of our specula, and whether they are regular; thus, what was true in Herschel's day, has ceased to be true now, on account of the advance we are making.

Mr. Calver has kindly offered to lend me a large aperture and short focus speculum, which is the very thing required to test the rule by, and I have received an 8in. With specula for testing, and am promised, through the kindness of our correspondent, Mr. Vallance, four others, two Withs and two Calvers. I hope by carefully taking the zonal foci of all these, and reducing these zonal foci to one size by calculation, and taking the average for each zone, to get at the true rule, at least very near, for I believe that these two makers produce, from their long experience, some of the best specula—*i.e.*, having their zones' foci for parallel rays brought to one point. The results I hope to give in my next letter. If I cannot get them ready by that time, I will commence with the machine. **H. A. Wassell.**

Addenbrook Villa, Love-lane, Stourbridge.

MR. WASSELL'S SPECULUM TESTING.

[20155.]—We who know something about working specula are all obliged to Mr. Wassell for the trouble he is taking in elucidating the mysteries of that art, especially the testing. I appreciate his difficulty—viz., to convey to a tyro what he himself thoroughly understands, and in testing by "Foucault," that is the difficulty. It is not the form of the shadings of the mirror, but it is the relative intensity of the various shadings. Now, that unfortunately cannot be delineated by engraving or described in writing, so that a novice will comprehend it properly; no, not after twelve months' constant practice, unless he has had someone by his side to guide him.

As to the amount of aberration, that can be arrived at mathematically. Mr. Wassell's proportion of twice the focal length is about the mark. Draper says eight times focal length; that is too much, and means under-correction:—

$$\frac{\frac{1}{2}\text{ diam. mirror squared}}{8\text{ focal length in inches.}}$$

There is one point in which I differ with Mr. Wassell—that is, using stops with Foucault test at centre of curvature. I tried it some years ago with the screen worked by a micrometer screw, and now abandon it as unreliable. When I use stops it is with the eyepiece and the image out of focus, when you see exactly which zone is in the wrong place. Suppose the eyepiece forward, giving a uniform disc but a bright centre, and suppose, without moving eyepiece, you stop off the margin inch, you then find the centre uniform. It shows your margin to be too short, and the bright centre was not due to centre of mirror at all, as you would naturally suppose. The same way you can find the exact zone that gives a ring either bright or dark. This I consider the only practical way to use stops in testing; to use them with Foucault I believe to be practically impossible, though theoretically you should be able to do so.

I use the Foucault test with the full aperture of the mirror, and from long practice can tell the figure better that way than any other, combined with the eyepiece test. I measure the aberration with the screen by taking the extreme points of confusion, and halving the difference, which should equal my calculated extreme distance between the inner and outer ray—that is, move the screen to and from the mirror, and mark those two points where the shading comes half-way on from each side. You then embrace between these points a length of the optic axis which includes all the errors, or, in the case of a perfect mirror, all the aberrations. In a 6½ mirror, 6ft. focus, this distance should not exceed ¼in., equal to ⅛th of an inch for the required quantity. This is a palpable, easy, measurable quantity, and the Foucault test will show you if the intermediate zones are lying properly.

I shall be glad to learn the result of Mr. Wassell's examination of the several mirrors he has received, but exquisitely figured mirrors will belong to those who have had a long experience and thereby acquired the art, independent of any mathematical formula.

The lamp I now use is a small sixpenny paraffin night-light, with a small round wick, and a flame considerably less than a wax match, a brass chimney 2in. long, and ⅝in. diam., a hole bored through the brass and covered with thin platinum foil, which is punctured by a fine needle, the hole being less than 1-200in. You can put your eye close to it with comfort. I first saw Dr. Blacklock use it, and it is amply sufficient.

Another point I have arrived at in my own experience is that with a parabolic mirror at centre of curvature you get perfect definition at one point in the optic axis, very similar to a spherical mirror, but within and without that point the two mirrors show a wide difference. To demonstrate the fact will take too much room, and I have already trespassed too much on the Editor's space. An artificial star, with jagged edges and particles of dust adhering thereto, is very useful for that purpose.

John S. B. Bell, C.E.

TESTING MIRRORS—STAR SKETCHES.

[10156.]—The papers on testing specula by Mr. Wassell have been read with considerable interest on this side the water, as I know from numerous letters I have received. Mr. Wassell is writing to clear up the mysteries of the subject for the benefit of the amateur, and deserves much credit for his painstaking and elaborate descriptions; and his writings are not so ambiguous as professionals frequently give us, for which he deserves all the more credit. The method of using the Foucault test, as described by Mr. Wassell, is substantially that given by your humble servant in No. 772, Vol. XXX., letter 16706, in which letter I noted the one difficulty to contend with,—namely, the bright diffraction rings at the edges of the diaphragms, which eventually led me to abandon the diaphragms altogether. The proper way, I would kindly suggest, is to get the proper and exact focus of the central zone and the outer zone, then if the amount of longitudinal aberration is correct, and the curve is regular from centre to edge, no diaphragms need be used. This has been already suggested by "Orderic Vital," and I much prefer it, though the lessons of Mr. Wassell are excellent schooling for the beginner. Like Mr. Wassell, I abandoned long ago the eyepiece test for measuring the aberration, as the eye will accommodate itself to small quantities; and if I would measure the aberration once, then move the eyepiece some distance, so as to remove all *bias*, and try it again, very frequently I found serious errors, that caused me to rely wholly on the screen test, as the eye never fails to see the focus of a zone when it has a little practical experience. As to the proper amount of aberration, I inclose a letter to "Orderic Vital," which, I hope, our Editor will forward to him, as I do not know his personal address. The letter was written me by Dr. Hastings, and as he sends a graphic description, I shall give "O. V." full liberty to publish it if he thinks best. The letter, I trust, will be of value and practical use to your readers. I have induced my friend Du Pont to write you a description of his method of printing, by the blue print process, stars, clusters, nebulæ, comets, &c. He has sent me some of the most exquisite sketches, and they look so much like looking right into the field of the eyepiece of a good telescope on an exquisite sky, that they come the nearest to Nature's pictures of any I have ever seen. Thanking "Orderic Vital" and others for the kind words spoken of my humble letters, I remain, yours truly, **J. A. Brashear.**

Pittsburg, Pa., May 27.

THE MOTION OF SIRIUS IN SPACE—ASTRONOMICAL EYEPIECES—"A GLIMPSE THROUGH THE CORRIDORS OF TIME."

[20157.]—Will "F.R.A.S." kindly say whether the motion of Sirius, announced in the *Monthly Notices* for March, and mentioned by himself on page 150 (letter 19935), has any connection with the revolution of that star round its companion, or, rather, round their common centre of gravity? I imagine that this is a revolution round some more distant centre.

Had I known before that "Aldebaran" is a paradoxer, I should not have attempted to prove anything, but have contented myself with contradiction. We are gradually learning the full extent of his curious ideas on the subject of theoretical optics; but my guess, in a previous letter, that he had been puzzled by the involved appearance of textbook diagrams, proves very near the mark. "Aldebaran" says (letter 20125, page 305) "All rays cross in the o.g." Cross what? They certainly do not cross each other. "Aldebaran" calls a place where rays of different series cross an "apex" of a cone of rays; that is, he would call the place E or F in "Orderic Vital's" diagram (letter 20126, p. 305) an apex, or apices, perhaps, neither of which it really is. He also speaks of blunt apices, and in using the word apex to signify several different kinds of things, he is defying the dictionaries, defying usage, and defying the science of optics. "Aldebaran" has confused the rays belonging to different series, whereas each series should be considered quite separately. I wish "Aldebaran" were here: I could soon show him, by the help of lenses, how the rays go. His assumptions of my complete want of practical knowledge, and of the uselessness of theory are incorrect, and the latter nonsense. My ignorance of practical optics exists only in "Aldebaran's" imagination.

"Interest" (query 47102, p. 316) should substitute "increasing" for "diminishing," in line nine of his query. If there is any tide—any friction—the day must lengthen, whatever the amount of the friction, and whether it is increasing or diminishing. **Paugul.**

ON THE ACTION OF EYEPIECES.

[20158.]—The criticism of "Orderic Vital" is written in a true Darwinian spirit, which we should all do well to accept as a model. Adverse criticism, though often a very salutary medicine, is one over which the best of us are apt to make a wry face. Your correspondent has, however, so considerately gilded the pill, that all its bitterness is gone. Of course, from his position he could well afford to be generous, but I appreciate it none the less, and hope he will accept my thanks. The aim of all controversy should be to arrive at the truth, and I am sure that any disputant who candidly admitted his error would not suffer in the opinion of our readers; but to this end each should endeavour to make it easy for the other to retract, and so far imitate the strategy of actual warfare as to keep all bridges in the rear in good repair.

The phrase "cone of direct rays from the object-glass" (letter 20069) certainly seems calculated to mislead, though I hope my subsequent letter has better explained my meaning. The idea I wished to convey was that the cone was useless, or nearly so, after the image had been projected, and that a perception of the image was due to other rays, none of which were delineated in textbook diagrams. This conclusion was arrived at by reasoning *a posteriori*, therefore, "Orderic Vital" is quite correct in his surmise that the confusion has arisen through a different interpretation of the meaning of the term *parallelism of rays incident to the eye.* And indeed, the whole gist of the question centres in this, for if it can be shown that the retina is insensible to rays that are vergent to its axis, the inutility of this cone will have been demonstrated.

That your correspondent is correct in his statements bearing on refraction goes without saying; but as regards the structure of the eye, I hope he will excuse me for saying I think he has taken too much for granted. For, though he has spoken of the eye as an image-producer, he seems to have overlooked the fact that, in this respect, its action is precisely similar to that of a convex lens, and I am sure he would be the last to allow that rays, "parallel among themselves," but falling on a lens at different angles to its axis, would all be refracted to the same point behind it.

The eye being movable, can accommodate its axis to all the angles of entering rays, and in this respect it closely resembles a mounted telescope, the field of which, like the image formed behind the eye, is composed only of rays that have entered the object-glass parallel to its axis. Other rays there no doubt are that enter, but these are converged to a shorter focus, and are thus lost to vision. To render my meaning clear we will take as an example a disc of this page, say about 4in. in diameter and at a distance of 10in. from the eye. If the attention be concentrated on the middle line of this disc, its axis will be parallel to the line of rays that pass between it and the eye, and the object will form myriads of images which will become coincident, and therefore distinct, at its principal focus, or in other words, on the retina. Whereas the rays travelling from any part of the circumference of this disc, though they will in like manner be super-imposed will be so before the retina is reached, and will have again separated and become blurred at the only point where they can be appreciated.

Perhaps, however, a more interesting experiment would be to place the eye in the position of A in my diagrams, Figs. 1 and 2, on page 259. The necessary conditions being a dark room and a fairly distant lamp or gas-flame for the object. Under these circumstances a bystander will see a very brilliant and erect image of the flame on the eye of the observer, while the observer himself sees only the inverted image. The rays that form the image on the outside of the pupil are, of course, divergent, and thus reach the retina before they are focussed, while the rays appreciated by the eye are parallel, as may be proved by the fact that the size of the image remains the same at any reasonable distance from the eye-lens. This experiment may be varied by substituting a concave or a terrestrial eyepiece, when the image will appear erect to the observer and inverted to the bystander. I could relate other experiments bearing on the same issue; but I think I shall have trespassed quite far enough on the forbearance of "Orderic Vital" if I ask him to explain these phenomena consonant to the generally-received theory of the parallelism of the rays incident to the eye.

Aldebaran.

NEW COMBINATION OF ALTAZIMUTH AND EQUATORIAL MOUNTING.

[20159.]—If Mr. Grubb so described the instruments figured on page 307, he has made a mistake which an optician should avoid. The principle is that known as "Smeaton's Block," shown in Plate XIII., Fig. 5, and in Plate XXIX., Fig. 6, in Rees's "Cyclopedia," Plates, Vol. 1; but Mr. Grubb's adaptation is far inferior to Smeaton's. There is a long and accurate description of this stand in the same "Cyclopedia" at the end of the article "Equatoreal." I have often wondered why amateurs of limited means have not adopted it; it is symmetrical, and should be very steady—two essential points which are notably wanting in Mr. Grubb's instrument. If you wish it, I shall be happy to send you a rough sketch for the benefit of those of our readers who may not have access to that "Cyclopedia."

N. S. Godfrey, F.R.A.S.

St. Bartholomew Vicarage, Southsea, 10th June.

MEDICAL REPLIES.

[20160.]—47088, 47097, 47118, are all cases not eligible for reply in English Mechanic. Read previous remarks as to such eligibility.

Optical Illusion (47092).—The halos described are probably diffraction halos, due to senile changes in the lens, or other optical media of the eye. See that the refraction of the eyes is accurately corrected by means of spectacles. If this does not suffice, have eyes carefully examined and reported upon by means of the ophthalmoscope. But new eyes cannot be put into old people.

Polypus in the Nose (47101.)—I do not understand what querist means by having his polypus "cut every few months," and if he is being quacked he should consult a good doctor, or go to a hospital if he cannot afford this. Polypus of the nose is often removed by being twitched off by means of a slender pair of forceps passed into the nostril to seize it by its base. But it often comes again; as a wart on the skin, if twitched off, would grow again. These polypi are soft excrescences from the mucous membrane of the nose, which increase and block up one or both the nostrils. Sometimes constitutional treatment removes them, as it does a certain kind of soft warty growth (condylomata) upon the skin, and this is a point that ought always to be considered before submitting to their mechanical avulsion. Sometimes the use of some sort of snuff, such as those named, is useful. Tannin, as snuff, I have frequently found useful. Gallic acid was effectual, but acting similarly. Zinc oxide again is useful, and perfectly innocuous and painless. Any one of these may safely be used by querist. The best way to apply such a powder efficiently is to blow it into the nostril out of a piece of indiarubber tube. The first named remedy is impracticable and dangerous, unless one understands clearly what "Dutch drops" is, and unless the polypus is so within sight that it can be touched and corroded away without corroding the contiguous parts of the nose. I daresay the last named remedy might safely be used, but I should not use it myself, and I have no knowledge of its effects. All the good that can be got will be—1st, by constitutional medication. 2nd, by mechanical avulsion. 3rd, by astringent or corrosive applications. Locally, I should limit operations to simple astringents, such as tannin or oxide of zinc, with the alternative of mechanical avulsion. Sometimes a snare of fine steel or brass wire may be used to tear off the polypus, and by that means I have often operated very easily and efficiently, and with a minimum of inconvenience or risk to the patient. This latter is the only form of mechanical avulsion which a patient or his friends should attempt, and I do not recommend that, if the patient be anywhere within reach of a skilled doctor. The constitutional treatment would be too large and complex a subject for me to enter upon here.

HÆMORRHOIDS (47132).—Piles are varicose veins of the lining membrane of the rectum. Sometimes, when the liver gets obstructed, they will swell and worsen. If cold be then taken, they will inflame, gather, and break, leading perhaps to fistula—perhaps to more or less plugging and obliteration of their venous channels, and then they remain as more or less painful grape-like growths around the end of the bowel. The treatment of this common and very painful affection is as follows:—1. Preventive and palliative. Live sparingly if corpulent or gouty, and avoid getting the liver gorged (read remarks on corpulence). Cleanse the end of the bowel carefully with a soft sponge and cold water *always* after emptying the bowel, and then press the perfectly-cleansed protruding mass carefully and persistently back until it is comfortably retained and supported by the sphincter muscle which closes the end of the bowel. Inject half a pint of cold water into the bowel every morning on waking, and then, on coming downstairs, one comfortable evacuation should take place, and be followed by the sponging process. *This treatment will often cure.* If the protrusion be very soft and tender, and oozing with blood, dab it (after sponging, but before returning it into the bowel) with an astringent lotion, consisting of ½oz. of white copperas (zinc sulphate), rubbed up with a drachm of spirit of camphor, and dissolved in a quart of water. Should the bowels become contiued, and the fæces hard, mechanical injury will be inflicted upon the tender parts, and large bleeding or inflammation will supervene. A teaspoonful of pure precipitated sulphur in milk at bedtime is the best laxative to assist the action of the cold-water morning injection. If the piles become inflamed, lay up and poultice till the inflammation subsides or the gatherings discharge, and then go back to the treatment. If much bleeding occur, purge freely with salts and senna and ginger, until the liver and other viscera are unloaded, then the bleeding will cease. After thus unloading the viscera, 30 drops of oil of turpentine on sugar, or in milk, may be taken thrice a day, if necessary, until the bleeding stops completely. 2. Radical or curative. If the piles have become large and painful, producing a sort of prolapse of the bowel, they must be removed by the ligature or other suitable operation, which, if properly done, is very safe, not seriously painful, and certain to relieve if suitable cases only are operated upon.

James Edmunds, M.D.

Grafton-street, Bond-street.

LEGAL REPLIES.

[20161.]—INHABITED HOUSE DUTY (47091).—The shop being occupied is liable to pay inhabited house duty at the reduced rate of sixpence in the pound. It is also liable to be assessed for the relief of the poor, and rated in the usual way; while, with regard to income-tax, that is of course payable upon the value of the property.

(47096.)—Where a wife goes away from her husband of her own accord, and not through any fault of his, he cannot be made liable for her support, unless indeed she came upon the parish, when other questions would arise. I do not know what proceedings can be taken against the husband in such a case, except by the parochial authorities. It is the wife's duty to return to her husband, and if she does not do so, he cannot be compelled to pay for her maintenance. As to the other part of the question, a wife has no right to take away her husband's property, though she may have a claim to what he has given her absolutely.

(47127.)—The best thing "Epsilon" can do in this case is to send in a written demand claiming the return of his models, or the payment of a sum such as he thinks they are worth. If they are not returned within the time stated, or the money paid, he can sue for the recovery of the same or their value in the proper county court.

Fred. Wetherfield, Solicitor.

2, Gresham Buildings, Guildhall.

ATMOSPHERIC AIR REQUIRED FOR COMBUSTION OF COAL — PEARL-ASHES—ALKALIMETRY—CHLORATE OF LIME—TO MR. ALLEN—COLOURS FOR CONFECTIONERY.

[20162.]—"ATMOSPHERIC AIR" can readily ascertain the quantity of atmospheric air requisite for the "combustion of coal" (query 47094, page 316) by employing the following data:—3lb. of carbon require 8 of oxygen to form CO_2; hence 88·42lb. require 235·79lb. of oxygen. 1lb. of hydrogen requires 8 of oxygen to form H_2O; hence 5·61lb. require 44·88lb. of O. So the carbon and hydrogen of 100lb. of the coal together require 280·67lb. of oxygen. Of this amount 5·97lb. is present in the coal itself; hence 274·70lb. will have to be provided. But this is the amount required for 100lb.; the amount for a ton will be 22·4 times as great, or, in other words, 6,153·28lb. Air contains 23 per cent. by weight of oxygen; hence the weight of air required for the complete combustion of 1 ton of the coal will be 26,754lb. In practice, it may be taken that coal requires twelve times its weight of air for complete combustion; but if burnt in a furnace which relies on a stack for the production of the draught, twice this amount of air requires to be employed.

"Pearl-ashes" (query 46953, page 249) may be assayed for their contents of carbonate of potash by titration with standard acid in the manner described in any work on chemistry. If litmus be used to indicate the point of neutrality, excess of acid should be added, the liquid boiled to expel carbonic acid, and the excess of acid employed ascertained by titrating back to the neutral point with standard caustic soda. By employing Poierier's methyl-aniline orange instead of litmus, the end of the reaction can be ascertained directly, in the cold, and without expelling the carbonic acid. The change of colour is extremely definite.

"Chlorate of Lime" (query 47058, page 293) is produced, together with chloride of calcium, by passing chlorine into hot milk of lime. The separation of the resultant chlorate of chloride is very difficult, and I am not aware that it can be perfectly effected on an industrial scale. Great advances in this direction have been recently made in France, whereby a very large proportion of the chloride of calcium has been removed. I should recommend the querist to try the addition of an equivalent amount of calcium chloride to commercial sodium chlorate, and then boiling down the liquid and allowing the sodium chloride to "salt out." Ultimately there should remain nearly pure calcium chlorate. Another plan would be to dissolve lime or marble in chloric acid obtained by decomposing potassium chlorate by hydrofluosilicic acid. What good the calcium chlorate will be, when he has it, the querist alone knows.

In answer to query No. 47070, page 293, headed, "To Mr. Allen," I don't think I should recommend any aniline colours to be added to confectionery. Arsenic is far too common an impurity in coal-tar products to render their indiscriminate use desirable. There are vegetable colouring matters which ought to answer every purpose.

Alfred H. Allen.

Sheffield, June 10th.

FORECAST OF STORMS.

[20163.]—LOOK in the *Almanac* and read this—Full Moon, July 1st, 6·8 morn; next look in Dr. Herschell's Weather Table, and it reads—"If the moon change between 6 and 8 a.m. in summer, expect wind and rain." The next and most important thing is that every one interested in meteorology (which, by the way, has not obtained the dignity of a science) should keep a daily register of barometrical pressure. He who does that may then connect his twelve months' sheets in one continuous band, reading from left to right: it will then be at once apparent that a periodical decrease of atmospheric pressure takes place over our islands. Next, it will be noticed that displacement occurs, followed by compensation. Thus we get small depressions in June, culminating, in all probability, in wind and rain about the time of Full Moon, at the latter end of June, or beginning of July.

In a similar way we may note wind and rain about five days after New Moon in July. The periods then follow: August 9th, moon about quadrature, so that the storm period may be accelerated two or three days, August 29th to September 4th; September 20th, moon about quadrature. In this way we get two periods in one month and one the next month. In closing, let me say that I am a poor man, and therefore, I made my own barometer, and have kept a daily register of atmospheric pressure since September, 1880, and this method of mine is founded upon observation and comparison of data, gathered within the period above named.

W. M. Gardner.

P.S.—I can give a short description of a very sensitive water barometer, having a range of eight inches rise and fall if it is desired.

ORNAMENTAL LATHE THREADS.

[20164.]—To help amateurs who have the ornamental slide-rests with a screw of ten threads to the inch, to cut their own screws for repairs, &c., I have given the setting of wheels: they are all within the set sold by Messrs. Lloyd and Co., for 12s. 6d.

	Wanted.	M.		S.	Cuts.
1	6·58	60	35		
			40	45	6·56
2	8·25	50	30

I think lathe-makers might make a great improvement in slide-rests and chucks by putting left-handed screws in places where the screw works in a nut that moves the part; but where the collar moves the part, the nut being stationary, the right-hand screw is proper. This is the rule of the best Lancashire makers, and saves a lot of mistakes in turning the screw the wrong way.

And in chucks they might follow the American practice, with great advantage to clients living a distance away from the workshop; as it is, in case a new chuck is wanted, the lathe itself has to be sent to make the new chuck upon, so that it will run true; whereas the chuck might be built in the workshop on any lathe with a small face-plate. A casting of the face-plate could be supplied with the chuck, which the amateur could fit to the lathe, and turn up for the chuck to fit on, without the inconvenience of being without the lathe a time, long or short, as may be required in the making of the chuck.

I think there would be more work for the makers if they would do so, as the objection is so great, that few would care to pack and send the lathe after it becomes an indispensable tool.

Will some one of your contributors kindly describe a transfer chuck? Not having seen one, I am at a loss to know how they are made; but I fancy that others would like to know as well as

W. W. S.

PHOTOGRAPHIC.

[20165.]—AT this season, many readers of the "E. M." are going into the country or off to the seaside to spend their holidays; and many, if not most, of these enlightened health and pleasure seekers will take with them a pocket or satchel photographic instrument. The ease, cleanliness, and certainty, with which negatives may now be taken, are indeed a strong incentive why we should bring home transcripts of places and friends, and it is like going over the scenes again—doubling our pleasures—to examine our photo transcripts in the calm and quiet of home.

Instantaneous views, expressing all the activity of life and motion, are just as easily taken, with suitable instruments, as any other, and generally have more interest and charm to attract our attention.

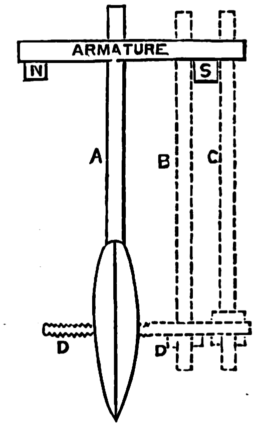
To take instantaneous pictures well, it is of the first importance to have a well-made, rigid, substantial apparatus. With many of the light, flimsy, pocket cameras, so cheaply got up, and which, with scarce an exception, are marvels of cheapness, excellent results are often obtained of landscape or architectural subjects, or studies of still life: but failure is almost the certainty when, with such apparatus, we try to work instantaneously, for they have no rigidity or sufficient weight to resist the action and reaction and shock of the spring or shutter, whichever it may be, which opens and closes the lens.

Whatever camera the tourist may select for ordinary pictures, I would advise him, if he desires instantaneous results, to get a substantial well-made instrument, which shall not be affected by the tremor, shock, or vibration of its moving parts. This is the secret of success.

E. B. Fennessy.

NEW E. MAGNETIC CLOCK—E.M. MOTORS.

[20166.]—Mr. Floyd (20101) says that my compensated pendulum (20077) is an abortion. Now, look at the figure herewith, and imagine the



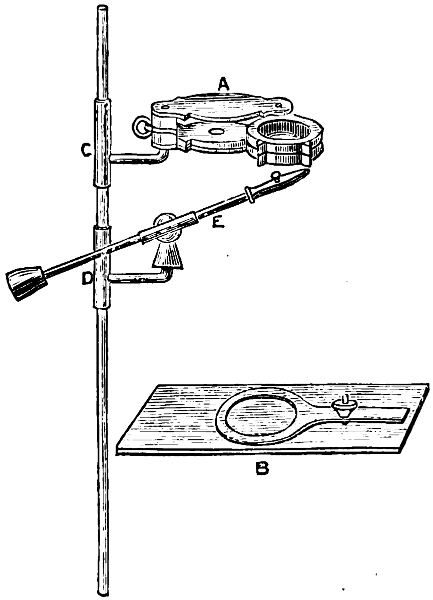
ordinary pendulum-rod A removed, and replaced by the rods, as dotted lines, B, C, D. What difference would it make to the working and vibration of the bob, except compensating? Why *must* the bob be in the *same plane* as the rod or rods? What is there abhorrent in an alteration to effect an improvement? I defy Mr. Floyd to give a valid reason. He does not say the works of a clock are an abortion because all the wheels are not in the *same plane*, or that the human leg is an abortion because it does not rest on the *middle* of the foot. I might go on;—but enough, and I conclude by observing that his other *assertions* are about equally valid.

With respect to the electro-motor (19997), I must inform Mr. Kanthack (20100) that the word "enormous" is Mr. Ponton's, not mine, although I still hold that the power is great—that is comparatively, taking into account the space in which it occurs. As to lengthening and shortening: authorities give some one and some the other; and as to the amount, I have seen it stated somewhere as between one and ten-thousandth part of length. I am also not responsible for the statement about rapidity, as I find an authority says, "If the pulsations of the current be produced at the rate of 1,000 per second, the alternate absence and presence of the magnetic virtue in the horseshoe will equally be produced at the rate of 1,000 per second." I look upon the magnet as the seat of power merely in a comparative sense, as acted upon by the current. The variation of length in a bar used as a makeweight, as proposed by Mr. Ponton, would not be one per cent. of the power used as I propose, whatever that may be.

Barry-road, S.E. **J. H. Huxley.**

THE MICROSCOPIST'S COMPANION.

[20167.]—Inclosed I send sketch of a small apparatus I rigged up from a friend's invention, and



which generally accompanies me on my microscopical rambles. B is one of Forrest's compressors, made by Mr. Bolton, of Birmingham, and I have a wooden stage with two clips for its reception. Instead of C and D my friend used a cork; the rod running through the lens A, the forceps E fixing in at right angles.

John Alex. Ollard, F.R.M.S.

Enfield.

THE CONCENTRIC MICROSCOPE

[20168.]—Mr. Wenham's remark, "By all means let him grasp what credit he can," is neither wise nor gentlemanly. It has been shown that I thought out and first published *pro bono publico* this new principle—a principle which will, I venture to say, govern the future construction of microscopes of the first class. The public questions raised by these attempts to expropriate a principle enunciated without reserve at a learned society have been efficiently dealt with by "Another F.R.M.S." It remained for me to give such evidence as would prevent patentees from expropriating the credit of my design, and from monopolising the manufacture of "the concentric microscope." This, so far as is necessary at present, I have done.

James Edmunds, M.D.

ADJUSTABLE ROLLER BEARINGS.

[20169.]—I should like to submit the following to the criticism of the readers of our Mechanic, as I feel convinced it is a marked improvement upon the bearings at present in use for bicycles and tricycles. I make the rollers conical and running upon a conical bearing-surface or spindle, the largest portion of roller running upon the largest diameter of spindle or shaft, and bore out case to fit outer circumference of rollers. In order to insure that the whole of the surfaces in contact shall travel at the same velocity, I make them by this rule: as largest diameter of spindle is to largest diameter of conical roller, so is smallest diameter of spindle to smallest diameter of roller.

It will be seen by Fig. 1 that in case of front-wheel bearings I show adjustment in bearing, but in hind-wheels and tricycles I prefer to place it upon spindle (Fig. 2). This bearing is subject to many modifications; but I claim that in this form we have the maximum of bearing surface with the minimum of friction together with a perfect adjustment. I trust this will explain itself sufficiently. I have made it as brief as possible to avoid infringing upon your space; but shall be happy to answer any inquiries, or give any explanation.

E. Martin.

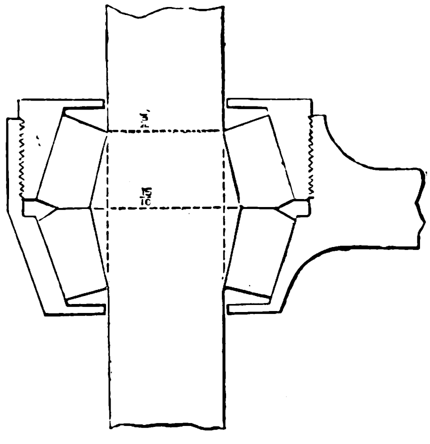


FIG. 2.

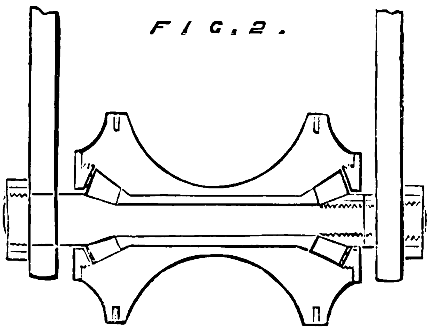
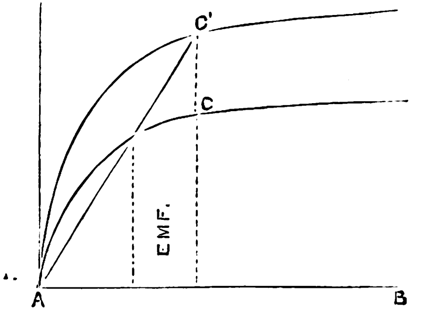


NOTES ON DYNAMO-MACHINES.—IV.

[20170.]—32. Referring to the characteristic curve for the ordinary dynamo-machine, it will be observed from Fig. 5 that if the resistance in the circuit represented by tan C A B, be constant, on increasing the speed of the machine the E.M.F. will increase in a greater ratio, so long as we are dealing with the curved portion of the line A C.

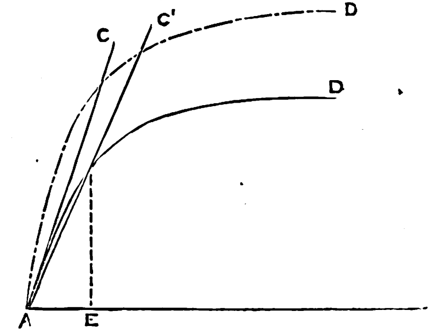
FIG. 5.



On approaching the flat part of the curve, however, the E.M.F. becomes approximately proportional to the speed, the field, by reason of the saturated condition of the magnets, now being constant. When the characteristic curve has been drawn for a particular speed it is easy to determine by construction the E.M.F. for a given resistance at any different speed.

33. Let A D, Fig. 6, be the characteristic curve for a dynamo at a particular speed. The speed being fixed, an increased resistance lessens the current and E.M.F. Let the resistance become of such magnitude that the tan of the angle C A B represents its value. Here A C is a tangent to the

FIG. 6.



curve A D, and when this is the case there can, of course, be no current. If the resistance, however, is diminished by the smallest amount, equal now, say, to tan of A C', we shall have a current equal to A E. The resistance represented by tan C A B is termed the critical resistance of the machine for that particular speed. If the internal resistance of the dynamo exceeds the critical resistance for the speed at which it is driven, it will not feed itself.

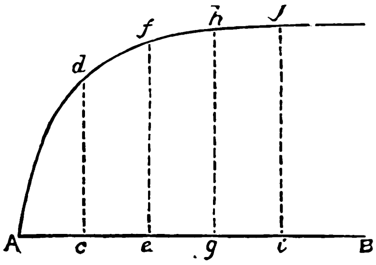
34. When the resistance in circuit is anywhere near the critical resistance, the current will be characterised by enormous fluctuations. It can readily be seen that a small change in the resistance causes a great difference in the strength of the current, when at the beginning of the curve, and the slightest misbehaviour on the part of a lamp would be followed by great irregularities in the current. If fluctuations are observed in the current which seemingly indicate that the resistance approaches the critical resistance for the speed at which the machine is being driven, the speed should be increased so that the line A C fall within the new curve A D' obtained for the higher speed. To obtain the steadiest flow of current, the field-magnets should be fully saturated, when the dynamo becomes practically a magneto-machine.

35. It has been shown in previous notes that in a dynamo-machine running at a fixed speed the E.M.F. is simply proportional to the strength of the field, this latter of course depending on the current flowing round the field-magnets. The ordinates *c*, *d*, *e*, *f*, and *g*, on line A B (Fig. 7) will consequently represent directly the strength of the field when currents A *c* and A *e* respectively flow through the machine. It will be seen that after the current has reached a magnitude A *g*, the field is scarcely strengthened by increased current, and it is important to observe this when producing the field by a separate dynamo.

36. If we have a number of dynamo-machines at work of similar construction and dimensions, it is advisable to take the current from the brushes to the lamps direct, and to use a separate dynamo for the purpose of producing the field in the lamp dynamos. This practically transforms the lamp dynamos into magneto-machines, and greater

steadiness and regularity is obtained, since an increase of resistance in the lamp circuit cannot react in such a way as to weaken the field. This plan is adopted by Siemens in lighting the Royal Albert Docks, London.

FIG. 7.



37. The use of a separate dynamo to produce the field renders it possible to burn a number of lamps on a machine not specially devised for this purpose. Suppose we have a machine giving a current of 60 ampères through a resistance 4 ohms. Such a machine would have an electromotive force of 240 volts, with a current of 60 ampères flowing through the field-magnets. Now, an increased resistance in the circuit when the machine is self-excited will diminish not only the current but the E.M.F., as well, from the weakening of the field. If, however, we excite this machine with a separate dynamo, sending a current of 60 ampères round the field-magnets, we render the E.M.F. of the machine practically independent of the resistance in the lamp circuit, and for a single lamp of 4 ohms resistance with 60 ampères of current, we can substitute half a dozen lamps of the same resistance, having a current of ten ampères through each—since 4 × 6 × 10 = 240 volts, the E.M.F. being approximately the same as when the machine was self-excited with a current of 60 ampères.

38. When producing the field by a separate machine, the strength of current ought to be such as to fully saturate the field-magnets: any excess is only adding a percentage of waste and heating to excess the machine, while anything less causes irregularities in the current.

E.

OHM'S LAWS ON ELECTRICITY.

[20171.]—Having recently taken up a number of a well known educational book, I found the following formulæ of Ohm's, of which the three latter were utterly inexplicable to me, and thought some of "yours" might no doubt enlighten me on the subject.

We will suppose we have six cells of our battery, and, for the sake of simplicity, we will suppose them to be simple elements of copper and zinc, the thicker plate in the drawing representing the zinc. Now, we can connect them in four ways. They can be arranged in a line one behind the other, as shown in Fig. 1, the zinc of one being connected with the copper of the next; or they may be arranged in two rows, each containing three cells, as shown in Fig. 2, or three abreast as in Fig 3, or lastly, side by side, all the zincs being connected together to form the negative pole, while all the wires from the copper plates unite to form the positive terminus, as at Fig. 4.

FIG. 1.

FIG. 3.

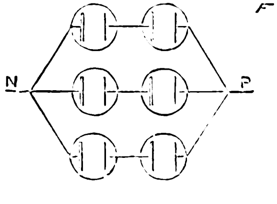


FIG. 2.

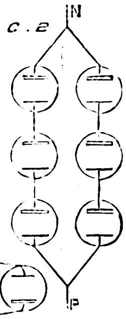

FIG. 4.

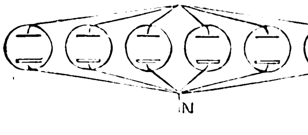

These different modes of arrangement have been investigated by several electricians. Professor Ohm, however, was the first to reduce them to a few general principles.

Hence we have :—

E = the power which a cell possesses of evolving electricity, or its electromotive force.

R = the resistance in the cells.

r = the external resistance on the conducting wires.

I = the total quantity of electricity or the intensity which passes along the conducting wire in any given time.

Ohm's law, then, may be enunciated as follows: $I = E / R + r$.

Now, if any number (n) of elements of a battery be connected together, there is n times the electromotive force, and also n times the internal resistance; the external resistance, however, remains the same, and hence the formula: $I = nE / nR + r$.

We will now suppose r to be represented by 4, and R by 1; that is, the resistance in the line to be four times as great as the internal resistance of the cells.

When the batteries are all connected in line as in Fig. 1:

$$I = \frac{6E}{6 \times 1 + 4} = \frac{6E}{10}$$

Now let them be connected so as to be two abreast as in Fig. 2, and we have then in reality three elements, each of double the size; the resistance, therefore, is only half, and therefore,

$$I = \frac{3E}{3 \times \frac{1}{2} + 4} = \frac{6E}{11}$$

When they are connected, as in Fig. 3, $R = \frac{1}{3}$, and the formula becomes

$$I = \frac{2E}{2 \times \frac{1}{2} + 4} = \frac{6}{14}$$

While, when all the zincs are connected together, and the copper plates also, as in Fig. 4,

$$I = \frac{E}{\frac{1}{6} + 4} = \frac{6E}{25}$$

We see thus that with this external resistance the greatest advantage is gained by connecting them singly. If, however, we suppose r to be just equal to R, these formulæ will respectively become

$$\frac{6E}{7}, \frac{6E}{5}, \frac{6E}{5}, \frac{6E}{7},$$

which shows that the greatest power is obtained when they are connected in twos or threes.

Now, the first formula works all right, but the last three certainly want explanation, as to the working, to

Stud. Inst. C.E.

ELECTRIC METERS—ELECTRIC v. GAS-LIGHTING.

[20172.]—The idea on the subject of electric meters which Mr. Leaper mentions (20132, p. 308), is described in my patent. But it is not an available means of measuring currents; at least, in the form which is most obvious—the decomposition of water, so-called. It is true that this decomposition gives us a very convenient measure when corrections for temperature and pressure are made; but it is attended with two drawbacks, which render it useless.

In the first place, it sets up an opposing electromotive force which absorbs energy, and would, therefore, uselessly consume part of the working power. Then, also, the resistance of surfaces giving off gas is constantly varying, which would introduce an irregularity in the action. Both effects would combine in producing a more serious evil, in that they would make it impossible to use shunts, and therefore would necessitate using the whole current, and levying a heavy tax upon it for the purpose of measurement. Mr. Edison also has patented a mode of using decomposition of water which is evidently impracticable. He proposes to let the gases raise a bell-jar of measured capacity, and then automatically explode them. This would do away with the loss of water, but it is difficult to conjecture how long the apparatus would work.

The utilising of the gases is chimerical; they would not pay for collecting, and would rarely be useful on the spot. The value of deposited metal is of course nothing, because it is only transferred from one plate to another. In my meter the one weight of metal simply passes to and fro between the electrodes continuously. Unlike gas generation, it absorbs no energy, except that of the electric resistance, and it introduces no complication of counter-forces.

I am sorry to see Mr. M. Williams pandering to a very stupid but popular fallacy, 20731, p. 308. He joins in the absurd and ignorant outcries about gas and its cost, and in doing so makes, as every one else does, statements which he would find it difficult to support. It seems to be adopted as a sort of axiom that gas ought to be provided by the public authorities as a public convenience, and not as a commercial enterprise. This is a fallacy, and one of the forms of a growing communistic theory. Let me ask any one to give even a plausible reason. As to water supply, there is a reason for the public supply, because water is a natural product and an inevitable universal necessity. Our congregating in cities cuts us off from the natural supplies, and we can best remedy this by collective control over those supplies and the distribution. But gas is a manufactured article, involving constant individual work to improve it. Every supposed reason for its public control applies with equal force to the supply of bread, of meat, of milk, and so on, and the result would be a pure communism in which private energy would be crushed out.

Mr. Williams says the prime cost of gas is nothing. If this be so, to whom is it due? Is it not the result of the work and business energy of gas-makers who have created the industry? In any line of business, if men improve it and make it profitable, ought they to be grudged the fair return?

He says: "If gas were subject to ordinary competition, we should be supplied at 1s. per 1,000ft." I much doubt if that could be done were no profit made by anyone, and capital not considered at all. But even if so, how has it come about? A few years ago, there was that competition. But, then, the price of gas was very much greater than now, its quality much inferior, and the gas companies got no profits. The existing conditions by which all have advantaged, and which excite the cupidity and animosity of people who ought to know better, are due to the efforts of a few wise and energetic men of business. The prosperity of gas companies is based upon two things: (1) the substitution of competition by a regulated monopoly, under conditions to protect the public interest, settled by the public authorities; (2) the substitution of clay retorts for iron ores.

Why should not those who produced the result reap the benefit? Is 10 per cent. an unreasonable profit upon a capital embarked in a trading and manufacturing enterprise? That it is subject to risks is obvious from the circumstance that it is now threatened with total extinction by the electric light—a threat, I may add, which does not greatly alarm, but none the less shows the enterprise to be one entitled to a profit covering it. Some railways pay 6 or 7 per cent., and they are not subject to any such risks. The fact is, that for many years gas companies paid small or no dividends, and then no one wanted to take their work from them; but because for some time they have attained a most legitimate reward for energy and ingenuity employed in doing a great public work, they become the mark of all envy, hatred, and uncharitableness.

Let the electric light supersede gas, and, of course, the same result will arise. As soon as companies have made it a success, and look for a profit, there will be the same outcry. Yet, what induces men to carry out these enterprises, but the hope of obtaining a benefit themselves?

Meanwhile, will Mr. Williams state the names of some of the towns, where, as he says, the corporations supply gas at "about half the price of London gas," and yet make a profit? Will he also show how the result of extensions can supply the only fair data for calculations. My experience in various matters indicates that extensions are very different from a complete affair, and would give very fallacious data.

As to the electric light companies, they will follow the usual course of pioneers in a great work. Just as gas, railway, and cable companies fared, so will they. But, suppose all their first capital is sunk, the country will be none the poorer. The case is very different from that of throwing away many millions in, for instance, a foolish invasion of Afghanistan; there money and lives were wantonly thrown away, with nothing but evils to show as a result. Here the money will not be lost: it will only change hands, and there will be a result in the establishment of a new and beneficial enterprise, which, in the end, will be a great boon to the community, and a legitimate and profitable source of employment for capital.

Sigma.

[20173.] — Your correspondent, Mr. Mattieu Williams, in 20131, makes some statements which seem to require reconsideration.

In this letter it is said, "the by-products—coke, ammonia, naphtha, &c., cover the cost of making the gas." Is this correct?

The Gas Light and Coke Company's account for 1881, give in round numbers the value of the residual products—viz.:—

Coke, breeze, tar, ammonia, &c., at ..	£615,000
The cost of coals at	963,000
The cost of manufacture of gas, including coal	1,460,000

showing the value of the by-products to be only 42 per cent. of the cost of making the gas. The account of another gas company, with a capital of over £700,000, shows 39 per cent., both much under 100 per cent.

Again, it is implied that one shilling per 1,000ft. would pay expenses, and a fair interest on the capital outlay.

The rates of the Gas Light and Coke Company in 1881 were, 3s. 2d. for common gas, and 3s. 11d. for cannel gas.

If charged at 1s., the company would lose above $\frac{2}{3}$ of their receipts for gas, or more than £1,312,000, and in that case there would not only be no dividend on nine millions of capital, but the expenses would exceed the receipts by half a million per annum.

C. E.

ELECTRO-MOTOR.

[20174.]—Two of your correspondents have pointed out the rock ahead upon which Mr. Huxley's idea (if put in practice) will founder—viz., the alteration of the length produced by magnetising iron, may be absorbed, by reason of the elasticity of iron, upon any attempt being made to use the force in the manner suggested by Mr. Huxley.

For example, using the figures given by one correspondent, the iron lengthens, one 272,000ths of its length when magnetised; hence, a bar 23ft. long, one inch sectional area, lengthens one thousandth of an inch when magnetised or when submitted to a stress of 94lb. Consequently, the whole stress produced by magnetising such an immense electro-magnet is neutralised by a stress of 94lb. From this statement it follows: Mr. Huxley must employ the unwieldly size of an electro-magnet 23ft. long and 2in. sectional area to lift 94lb. one thousandth of an inch, and from that datum he can easily calculate the horse-power of his proposed electro-motor—taking care, however, to make allowance for the friction of the iron particles "inter se" when calculating the strength or force of the electric current. As Mr. Huxley takes exception to my use of the expression "friction of the particles of iron," may I be allowed to state such an expression is not difficult to be understood, and means a definite force of electric current is required for any magnetism to be produced in each cubic inch of iron, just in the same way as a definite stress is required to produce the first strain in each cubic inch of iron, and that owing to the friction of the particles of iron "inter se," strains proceed "per saltum"? Sir W. Thomson made experiments on iron magnetised under different stresses, and Mr. Huxley ought to study these.

10th June. A. C. Ponton.

LECLANCHE BATTERIES WITH PEROXIDE OF MANGANESE V. LECLANCHE BATTERIES WITHOUT MANGANESE.

[20175.]—I THINK the following lines on the above subject may be interesting to some of your readers.

To test the value of G. Tolman's assertion that Leclanché batteries without manganese would work equally as well as those containing manganese, I determined to test the fact myself. On May 1st I fitted up four batteries, two of which contained four cells of the gravity form, and two eight cells of the form in use by the Post Office Department.

One battery of each kind was fitted with the usual mixture of broken carbon and peroxide of manganese, and the other two with broken carbon only. The four batteries were charged with sal-ammoniac in the usual way. These batteries were running the same length of time each day, and when examined, June 5th, those containing manganese were found in good working order, while those prepared with broken carbon only were practically useless. When they were first fitted up they each gave the same resistance and the same electromotive force; but on testing them, May 7th, although the resistance had not changed the electromotive force of those without manganese, had run down considerably. They were tested again on the 15th May, and I found that the electromotive force of those charged with manganese was more than 50 per cent. greater than those not so fitted up. They were again tested on the 22nd May, when I found that the electromotive force of the cells charged with peroxide of manganese was exactly double that of the others. Both batteries without manganese failed on June 5th.

I am convinced, however well the Leclanché battery may work without manganese, it works infinitely better with it.

Arch Key.

THE BERLINER VIOLIN.

[20176.]—I SHAKE hands with Mr. Berliner, and congratulate him on his success. Through the kindness of our editor I have had an opportunity of perusing this new patent violin. The resonator does improve a weak-toned cheap instrument—viz., 15s. 6d. German make, 30s. retail; but there is a shorter French make at same price that I think would produce better results? Why? Because the bass wants consolidating; the reaction is not quick enough. The 1st string is all good, 2nd string partly so, the 3rd and 4th want power. But this is the case with most violins that have a soundpost: the difficulty is to get an equal weight, tension, or resistance over the whole of the soundboard to suit the various tones. This is not theory, I'm putting it into practice. Note.—The Berliner violin is strung (without a tail-piece) on to a continuation of the finger-board, so that there is no tension on the hinder part of soundboard but what already exists, in the pressure of form, sides, back and front, glued together. If this normal pressure or tension could be increased, the bass would be louder, and the 3rd string firmer—a most important consideration. I do not think that because the treble part of soundboard is apparently as free as the hinder or bass part, that it is not affected by the metal and ebony stringholder, and the internal strip; the fact is, the increased weight, 3 or 4oz., is the cause of increase of sound all round, and more especially in the treble region, because it is to this part that the resonator, &c., is *indirectly* attached. This attachment is managed so cleverly, that the vibrations are not stopped or absorbed, but thrown back with increased force, as a shuttle in a loom. Now, this is the difference between a good or bad violin—if you have not sufficient resistance there is no tone. The mere attachment of weight is not what I mean; but what in electrical parlance is called internal resistance; it must be in the wood, in the make up of the wood into form or shape, in the strain of the strings; this can only be done by adding pressure or weight without stopping the vibrations—indirect action to produce reaction—positive and negative. I apologise all round for this digression, and beg to say that Mr. Berliner's patent is valuable when applied to weak instruments; but where all is provided for in a first-class violin, its application is not needed, and would be dangerous. The tone of the Berliner violin is soft or suave, and forms a delightful musical acquisition.

I wish to know the price of violin; also of patent resonator, if our friend will oblige by making them known through the Sale Column.

Fiddler.

A DOUBLE TRICYCLE.

[20177.]—I AM now contemplating the building of a tricycle to carry two riders, and shall be very pleased if some of the able contributors to the ENGLISH MECHANIC will tell me whether my plans are likely to turn out a success.

The machine will be a 50in., with a track of between 50in. and 60in., the axle in two parts, each part being a double crank of 5½in. throw, and driving its respective wheel. The saddle or seat will be about the same height as a bicycle seat of a 50in. machine, and about 9in. behind a perpendicular line passing through centre of axle. The frame work will consist of three curved pieces of steel tube, united together by two horizontal pieces and meeting together at the head of small wheel in the rear. The curved tubes will carry the bearings for the axle, the centre tube having a double bearing for the ends of the two cranks. The horizontal bars will carry the sockets for the saddle or seat.

I also propose adding two levers worked by hand, to be used when mounting hills, and to act with greatest force when the cranks are at their dead points.

The advantages I hope to get from this machine are—1. Simplicity of construction. 2. Ease in working, as the power will be applied directly on the axle, after the manner of a bicycle. 3. A good view of surrounding scenery. 4. Ability to apply extra power by means of the levers when travelling is difficult. 5 Ease and readiness in turning, as the crank being divided, one rider can remain inactive, or even back his crank, whilst the other works his machine round. The disadvantage I fear is a great liability to upset, but this will be mitigated by the width of the machine and position of seat behind the axle and between the rear and front wheels, and also by the position of the point of application of the driving force.

Why are cranked axles and levers abolished except in the case of the "juvenile machines"? The chains and cog-wheels used as a substitute seem to involve a very complicated construction and waste a deal of power.

I am led to propose this question from having lately made a short trial of the "Velociman," essentially a lever tricycle, and being struck with its immense superiority over my own, a chain machine. I ought to state that the wheels of these two machines were exactly of the same height.

A Littlemore Mechanic.

FITTING NEW TEETH TO WATCH AND CLOCK-WHEELS.

[20178.]—IN accordance with an intimation given by me several weeks since, I now contribute a little instruction on the work of fitting new cogs, or teeth, to watch and clock-wheels, premising that in so doing my remarks will be of benefit to a few of the younger members of our fraternity, and, at the same time, give a few serviceable hints to amateurs. I am aware that many high-class workmen discountenance the "patching" of wheels; but every *ordinary* watch and clock jobber knows that such repairs must frequently be done. It is obviously a more simple and less expensive job than fitting new wheels, and, I am bold to say, is more often resorted to. Although the difference of size between one and the other is so great, the manner of fitting is nearly identical, the tools only varying in their sizes. There are various ways in which teeth may be fitted, and the precise manner of fitting must be governed, in great measure, by the class of wheel to be operated upon. I will proceed at once, then, to describe the several modes of fitting, and the manner in which the repairs may be done. Taking the wheels of a verge watch seriatim (I have elected to take a verge watch because it has the largest kind of watch-wheels, and is more easily operated upon), we have the fusee or great wheel; this is the stoutest wheel in the watch, and seldom, but sometimes does, get ruptured or broken. Generally speaking, this wheel has a broad rim or ring, which will admit of deep cutting without in any way diminishing its strength. The teeth, from their large size, are comparatively easy to fit. Presuming that a tooth of the fusee-wheel is broken, remove the pin, collet, and the coned part, and secure the wheel in the hand-vice, or the bench-vice, between two pieces of cardboard or thin metal, to prevent bruising by the screwing up; then, with a fine saw, or saw-file, cut down into the rim of the wheel to about two-thirds the length of the teeth, and with a suitably-shaped file undercut the slot the form C, Fig. 1, after the manner of dovetailing. Then take a piece of brass wire and hammer it moderately, to harden up; afterwards file and shape the extreme end to fit the dovetailed slot. Make it a close fit, and, as nearly as can be, make the part which will form the new tooth the precise stoutness. The tooth can be secured either by riveting or soldering. The former is preferable, because soldering, by reason of the heat required, is sure to bring about a little weakening of the parts. Where the wheels under repair are small, the teeth can hardly be sufficiently secured without solder; but great care has to be exercised in using it. A small soldering-bit is very useful in this work, as the wheel need not, by its use, be brought in actual contact with the flame. I use the blowpipe but little in soft-soldering. I keep a few differently-sized bits, and find them, in the majority of jobs, all that can be needed for the work. Having fitted the new tooth fairly tight, and you desire to solder it, apply a little zinc solution to the parts, and having a small quantity of solder on the bit, heat up, holding the wheel in the tweezers. Place the point of the bit at the base of the new tooth and the protruding end of the wire in the edge of the flame—as this will assist the solder to flow correctly when it runs to its place round the tooth. The job should be done quickly, so as to prevent overheating of the wheel. The surplus wire must then be cut away, and the remaining portion reduced and shaped to the exact form, taking care that the tip of the tooth is true to the circumference of the wheel. If you rivet the tooth in, the edges of the slot must be slightly bevelled, and the metal of the new tooth hammered over. The finishing off should be done with Ayr stone and burnisher.

Coming next in order to the centre wheel, we have one of about half the thickness of the fusee-wheel, and, like it, a solid one—i.e., not cut open into a bar-wheel (a few exceptions occur); and admitting of a deep cut for the new tooth or teeth, for it sometimes does happen that several teeth give way together. Whether this is so or not, a fairly deep cut should always be made, and be dovetailed as before described; or, in the case of a single tooth, the wheel should be drilled at the base of the old tooth as at B, Fig. 1, and cut into with a saw or notching file. As before, the brass should be hardened previous to insertion, and fitted as closely as possible before soldering or riveting. A very small speck of solder will suffice to make all secure if the fitting is perfect. The thickness of new teeth should in no case exceed the thickness of the wheel itself, so whether it is soldered or riveted the true flat of the wheel should be retained. Some little care is always needed in riveting, to prevent the adjacent parts being swelled out of truth. Now we come to the third wheel, which is one having a narrow ring, and cut open with bars. In these wheels there is seldom more than about the same breadth of ring as there is in the teeth, so only about half of it must be cut away for the insertion of the tooth. It is advisable not to rivet teeth in these wheels, as they are almost sure to get out of round in so doing. If the wheel is a thick one, it may be drilled through from its edge inwards, as at A, Fig. 1, but in this way the tooth cannot be made of the same form as the existing ones, inasmuch as the drilled hole must of necessity be less in diameter than the wheel's thickness, and the pin inserted less than that, and somewhat round in form. After the tooth has been roughly shaped up, soldered in, and cut off, the end may be trued off in the turns, as in ordinary "topping," and then shaped at its sides to match the others. The teeth of these wheels may also be fitted as at B and C, Fig. 1.

The contrate wheel is next in order. This wheel will require somewhat different treatment to the others as, owing to the usual narrowness of the ring, no space is left for cutting; therefore a hole must be drilled through its edge.

This wheel is more liable to breakage than any other, owing to its proximity to the edges of the plates and consequent interference by the wearer. I have frequently had verge watches brought to me with ten or a dozen teeth turned over or broken off. Obviously, a wheel in such a state should be replaced by a new one. In drilling a wheel for a tooth, it must always be observed to start and keep in the centre of the ring, and central between the two next to it, and the diameter of the drill must be less than the wheel's thickness. If this cannot be accurately determined by the eye it must be gauged. The drill, as in Fig. 5, should be nicely shaped, and left with a good clearance aft the cutting edges. When the hole is correctly drilled insert a tapered pin, and apply a little solder to the underneath part and cut off flush. I advise a tapered pin because a small hole will suffice, and the part forming the tooth be larger in consequence, and be nearly, if not quite, the same size as the existing teeth. The finishing off may be done as was the third wheel. The wheel next in rotation is the 'scape-wheel or balance-wheel, as it is by some called (Fig. 2). Great precision is necessary in repairing this wheel, so as to make it effective in its action. So much depends upon the escapement, that the most trifling error in shape, thickness, or length, may cause the watch to stop.

FIG. 1.

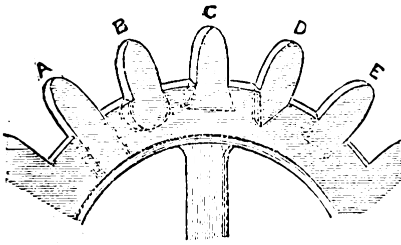

FIG. 2.

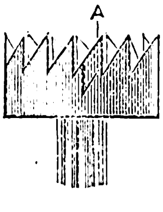

FIG. 3.

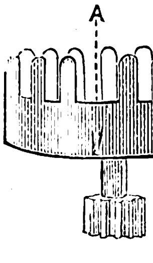

FIG. 5.

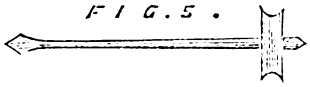

FIG. 4.

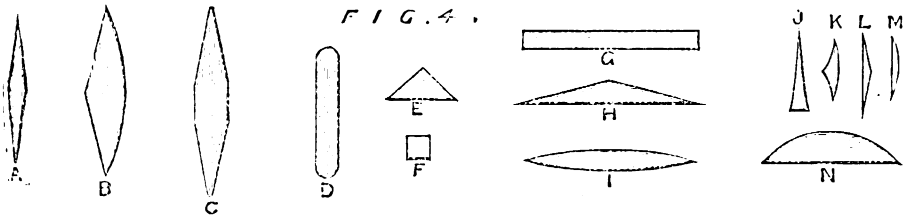

FIG. 6.

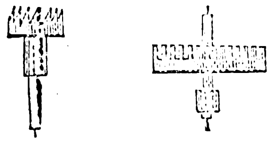

FIG. 7.

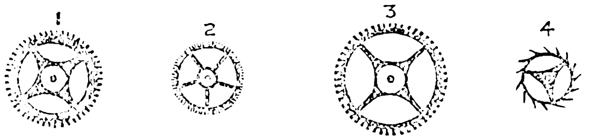


If the wheel is a very thick one, and only the extreme end of the tooth is broken, it may be drilled for the new one. Otherwise, it must be cut with a thin-edged file, A, Fig. 4. In doing this, observe the pitch of the teeth, and make the cut in the wheel at the same inclination. Insert a piece of good hard wire, which has previously been shaped as nearly as can be to what is required, and no thicker than the existing teeth. This repair must be done with the soldering bit, and care must be taken that there is no overheating. Any excess of solder must be removed, or the wheel will be out of poise—*i.e*, it will be heavier on one side than the other, or may become blocked in the potence. With a balance-wheel file K, Fig. 4, shape up the tooth to the correct form, and, with a piece of Arkansas-stone tip the tooth until it is the same height as the others. This may done upon a piece of perfectly flat stone, but it is best done in the "turns." To quickly ascertain if the wheel is correct, set it in the depthing tool and bring one of the poppets flush with the teeth-tips. On revolving the wheel, it will at once be seen if correct or not; another way is to place a flat burnisher on the teeth, and look closely at it with the eye-glass when held between you and the light. If the tooth is too short, another must be put, or the the others must be cut back to it. This, however, entails, in most cases, the cutting away of the potence-face and the counter potence; so it will be apparent that more than ordinary skill is required in fitting teeth in a 'scape-wheel. The tip of the tooth must be equidistant from the next ones on either side, and a simple way to determine this is as follows: Press the wheel's teeth slightly upon a piece of white paper, and, opposite to the marks made by the new tooth and the two next, make dots with pen or pencil to distinguish them; then bring round the other side of the wheel, which is, presumably correct. If these teeth fall exactly into the marked holes without deviating in any degree, the tooth is truly pitched and perfect so far. The verge being void of what may be called teeth, little or nothing need be said about it here. I only speak of it to say that I have seen worn verges so twisted about that what was formerly the back of the pallet has been made its acting part. I do not intend to advise its adoption, so will say no more about it.

D and E, Fig. 1, are examples of modes of fitting teeth, but they are not so reliable as the others. The wheels of other watches, such as chronometer, duplex, lever, and Geneve, may be repaired in the same manner as those already described; but all being, more or less, of a delicate make, or requiring greater nicety in fitting and finishing, a skilful hand is needed to make a good job. I must admit that it is advisable to have new wheels where exceedingly fine work is in hand, such as will be found in 2, Fig. 7, which is the actual size of a Geneve wheel of small make, and having about 90 teeth in its circumference; but every jobber will know that repairs of this kind have frequently to be done off-hand, without any consultation with the owner, who, if advised of the breakage, would possibly object to the inevitable outlay attaching to a new wheel, some wheels costing from 3s. to 10s., or more, each.

It is needless for me to go into detail with every kind of watch-wheel. because the already-described modes of fitting hold good for nearly all, the most suitable being adopted according to the ideas of the workman. Nor do I think it necessary to do so as concerns clock-wheels, because anyone who can correctly fit teeth to watch-wheels must, without doubt, be competent to fit teeth to those. The form of fitting is the same on a larger scale. There is this much to be said, though, as regards them. In the case of large and heavy wheels and toothed barrels, the drill-hole and the tooth may both be threaded to screw in. This is an advantage, as soldering and riveting are dispensed with, and the wheel is in no way softened or misshaped. A more correct shape, however, can be got if the teeth are dovetailed in, as a pin-tooth cannot be the same thickness as the wheel.

In conclusion, let me say that a feeling of satisfaction always comes to a man who loves his profession when he is conscious that he has done his best to turn a job out of hand well. I regret much to see how badly work is done by some watchmakers (?)—notably in the way screws are fitted. It is no uncommon thing to see screws set in the plates or bars of watches, which are as rough as they left the makers' hands, and entirely without colour. No good workman would ever be guilty of such a disregard for appearance. Just so with the teeth. Always strive to make the new ones as nearly as possible to match the old, and never have it on your mind that you have inserted rough pins and called them teeth.

A, B, C, D, E, F, G, H, I, J, K, L, M, N are sectional examples of files used in watch and clock work. Figs. 6 and 7 are examples of verge, Geneve, and lever wheels, actual size.

Alfojoe.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[46443.]—**Handel Organ.**—The account of the repairs and alterations to the Crystal Palace organ appeared in the *Engineer* of June 2.—J. W. W.

[46495.]—**Silicate Paints** (U.Q.)—I presume M. Pineard's silicate of soda; try "transparent silicate paint." I have used it for preventing the rain beating through the gable-end of houses. The whitewashers and painters applied it. First of all the mason pointed any loose bricks there might be with mortar. The silicate was poured into a bucket, and then put on with whitewashing brushes, exactly as whitewashing is done. Three coats were put on, allowing each to set before the next was applied. It must be done when the weather is fine. When ordering the second lot I wrote to the maker describing the method I had used, asking if it were a good one. I was told it was a very good method. The water was running in streams down the walls of one house, which the silicate entirely stopped. I shall be glad to give "M. P." any other information I can, should he require it.—W. L.

[46549.]—**Science Questions** (U.Q.)—It is quite impossible, within anything like reasonable limits, to do more than give an outline of the method to be adopted for the analysis of the mixture given, namely, O, H, CO, HCl, CO_2, and N. The HCl must be absorbed by a bullet of crystallised sodic phosphate ($HNa_2PO_4, 12H_2O$); it owes its absorbent power to its water of crystallisation, and should be of ample size to avoid deliquescence. The CO_2 is next absorbed by a bullet of potassic hydrate (KHO). The O is next got rid of by a bullet of papier-mâché with potassic pyrogallate. There now remain H, CO, and N, which are best determined indirectly; a known volume of oxygen is added, and the mixture exploded, whereupon the CO takes up half its volume of O and forms CO_2, which occupies the same volume; the H takes up half its volume of O and condenses to water. Call the original volume A, the contraction after explosion C, and let O be the volume of CO_2 produced, determined by KHO as before. Then we evidently have $CO = D$, $H = 2C - D/3$, $N = 3A - 2C - 2D/3$. In practice there are all sorts of details to be attended to, and various corrections of volume to be made for pressure, temperature, moisture, &c. Let x = weight of C $SrCO_3$ in mixture, then it will evolve $44x/147{\cdot}5$ of CO_2. $(1{\cdot}3332 - x)$ will be weight of $CaCO_3$ in mixture, and it will evolve $(1{\cdot}3332 - x) \times 44/100$ of CO_2. So we get $44x/147{\cdot}5 + {\cdot}44 \times (1{\cdot}3332 - x) = {\cdot}5104$. Thus equation multiplies out to $44x + 86{\cdot}52468 - 64{\cdot}9x = 75{\cdot}284$, $11{\cdot}24068 = 20{\cdot}9x$, from which we get the amount of $SrCO_3$ in mixture $= {\cdot}5378$ grm. Thus quantity of strontium carbonate contains ·319grm. strontium, and the mixture, therefore, contains 23 9 per cent.—WM. JOHN GREY, Elswick Science School.

[46690.]—**Waterproof Clothing.**—I am sorry I have not been able to give my experience here sooner, as it may interest your readers. I have had a great coat, a thin serge suit, and a very light Inverness waterproofed, the mode being, I understood, that the cloth is dipped in acid, and whenever it comes in contact with moisture it closes the fibres. The advantages are the air passes in and out, and you have not the unpleasantness of a mackintosh. The disadvantages are that in a cold dry wind the clothes are cold; in moist, rainy, warm days intensely hot. The wet does not run off, but hangs on. With regard to the great coat, it is made of a furry cheviot, has been in constant wear for over five years in all weathers (no umbrella), and only once let the wet in when I accidentally tried the experiment of sitting in a puddle. I have carefully avoided further experiments of a like nature. You can see through the cloth. It is extremely light, but takes some time to dry. The serge suit was a failure, being too thin. It stood a heavy shower for some time, the wet congregated, and the result was a shower bath. I had no further reliance in it. The Inverness is now being worn, and answers fairly well. Cloth when thus waterproofed will hold a basin of water provided nothing touches it so as to cause suction, which shoulders and knees generally do. There is a smooth brown (also black) cloth, which I would recommend, but I believe it is expensive, at least. at my tailor's, who dwells in the West-end. I think waterproofing adds about 5s. to the cost of a coat, and is done before the coat is made. Do not animals with waterproof clothing shake off the wet?—JOHN ALEX. OLLARD, F.R.M.S., Enfield.

[46700.]—**Intensity-Coil.**—To Mr. Lancaster.—I am pleased to be again able to write answers to correspondents. The principal cause is now removed. My thumb ceases to pain me when writing, and I shall hope to speedily fulfil my promises. I shall be pleased if any querist that I have apparently forgotten will point out to me anything that remains unanswered, and I will do my utmost for his benefit. Being unable to write to "ours" has been a source of much pain to me. Life is at the best short, and what little good we can do should be done at once, or it may be too late. I do not know whether anyone else has been good enough to answer this query; but I can assure "Brontes" I shall be only too pleased to answer any question he may now have to ask. Will "Brontes" tell me whether or not he has now any difficulty with his coil?—W. J. Lancaster.

[46711.]— **Terra-Cotta.** — Terra-cotta colour can be make to look best, if the plaster to be painted on has not been previously oiled. Give the plaster a coat of size first, and when that is dry mix the following colours:—Indian ink, yellow ochre, chrome yellow, white lead flatting, with turpentine. The colours to be got dry, and ground down and mixed to the right shade. To paint on plaster that has been oiled:—Mix a *little* lampblack and red-lead with oil, and put with the colours before mentioned: these colours to be ground with turps as before.—Sculptor.

[46719.]—**Reading-Lamp.**—This, and some other lamps on the same principle, act as the thermometer does. They are put away in a cooler place, and perhaps not quite filled when they are trimmed; the consequence is, that when they are brought into the sitting-room and are lighted, and get a little warmed, the air in the reservoir expands, and sends out the oil too fast. This is the worst of that kind of lamp. Care should be taken always to fill the reservoir with oil; they won't run over then.—Edw. Thos. Scott.

[46737.]—**Wild's Anemometer.**—I am sorry I cannot just now call to mind any anemometer invented or made by Wild. There are a number of anemometers with swinging plates, but I do not remember one of Wild's. Let me know as much as you know about it, and I shall then be able to find out which it is you refer to.—W. J. Lancaster.

[46760.]—**Making Boiler.**—The model adopted for your boiler is a bad one, and if you have not gone too far you should alter it to represent an ordinary vertical boiler, or make a plain horizontal shell. The parts can be brazed together, but no one should attempt to do that with boiler work who has not had considerable experience. You had better rivet the seams. Fix the tubes in your "furnace" plate, but leave them only a tight fit in the dome. Calculations as to the pressure such a boiler would bear are altogether beside the question; for though there may be some empirical rule stowed away in a wonderful note-book, it would be unsafe to trust it, even if it does allow for a large margin of safety, for the simple reason that no rule can possibly take into account the workmanship. It is obvious that a coppersmith, accustomed to such jobs, would turn out a stronger affair than any tyro possibly could with the same materials. But "Juno" may do this safely: Let her decide on the pressure she wants to work at, or somewhere near it, and then load the valve to four times that. Say, 20lb. is wanted, then put 80lb. on valve, fill up brimming with cold water, and start the "fire." If the valve lifts without any weeping at the seams or any distortion of the shell, she may then safely work with steam at 20lb. or more. As a matter of fact, with care it would be safe to work at 40lb., or one-half the testing pressure, but it is as well to be over-cautious with these little affairs.—Essar.

[46761.]—**Compensated Watch.**—If "M. F." would take his watch to any respectable watchmaker, such as Dent, Webster, Barraud and Lund, or Frodsham, he can have the compound balance carefully adjusted and compensated for £2 or £3, and his watch will then be as good as any chronometer—if anything, a little better, as the lever escapement is not so delicate and likely to get out of order as the chronometer escapement.—E. G. H.

[46763.]—**Coil.**—To Mr. Lancaster.—A coil 9in. long, with a core ¾in. diameter, three layers of 16 silk-covered primary, and 1lb. of 36 secondary, will give you a good ¾in. spark; then for a longer spark you can double the quantity of secondary.—W. J. Lancaster.

[46764.]—**Punch for Boiler-Plates.**—If your correspondent will look on p. 78 he will see one of the best punches in the market. As to a full-size sketch, showing how a punch is held in the machine, it would be a great waste of space. Many are simply fitted into the ram or plunger, and held there by friction; others are held in by a set-screw. The reason that many holes are ragged is either the punch is not adapted to the work, or the metal punched is of inferior quality.—C. G.

[46771.]—**Zincography.**—A "Canadian Subscriber" should refer to p. 141, No. 656, and to Vol. XXVII. for much information on this matter. The zinc plate should be smoothed up to a polish first, and then be grained by means of very fine moulding-sand worked over it with a zinc muller. After the transfer is on the zinc, gum it up with gumwater dosed with phosphoric acid, taking care to wash all the gum off again. From your query, you applied the ink roller without washing the gum off plate. You must also damp plate between each application of the ink roller, with a sponge and hard water preferably. If the plate was free from grease, the ink will then adhere only to the lines where it is wanted. While writing on this subject I send a short note of the process as carried out by photography—for line drawings only, of course:—The zinc plate is first prepared by cleaning, and then a solution of gallic acid and gum is flowed over it; this is wiped off, and when the plate is dry it is coated with a solution of bitumen of Judæa in benzine; it is exposed behind the original drawing—that is to say, a positive—and the bitumen which has not been rendered insoluble by the action of light is dissolved out by means of spirit of turpentine. The lines of the drawing appear everywhere where the metal has been laid bare. It is next treated with water acidulated with acetic acid, a solution which restores to the zinc the property of retaining a fatty substance—that is, the property of which it had been deprived by the solution of gallic acid. A roller charged with fatty ink is then passed over it, producing a picture in black, and the whole plate is then cleaned up with essence of turpentine. Impressions can now be immediately taken in the lithographic press from the zinc, and we obtain positive prints identical with the original drawing.—P. N.

[46772.]—**Steam-Launch.**—If you look through back numbers you will find a variety of notes on steam launches. Probably a two-bladed propeller would run best, but it is purely a question for experiment in each boat, unless they are built to the same lines. A mean speed of about six miles an hour is all you will get out of such a boat.—C. J. V.

[46779.]—**Bleaching Cotton.**—If the chloride of lime process is not suited ("Dix" appears to have omitted the important dip into the sours or water made slightly acid with oil of vitriol), try exposing to the fumes of sulphur, or subject them to ozone. The latter is rather too expensive at present, though in the same number as the query there is an article on the application of ozonised oxygen for bleaching, which seems to point to an extensive use of that agent.—T. P.

[46783.]—**Battery for Continuous Current.**—A Daniell would, I should think, be the best.—E. G. M.

[46786.]—**Ventilating Weaving Shed.**—If the only air-inlets to the shed are covered with screens of scrim canvas kept constantly damp, the air will not only be cooled, but will be kept damp. There might be so many of these inlets as to prevent any draught.—Nun. Dor.

[46788.]—**Varnishes and Stains.**—If "Wood-Turner" will apply to any good firm of varnishmakers they will supply him with just what he wants. He can make it easiest by dissolving pale or brown shellac in methylated spirit. The "colour" is dragon's blood dissolved in alcohol, 1oz. to the pint; but cheaper work is done by boiling in decoction of Brazil wood.—T. P.

[46792.]—**Aquarium Front.** — Patent plate, ⅛in. thick, would be strong enough for such a tank. The pressure on the glass is a question for calculation. Clearly it would not be so much 1in. above the water as 1in. from the bottom, and as the querist does not state where he wants the calculation made, he can easily arrive at the total by remembering that a cubic foot of water weighs, say, 62lb.—T. P.

[46797.]—**Academy Boards.** — Would this querist kindly say what are "academy boards?" I have asked the question of draughtsmen and others, but the invariable answer is, Don't know: never heard of them.—Nun. Dor.

[46803.] — **Movable Bookshelves.** — The old form, so many boards held on cords, or shelves neatly framed together, and hung on brackets or wall-hooks.—Nun. Dor.

[46804.]—**Furniture Cleaning.**—I am afraid you are asked to accomplish an impossibility, for whatever will remove the "nasty black stuff" will certainly take off the polish, too. The only remedy is to scrape off and repolish.—Nun. Dor.

[46806.] — **Mounting Plate Machine.**—No doubt you have mounted your machine before this; if not, I shall be pleased to give you full instructions how to do it. The Winter's ring should be same diameter as the plate.—W. J. Lancaster.

[46806.]—**Plate Machine.**—This querist should refer to back Nos.—say No. 836 for instance, p. 95, where he will find a Winter's ring. As to the general mounting, cannot he contrive to see a machine. Answering queries put in such general terms, is not altogether satisfactory to any one.—T. P.

[46809.]—**Restoring Leather Bag.**—Wash over with a strong hot decoction of logwood, and if the colour does not please, go over afterwards with solution of green copperas.—Sabbas.

[46809.]—**Restoring Leather Bag.**—A bottle of the black varnish, sold in square pasteboard box, with brush inside ready for use, and which dries on the instant, will make your bag look quite "spiff and 'spectable." Try it! I have done so again and again at a cost of a few pence only.—H. O'B.

[46817.]—**Griscom's Electro-Motor.** — This query can only be answered by someone engaged in the manufacture or who has taken one of the machines to pieces; but it may be said that it is a simple little dynamo or motor about 4in. long over all. Some particulars will be found on p. 387, No. 823. The "alteration" to make it a "dynamo" consists merely in revolving the armature by power, and providing something to take off the current.—C. P. V.

[46820.]—**Piston Ring.**—Hammer it straight again.—Blacky.

[46825.]—**Electric Bell-ringing by Cylinder Machine.**—You will ring your bell much more easily by using a small battery. You can get a piece of copper and a piece of zinc, say, 6in. or 8in. square each, and put them into an acidulated solution, say, sulphuric acid 1, water 10; then join a wire from each to the binding screws on bell, and your bell will ring easily.—W. J. Lancaster.

[46826.]—**Dulling Brass.**—Take one part by weight of iron rust, one part white arsenic, and 12 parts hydrochloric acid, mix. Clean the brass thoroughly, and apply with a brush until the colour desired is obtained; then oil well, dry, and lacquer.—S. D. R.

[46828.] — **Railway Brakes. — G. W. R. Vacuum Brake.**—I am much interested with the description which "North Star" gives of the above brake. Will he kindly favour me with a few further details? How is the vacuum created and maintained—by pump or ejector? When put on, does it leak off, or will it remain on until released? I mean, is it a two-minute brake like we use on the Midland? What kind of hose couplings are used between the carriages? I agree with all which has been said against the use of two-minute brakes, and it may interest all your readers to know that in view of the danger of trains breaking loose and running back down inclines, every passenger-guards' van upon the Midland Railway is now provided with two hand-scotches, to be used as directed by Messrs. Bramwell and Cowper. This seems to me a poor substitute for a really good brake. With regard to the Board of Trade Returns, I noticed lately in the *Engineer* that all failures of brakes are not reported. What is the law and penalty upon the subject? I know for a fact that the returns are very incorrect, as I was once driving a train when the automatic vacuum leaked away and let my train run its full length past the danger-signals. Well, Sir, I reported the case, and it was investigated by my superior. I bought a brake return, and to my surprise found the case reported as one of "Slight difficulty in applying the brake; no delay." You will see that this hushed up the matter, and did not give a true account of the case, making it appear a little matter, when, indeed, it was a very serious one, and might have been more so had not another train started in time.—A Driver.

[46841.]—**Vacuum Pump.**—You must have made some mistake in constructing your pump if air once forced out can get back again. You speak of "the vacuum in G sucking up the mercury in F," but obviously it cannot do that unless air-pressure on outside is greater than in G. Are you sure you have not some leakage? If you can visit the Crystal Palace, in the eastern gallery you will find one of the simplest, quickest, and best of all air-pumps of the kind, exhibited by Mr. Müller, I think, in which the mercury is forced in by elevating the vessel containing it. In this pump the air is dried by taking it through sulphuric acid.—Nun. Dor.

[46842.] — **Estimation of Tannin.** — The following extract from the report of the United States Commissioner of Agriculture for 1880, may possibly be of use to the querist: Of the several methods tested in this laboratory for the quantitative estimation of tannin in the different tanning materials found in the market, the volumetric one proposed by Estcourt, and modified by Löwenthal, has thus far given most satisfaction. This method depends upon the oxidation of a tannin solution by an acid permanganate solution, a definite amount of indigo being added to serve as indicator in the titration. In order to obtain as nearly as possible the reducing coefficient of the tannin of sumac leaves, about 100 grams of the latter, after being powered, were treated as follows, with a view of procuring a sample of nearly pure tannin. An extract was made with hot water, which, after being evaporated to a small bulk, was added to enough alcohol to make the mixture about 80 per cent. alcohol; after filtering, this alcohol was in turn removed by evaporation, and the diluted filtered solution treated with normal cupric acetate, which gave a soft brown precipitate of a compound of tannin and copper. This precipitate, after being separated and washed several times with water, was suspended in water and decomposed with sulphuretted hydrogen. The resulting cupric sulphide was filtered from the solution, the filtrate slightly acidified with sulphuric acid, and, after being neutralised by means of barium hydrate and filtered, was evaporated nearly to dryness, dissolved in 90 per cent. alcohol, and then treated with sufficient ether to form about a 16 per cent. ether mixture; a dark-coloured precipitate of small amount was filtered off, and the solution evaporated upon glass plates. The dried residue was scraped from the glass in scales of a dark-yellow colour. This sample yielded 0.01 per cent. of ash, 0.83 per cent. of organic impurity, 7·25 per cent. water at 100° C. After making deductions for these amounts, 1 gram of pure tannin required for oxidation 0·6239 gram of potassium permanganate, 1 gram of the latter requiring 1·6028 grams of tannin. A sample of gallotannic acid, obtained in the market, was also tested in the same way, and, after making similar deductions for impurities, 1 gram of the tannin required for oxidation 0·7153 gram of potassium permanganate, 1 gram of the latter requiring 1·3981 gram of tannin. In carrying out these titrations, a water solution containing 0 5 gram of tannin in 1,000 grams was used, 25 grams of the solution being taken for each titration, to which were added 20 cc. of a solution of potassium sulphindylate, containing about 7 grams of the salt per liter, about one liter of water and a few drops of sulphuric acid. This was titrated with a one-fortieth normal solution of potassium permanganate, this concentration giving much more constant results than stronger ones. In the above formula the indigo solution requires for oxidation about one-third of the entire volume of potassium permanganate used. This relation has been found to work as well as one in which the indigo present would require two-thirds of the volume of potassium permanganate used, the latter being given by some writers as the lowest ratio in which the indigo should be present in order to secure the complete oxidation of the tannin before the solution becomes bleached. When solutions of the above strength are used, and the titrations carried out very slowly, taking at least five or six minutes for each one, this process serves as one of the best for the estimation of commercial tanning materials; the end reaction, indicated by a change of colour from indigo-blue to straw-yellow, being quite distinct. In testing a sample of bark or leaves, a weight of from two to five grams should be percolated with petroleum naphtha (boiling below 70° C.) in order to first remove as many substances not tannin as possible, and then the tannin extract should be made by percolating with eighty per cent. alcohol, the alcohol evaporated and replaced by water, this solution filtered and diluted to two hundred or five hundred cubic centimeters. Ten cubic centimeters of this solution are then titrated under the same conditions as above described. The amount of permanganate required, less the amount necessary for oxidation of the indigo used, is the amount necessary for the oxidation of all reducing substances present in the extract. One hundred cubic centimeters of the latter are now treated with ammonio-cupric or ammonio-zinc acetate, and the tannin precipitated as a compound of tannin and copper or zinc. After standing a few minutes, the precipitate is filtered off, and the filtrate titrated in the same manner as the original solution. The amount of permanganate required to oxidise the entire oxidisable material of the extract, less the amount necessary for the oxidation after the removal of the tannin, gives the amount reduced by the tannin alone.—N.R.

[46844.]—**Clock.**—If you cannot burr the hand so as to fit tight on the square of the minute-hand spindle or arbor, you can surely drop a piece of wax or something on it when it is in right position. You indicate the remedy yourself when you say the hand is loose. Make it tight—on the proper side, and it will be right.—Horologos.

[46847.]—**Equation.**—To "M. I. C. E."—Thanking "M. I. C. E." for his kind attention, I take the liberty of giving a second solution of the adfected quadratic equation. I would have done so before had not examination work prevented me from writing. As in my first solution, so here, an adfected quadratic occurs in the course of the solution, which has, however—as was pointed out by "M. I. C. E." and Mr. J. Lane Davies—the drawback of having an equation of the 4th degree to be solved; one solution—and the only one suitable—is obvious. I hope this solution will prove satisfactory, for it is quite sufficient that an adfected quadratic makes its appearance in the course of the operation, which, however, must be essential for the further proceeding of the equation. It is not necessary that the final result is found immediately from an adfected quadratic. I almost think that any other way of solving the equation in a satisfactory way is impossible. Usually, when engaged with such an equation, I consider a solution satisfactory which brings out the correct result in a correct way, without limitation to any one method. According to my opinion, the advantage of a method is that it gives a definite mode of attacking a problem, while at the same time one is not rigorously bound to the method throughout, and so may make a departure from it, if it be likely to prove either easier or more serviceable. But then, in the present case, an adfected quadratic was wanted, and this condition I have tried to satisfy. I do not know how far I have succeeded, but humbly submit my solution to your and my opponent's criticism:—

$$x + y + z = 11 \quad \text{(i.)}$$
$$x^2 + y^2 + z^2 = 49 \quad \text{(ii.)}$$
$$yz = 3x(z - y) \quad \text{(iii.)}$$

Since—

$$2yz = (z - y)^2 - (z^2 + y^2)$$
$$= (z - y)^2 - (49 - x)^2,$$

we have, by (iii.)—

$$(z - y)^2 - (49 - x^2) = -6x(z - y)$$

or—$(z - y)^2 - 6x(z - y) - (49 - x^2) = 0$ (an adfected quadratic).

$$\because z - y = -3x \pm \sqrt{49 + 8x^2} \quad \text{(A).}$$

Again, by (i.) (ii.) $2yz = (y + z)^2 - y^2 - z^2$
$$= (11 - x)^2 - (49 - x^2)$$
$\because$ by (iii.), (A) B $= 2(36 - 11x + x^2)$ .... (B).
$$36 - 11x + x^2 = -9x^2 \pm 3x\sqrt{49 + 8x^2}.$$
Or, $10x^2 - 11x + 36 = \pm 3x\sqrt{49 + 8x^2}.$
$$\because 100x^4 - 220x^3 + 841x^2 - 792x + 1296 = 441x^2 + 72x^4.$$
$$\because 7x^4 - 55x^3 + 100x^2 - 198x + 324 = 0$$
$$(x - 2)(7x^3 - 41x^2 + 18x - 162) = 0$$
$$\because x = 2 \quad \text{(C).}$$
$$\because y + z = 9$$
$$yz = 6(z - y) \quad \text{(E).}$$
$$y^2 + z^2 = 45 \quad \text{(D).}$$
By (C) (D) $yz = 18$
$\therefore$ by (E) $z - y = 3$
and by (C) $z = 6$
$y = 3$

—A Medical Student.

[46852.]—**Swollen Glands.**—Let "Inquirer" use a "wet bandage," fastened round the affected part, every night, viz., a pad of linen three or four folds thick, wetted—and squeezed not too dry—outside this a thicker and larger pad to check the drying of the wet one; fasten all round the neck, or the head, according to the situation of the swellings. Put on so tightly that air shall not get in between the wet bandage and the skin, but not so tightly as to impede circulation by pressure. Apply for weeks or months until the lumps are dispersed. In the morning, rinse the pad in clean water, and dry it for use next night.—Experience.

[46900.]—**Mounting. Micro. Lens.**—For mounting a plano-convex with the plane side outside, turn a concave shoulder into which the lens will fit, as truly as you can turn it; then turn a sharp bevel, not a long one, but short and sharp, so that only a little will roll over; put lens in position, hold it there, and burnish over. It requires care, but you would soon do it.—W. J. Lancaster.

[46903.]—**Electric Bell.**—Make the bobbin same thickness as the diameter of core, then let the armature be $\frac{1}{8}$in. away from poles when at rest; then paste on the inner side of armature a piece of thin cardboard; this will prevent the armature sticking, and will prevent any jarring noise.—W. J. Lancaster.

[46905.]—**Incandescent Lighting.**—The question put by "Seaweed" cannot well be answered without trial. The battery named is not suited to the purpose; but if "Seaweed" has the cells and the lamps, he might try for the benefit of fellow-readers.—J. L. M.

[46940.]—**Soap-Making.**—To determine approximately the amount of soda in the leys, "Svenska" must ascertain the specific gravity of the solution—by means of a hydrometer, or otherwise—and then refer to some table which gives the percentage of soda in solutions of different densities. (Bayley's "Pocketbook for Chemists," Spon, 5s., contains the required table.) "Svenska" would, however, obtain a far more accurate result if he determined the amount of soda by means of a standard acid solution. So many degrees "B." denotes so many degrees of Beaumé's hydrometer; a table comparing the degrees of the hydrometers of Beaumé and others, with specific gravity degrees, is also given in Bayley's admirable little book.—Pygmalion Phibbs.

[46941.]—**Soap-Making.**—I have not noticed an answer to "Svenska's" question, and I only write a line to tell him to beware he don't get the Excise upon him, which, unless things are altered, he may do.—Edw. Thos. Scott.

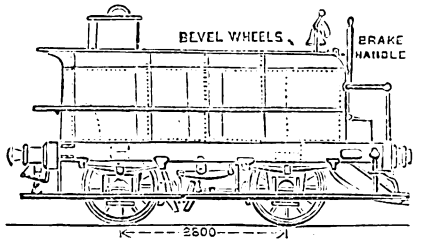
[46944.]—**To Mr. Lancaster.**—Perhaps the simplest method for you to adopt is to drill a hole into the top of the carbons, right through, then widen the hole in the centre, run a wire through, and fill up the hole with solder, then take the wire upwards, and soak the whole of the upper part of the carbon in melted paraffin, and you will have a connection that will last a long time.—W. J. Lancaster.

[46945.]—**Leclanche Battery.**—The carbon, &c., will do again, but you had better have new porous pots; the old ones would be a source of annoyance if used again. Well wash the carbon, &c., before putting into cell again, and add some fresh manganese. Ordinary sal-ammoniac answers every purpose; there is no necessity to pay a high price for it.—W. J. Lancaster.

[46958.]—**Half-Chronometer.**—In correction of reply to same by "T. M.," I beg to say that the reply by G. H. Stockton, which appears on p. 270, is a correct description of the escapement called "Morton's patent," to which the term "lever-chronometer" or "half-chronometer" is quite applicable. But his remark that "it is not liked by watchmakers" is only partially correct. I have never met with any who thoroughly understood it who had any objection to it. It is no more difficult to adjust or repair than the chronometer, or even the lever escapement, and as a pocket timekeeper it is much more reliable, being less influenced by any shaking or motion to which it may be subjected when being carried in the pocket. "T. M." says that "Morton's patent is an escapement never used." To the contrary, I may state that before commencing business on my own account, I was employed by Mr. Morton in the manufacture of his patent watches until he left Liverpool, and afterwards by the man who bought an interest in the patent, during which time a great number of them passed through my hands. Since then I have had many of them in hand for repairs, &c., and only a few days ago I had one to clean. With regard to lever watches being passed off as chronometers, I can only say that I never knew of it being done by any practical watchmaker; but, unfortunately, too many jewellers, drapers, tailors, and such people have lately gone in for the sale of watches, and they mark them up and represent them as being all that is wonderful and good, without having the slightest knowledge of what the articles really are; so whoever goes to buy from them, instead of from practical men who have reputations at stake, must expect to be served accordingly. Plenty of people have the ambition to be possessed of first-class watches, but begrudge a reasonable price for them, and it is such bargain hunters who are always taken in by unscrupulous traders, who are always ready to humour such customers, and extract the money from their pockets by representing the articles as being worth three times as much as they are asking for them, said articles being got up to imitate genuine ones, and to deceive the unpractised eye.—J. C., Liverpool.

[46962.]—**Stereoscopic Camera.**—I gave, some time ago, all the information you require about making a camera, and all that you will have to do will be to make the camera to take a plate 6$\frac{3}{4}$in. by 3$\frac{1}{4}$in.; then have a division in the centre of the camera to keep the two halves distinct, and use two lenses. "Le Merveilleux" is the kind of camera you should make, and the easiest way to go to work would be to make two bodies, 3$\frac{1}{2}$in. square, instead of one wide one, with a division in the centre.—W. J. Lancaster.

[46986.]—**French Locomotives.**—To Mr. E. E. R. Tratman.—The sketches I sent were the elevations of standard fast locomotives for the Western and Northern Railways of France. For ordinary and goods trains there are special types that mark an epoch in the history of the French locomotives. The single driving-wheel engines are not now used for main or branch traffic. These engines have been transformed, either into four-coupled ones or into tank-engines only. We must except, however, the following companies:—Paris-Orleans, two types: the oldest, by C. Polonceau, was built in 1855, according to what is named here, the Allan or Crewe type; the more recent by M. Forquenot, inside frame, outside cylinders and valve gear. The Northern Railway, along with the Eastern, still use the Crampton, the former for the tidal trains. The Paris, Lyons, and Mediterranean Railways had also Cramptons, but, through pressure of traffic, they had to build more powerful engines (1868), and so they sold their Cramptons to the Northern. I must not forget to say that the Northern was the first to adopt this beautiful engine in 1847, whence Mr. Crampton made his money. The adoption of this peculiar system marks the beginning of a new epoch in French practice. Afterwards, the French locomotives borrow from the Crampton all their leading features; the boiler, the regulator-box, the outside gear, mounted on a return crank, designed by Sangnier; all these improvements have originated with the adoption of the Cramptons. The result was, also, that from that time, express outside cylinders would be preferred, since facilities were provided for putting the gear outside. But the Northern Railway of France seems to have taken lately to the reproduction of English practice. I am sending a sketch of the tender of the Western engines. I am sorry I cannot get that of the Northern, as they were only beginning to design it when I left France. It is very difficult to understand why the majority of our tenders in France are only four-wheeled. This one is also mounted on four wheels. It is built like the Great Northern and North-Western tenders—viz., with timber and frame-plate for the carriage. Stilman's brake is used, as is so favourite with the Western of France; this disposition does not at all preclude the use of the Westinghouse brake-cylinder; on the contrary, the Westinghouse disposal is a powerful complement of this peculiar sort of brake. The bell on the tender is for the use of the train's guard; but, as the Westinghouse Company have found that their brake can be made a means of communication between driver, passenger, or guard, this bell is not so important now as it used to be. The following are the dimensions:—Wheel base, 2,800mm.; diameter of wheels, 1,120mm.; Contents of tanks, 6,500 litres; weight full, 21 tons. Plate thickness: External, 4·5mm.; horseshoe, 4mm.; top and bottom, 5mm.—ED. GOBERT, B.Sc., Islington.



[47001.]—**Miniature Electric Light.**—To MR. LANCASTER.—You can have a small globe containing a short piece of platinum wire, and carry some Leclanché cells in your pocket; or you can have chloride of silver cells. But at the best, it is not worth the trouble and carriage.—W. J. LANCASTER.

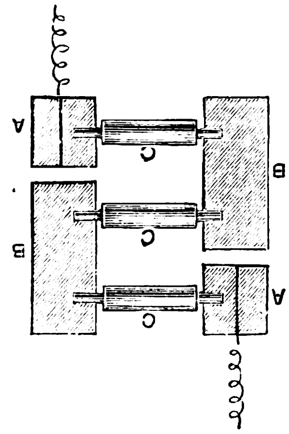
[47007.]—**Photographic.**—Probably, owing to small air-bubbles adhering to the surface of the plates, and preventing the action of the developer. If rocking the tray does not remove them, touch them with the tip of the finger or a small, soft-haired brush. To remedy any which should be overlooked, spot out on negative with black varnish, and on prints with suitable colour. To prevent frilling, if treatment with common alum, as per Swan's instructions, does not answer, try chrome alum, about 20gr. to 1oz. water.—W. ROBINSON, JUN.

[47010.]—**Magneto-Electro Machine.**—Of course you can magnetise the steel magnet with the current from 60 Smee's cells. Wind three or four coils of insulated wire from one end to the other, then send the current through until the magnet will hold up at least 7lb. when the circuit is open. You can use the electro-magnet instead, and magnetise the steel with it, if you have the electro-magnet already made.—W. J. LANCASTER.

[47011.]—**The Voice.**—Good singing is dependent on command of the breath and the muscles of the vocal organs, on good quality of tone, and clear, active pronunciation. Sustaining power can be gained by singing a steady tone until it is possible to hold on for nearly a minute. Inspirations should always be through the nose. The lungs should be filled from the bottom first. The shoulders should on no account be raised in breathing. Good quality can only be produced by making the tones "forward," or by directing the breath to the lips. Nasality is corrected by practising the gape. Flexibility or agility of voice is best attained by practising the interval of a semitone to the word "koo." Strength of lips, tongue, and throat is obtained by practice of alliterative groups of words introducing labials, dentals, and gutturals. Hoarseness and dryness of the throat during singing are often caused by nervousness. The best remedies I have met with for sore throat are Phelps Brown's catarrh cure and an iron tonic, both used as gargles. It is impossible to do justice to this subject in a condensed reply. If the Editor thinks a few articles would be useful, I shall be glad to write them. I shall also be glad to receive any communications, and will reply to any queries which I am able to answer.—J. WALLIS, Ryde, I. Wight.

[47012.]—**Transmitter.**—A pair of Bell telephones will do all you require, and will save a lot of trouble in keeping in order. The articulation of the "bell" is much purer than in the loud-speaking transmitter. You can get any amount of noise, but the articulation is nothing like so clear for so short a distance. I would have a pair of "Bells." You would find a speaking-tube much less trouble than the telephone, and really more efficient.—W. J. LANCASTER.

[47012.]—**Transmitter.**—I inclose sketch of a transmitter which I have found to give good results. The two carbons A A are $\frac{3}{4}$in. square; B B are the same thickness, but $1\frac{1}{2}$in. long; the three rollers C C C are 2in. by $\frac{1}{4}$in., rounded at the ends, and are fitted loosely into the carbon-blocks; a piece of copper wire, 24 gauge, is twisted round the two carbons A A—one end to telephone, the other to copper of battery. The four carbon-blocks are glued on a piece of pine $\frac{1}{4}$in. thick, which forms the lid of a box 9in. by 7in. by 3in. Any question answered.—ELECTRIC.



[47015.]—**Greenhouse.**—Why not cut them square and put an extra pane in. You can get an efficient glass-cutter for 1s. 6d.—W. E. K.

[47016.]—**Repairing Ebonite Dish.**—I should use a little guttapercha applied with a hot iron.—W. ROBINSON, JUN.

[47018.]—**Mus. Bac. Degree.**—To take this degree in Trinity College, Dublin, the candidate must be matriculated in arts, and must pass an examination in the following subjects:—1, English composition, history, and literature; 2, a modern language (Italian, German, or French); 3, Latin, or, instead of it, a second modern language; 4, arithmetic. He must also compose a piece of vocal music, of which a portion at least shall be in five real parts, with accompaniments for a stringed band or organ; this composition, if approved of by the board, is to be publicly performed, in such place and manner as they shall direct, at the expense of the candidate. The candidate must produce a certificate proving that he has studied or practised music for seven years. Before the private grace of the house is obtained, the candidate must pass an examination in the theory and grammar of music, and in thorough bass. He will also be required to write extempore, and within a given time, a piece of counterpoint on a proposed subject. Now, as to fees. In order to matriculate, the candidate will not have to pass any examination except that mentioned above; but I believe he will have to pay the regular entrance fees of £15, which also keeps his name on the college books for the half-year then current; if he does not complete the entire matter during that half-year, he will have to pay £8 8s. to keep his name on for the next half-year, and the fee for the degree is £10 unless the candidate is already a graduate in arts, in which case it is £5: there is also a fee of 30s. for the "Testimonium" of the degree. The half-years commence on 1st April and 1st October, and commencements at which the degrees are conferred are held in October, December, on Shrove Tuesday, and in July. The full score of the musical composition required for the degree must be lodged with the Senior Proctor one month at least before the commencements at which the degree is to be conferred. This is about all the information I can give; but the querist, if he has any idea of taking out the degree in Dublin, should write to Sir Robert P. Stewart, Mus. Doc., Professor of Music, Trin. Col., Dublin, for particulars of the various examinations, and the best time to go in for them; he should do so at once, as the long vacation will shortly commence, and no one will be in college till October. As to time it will take, if querist is able to do it, he can have his degree by Christmas, or, at any rate, by Shrove Tuesday, but, of course, it is impossible to tell how long he will take to prepare for the examination. By the way, does "Medical Student" really know anything about musical degrees at the English Universities? If so, there must have been great changes, at Oxford, at least, of late years, as some years ago residence was certainly not required for musical degrees at Oxford, but I can give no particulars of what is required.—G. J. H., M.A., T.C.D.

[47020.]—**Mus. Bac. Degree.**—Residence used not to be required at Cambridge for a degree in music, but many changes have taken place of late years. A letter addressed to the tutor of any college (Pembroke, Caius, Trinity Hall, for example), would receive attention, and the inquirer would obtain all particulars.—ROSICRUCIAN.

[47020.]—**Mus. Bac. Degree.**—Residence for musical degrees is *not* required either at Cambridge or Oxford. It is necessary first to pass a preliminary Arts test; certain sections of the senior local exam. will suffice. All particulars may be obtained from the University Calendar.—A MUSICAL STUDENT.

[47023.]—**Sea-Sickness**—If the querist will refer to a reply on this subject in Vol. XXVII., p. 532, he will find a remedy on the principle of Dr. Edmunds' recommendation to adapt his body to the motion of the vessel. The reply referred to gives details of how to do this. Lately, I was told by a person who had tried it, that it was successful.—BRICKWALL.

[47032.]—**Stonehenge and Sun Worship.**—In letter 20088, "A Fellow of the R.A.S." promises "Neo" some information about the point of earliest sun-rising. Will he please do the same for me with regard to Stonehenge, as it is very probable that I shall be there at the right time to make a few observations; and should any results accrue, they shall be reported. I think Sun Worship should not have been entered into the question; it seems more likely that the stones which we are noticing—i.e., those pointing towards earliest sun-rising—were placed there for astronomical purposes.—H. STOOKE.

[47034.]—**Dog-Chuck.**—"E. D.," in your number for May 26th, asks for a description of a dog-chuck. The only one I know of that name is an ordinary face-plate used with dogs for gripping work by the edge. Fig. 1 is a front view of same, showing four dogs in position, with pinching screws set radially; but they may be turned round in any position to suit shape of work. The face-plate may be merely drilled with a number of holes, or have four radial slots for use with holding-down bolts, and a number of holes in the intermediate spaces, as well as in the one shown. Fig. 2 is an enlarged view of the dog; it consists of a square-headed bolt, with another screw tapped crosswise through the head. The shank of bolt is inserted in whichever hole on face-plate suits, and is clamped by the nut at back of chuck; the shank should be left as

FIG. 1.

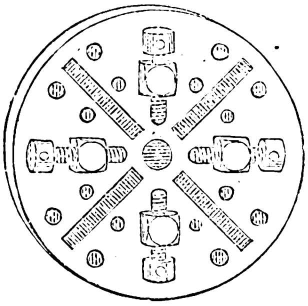


FIG. 3.

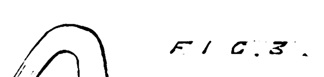

FIG. 2.

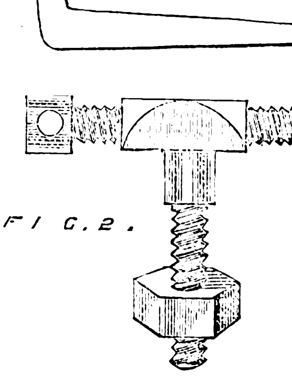


long as possible, as it is often necessary to raise head of bolt on washers to suit different thicknesses of work. The heads of mine are 1in. square and ½in. thick, the pinching-screws are ⅜in., and may have a travel of 1in. The plain part of shank is ⅜in., and the screw part ¼in. diameter. Fig. 3 is a Tommy to be used in turning the capstan heads of pinching screws. I often use these dogs on the catch-plate of my lathe when turning square bars of wood or iron between centres, and they serve as both carrier and driver-arm.—F. W. G.

[47035.]—**Safety-Valve for Kitchen Boiler.**—Mr. C. Stuart, of Bletchley Ironworks, makes a novel safety-valve for kitchen-boilers. If you communicate with him, I have no doubt he will send you full particulars of same.—H. A.

[47042.] — **Fixing Alarum to American Clock.**—In these days of electrical science you should state whether you require a mechanical or electrical alarum. Say if latter, and I will reply.—H. Stooke.

[47043.] — **Camera.** — The lens described I should take to be a quarter-plate one (4¼ by 3¼), but the front combination used alone for landscape purposes would probably cover at least half-plate size (6½ by 4¾).—W. Robinson, jun.

[47051.]—**Crutches, &c.**—Tough wood, not too light, is what "R." wants. He will find ash about the best timber to use. On his own (or his joiner's) judgment rests the choosing of a straight-grained piece. We have had more than a little experience in our family.—H. O'B.

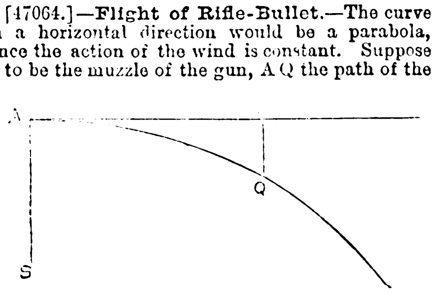
[47053.] — **A Question for Spectrum Analysts.**—Ground glass has no effect whatever upon sunlight beyond softening and diffusing the rays. Unless, therefore, there is something peculiar about the composition of the glass which would render it unsuitable even if unground, some other cause must be sought for the plants failing.—W. Robinson, Jun.

[47062.]—**Plaster Casts.**—Soak the casts in milk, add an atom of boracic acid to keep the milk from turning. When dry, the casts will take a good polish.—Zelia Naien.

[47062.]—**Plaster Casts.** — Casts ought to be left alone after they are taken from the mould, unless the querist understands anatomy and drapery. If he will write again and tell me whether the casts are from a piece mould or waste mould, I might be able to help him. The cast can be made to look a slight creamy yellow if he oils it with boiled linseed-oil, taking care to evenly cover the cast, and that no froth-bubbles are in the corners.—Sculptor.

[47064.]—**Flight of Rifle-Bullet.**—The curve described will be a parabola, with the muzzle of the gun for vertex, since the force of the wind is a uniformly accelerating force. In calculating the deviation in horizontal direction, we may imagine that the force of the wind is the only force acting upon the bullet. Let a denote the acceleration in feet per second of the force of the wind, S the deviation in feet in the time t. Then $S = \frac{1}{2} a t^2$ $\therefore a = 1 / t^2$, since here S = ½ft. Now since the horizontal velocity of the gun is uniform, if the bullet travels 100 yards in time t, it will travel 200 yards in time $2t$, and so on; therefore, in above equation, substituting the value $1 / t^2$ for a, and for t the successive values $2t$, $3t$, $4t$, &c., we get for the deviations at 200, 300 yards, &c., 2ft., 4½ft., 8ft., 12½ft., 18ft.—Slide.

[47064.]—**Flight of Rifle-Bullet.**—The curve in a horizontal direction would be a parabola, since the action of the wind is constant. Suppose A to be the muzzle of the gun, A Q the path of the bullet, and A P a horizontal line. Let P Q be drawn perpendicular to A P. Then by conic sections we have the formula—$PQ^2 = AP^2 / 4AS$; where S is the focus of the parabola. Since the deviation at 100 yards is 6in., we find from the formula, A S = 15,000 yards. $\therefore PQ^2 = AP^2 / 60{,}000$, from which we get required deviations; i.e.,



at 200 yards 24in.
at 300 yards 54
at 400 yards 96
at 500 yards 156
at 600 yards 216

—Hemisus.

[47065.]—**Gaiffe's Medical Battery.** — The cause is that the resistance of the primary suits the cell.—George Tolman.

[47067.]—**Dynamite.**—1. By all means put it in a hole bored for the purpose—in a root as near the centre of the solid part of the root as possible—not the stem, but root; and it breaks better. The stem is more apt to split, but plenty of power will smash it in any case; in a rock towards the centre, but about 9in. deep in a stone 30in. diameter is ample. Avoid drilling into or to a joint, it will take from three to six times the quantity if applied loose on the top or bottom. It is a sheer waste of money to use it so upon roots. 2. All nitro-glycerine compounds will give you a fearful headache after explosion—*i.e.*, the fumes, and much more so if the explosive is burnt and not properly exploded; but all miners avoid going into it till the fumes have cleared somewhat. Dynamite is the worst for doing so, owing to its high percentage of nitric acid which is diffused, as it were, into a fine spray at the explosion, and is inhaled by the men. If you handle it freely or smell at it strongly, you will soon find the headache, and perhaps the most agonising one you ever had; but miners seem to get wonderfully used to it. 3. For that particular purpose dynamite is best—powder is next to useless. For general mining work, dynamite for all wet, close-cornered, or bad ground, still keeps the lead; but otherwise it is quite worth a user's time to see what lithofracteur and tonite will do. Tonite has of late made good improvements, that it amounts to a question of time to prove which is the best universal explosive for mining purposes.—M. C.

[47068.]—**Swelled, &c., Knees and Joints.**—I have proved the efficacy of the two following remedies:—For any swelled or stiff joint, from whatever cause—if the bone seems to be affected—use a poultice of the green herb called "Mouse-Ear Chickweed." It is now (June and summer months) well in season. Chop up fine a good handful of the green plant, put into a clean pan with some nice sweet lard; stir them together over a clear fire until you have the herb cooked enough to make a nice soft poultice. Pour this out into a double piece of rag, and bind it, nicely hot, upon the affected part at bedtime. Of course, you wrap all up warmly. Renew the poultice in the morning. Three or four days should produce considerable improvement. This plant is coarser and larger than the common chickweed. Another: Make a poultice of white bread, or of fine oatmeal very well boiled: sprinkle the surface well with finely-ground cayenne pepper, and apply it to the weak limb, the pepper next the skin. It may be renewed after a few hours—that is, when its peculiar stinging has subsided, and before the poultice becomes dry, which makes it stiff and uncomfortable, as well as useless. I knew a case of incurable disease of the knee-joint, the patient suffering agony when the paroxysms of pain recurred, continually disturbing sleep—a case of years' standing, and quite beyond recovery—but through the soothing effect of cayenne poultices at night, sleep was obtained for five to six hours at a time—sound and refreshing sleep!—greatly to the astonishment of the attending M.D., who had believed that he had previously exhausted all the resources of science, but could not equal the cayenne. It rouses nature to a more vigorous healthy action, and thus promotes the restoration of health.—H. O'B.

[47068.] — **Swelling and Pain about the Knees** —From the description given by "Pontus" of his son's knee, I should think it is very much like, if not the same, as my wife suffered from some 14 years since. If so, and if what I strongly advise him to try does him any good, I shall be amply repaid from the trust placed in my recommendation. My wife's knee got bad very suddenly from a cold caught from walking through some fields. She went to a ball on the Wednesday; on the Thursday she took this walk, and on the Friday morning, about 11, feeling something serious the matter, she sent for the doctor; and when I say she was on her back from that day for three months, you will own she was very bad. The remedy consisted of hot bran poultices applied every quarter of an hour—at least that was the doctor's order—but it could not be done oftener than every 20 minutes at first, owing to the very great difficulty in being able to get them ready. We tried by making them with fresh bran and boiling water; then by pouring fresh hot water to the already-made poultices, and squeezing the surplus water from them; next by emptying the bran into an iron saucepan; but this was found to burn very quickly, and before the bran got hot enough, for you must bear in mind we were limited to, if possible, a quarter of an hour; and, lastly, we were recommended what turned out to be the best of all—viz., to put the (newly-made) poultice into a flannel bag, and sew the end up flat. This was always put into a steamer over boiling water, and the steam playing round it penetrated it so thoroughly that it was always hot enough by the time it was wanted. It must be understood that two poultices were in use at the same time, the one getting hot while the other was on the knee—and they were always placed on as hot as it could be borne on the back of the hand. The clothes were lifted up at the side to change the poultices, which was done for over two months every twenty minutes, night and day, three of us taking our turn to attend to it. Towards the last the knee was painted with iodine, and the leg was put in a guttapercha splint, with the knee slightly bent. This was kept on some little time after she got up; but not being able to use her leg she was at first carried up and down stairs; then the leg was supported while she lifted herself backwards upstairs. After a time she used crutches, and about eight months after that she went to Buxton to the baths, and it was not till she had been there some time that she was able to get about with one crutch and a stick, but when she left she used a stick only. Altogether, she used crutches for twelve months. She can now walk very well, but cannot bend that leg more than at right angles—thus ⅂. The editor has my address, and I shall be very pleased to give "Pontus" any further information should he desire it. I might add, the complaint my wife had was "inflammation of the knee-joint," and caused an accumulation of some soft matter on the upper inside part, and just above the knee-cap, and shows itself now at times very plainly, especially when she has over-exerted herself.—Cured.

[47069.]—**Fruit-growing.**—There is no scarcity of books on this subject—quite the contrary. Your correspondent will find a good one by D. T. Fish, called "Hardy-Fruit Gardening," I think, published at 170, Strand; and the *Journal of Horticulture* office, Fleet-street, also publishes handy books on the subject. Any bookseller up to his business will have a list of the published books, and will be able to give the querist hints as to what will suit him.—Nun. Dor.

[47073.] — **Astronomical Eyepiece.** — The dulness "Tiro" mentions is more likely to be caused by the lenses of the eyepiece having lost some of their polish than through the greenish hue of the object-glass. I have myself a 7in. object-glass—said to be an original Dollond—with just the same tinge, and have no reason to complain of the quantity of light it transmits. I do not say it might not be better if the glass were clearer, but there are a great many chances that it would be nothing like as good, for with all possible objections against lenses of this tint, there remains a pretty fair certainty that they were turned out by the hands of a master who would rather smash a dozen glasses than allow a faulty one to leave his hands. For celestial observations some light would be gained if the erector were removed: there would then remain a Huyghenian eyepiece of low power (perhaps 20 diameters), which would be very suitable for observing nebulæ and star-clusters, and would, perhaps, serve for picking up the lost comet. I have also very usefully employed one of the astronomical eyepieces from a "combination" telescope; these may be bought at about 5s., and if too small to fit the tube, might be made larger by rolling round it a piece of cloth. A Ramsden eyepiece, though not quite so achromatic, is, perhaps, better adapted to a small aperture, as it will give a larger and flatter field. It is also much easier of construction, and "Tiro" would gain much experience by trying his hand at making one. For this purpose, it will only be necessary to prepare a tube of brown paper to fit the eye-tube; this should be 1½in. long, and fitted with an inner tube of the same material, ¾in. long, for the lenses to bed against. The lenses should be plano-convex, both of 1in. focus, and placed as in the diagram on page 259. They may be kept from shifting by placing spare pieces of the inner tube at their outsides. If the insides of the lenses are carefully cleaned before placing them, these pieces of tube may be glued in, as the lenses would never require taking out; but before doing this it would be better to ink the insides of the tubes. Such an eyepiece would give a power of about 40 diameters, and would, I am sure, be altogether so satisfactory that "Tiro" would not be long before he attempted others of greater pretensions.—Aldebaran.

[47077.]—**Casehardening.**—I don't think that K. Paxton (page 315) has any practical knowledge of casehardening; 'tis something novel to my experience to be told that soaking iron in "coal-dust" will convert any part of it into steel. My "Nut" thinks that the oftener steel be "stewed" in a coal fire, the worse for said steel, but the more 'tis hammered (whilst kept square in section) the better will its nature become. (Memo.—This also applies to malus puers). Healthy pabulum for good steel is to be found in a "charcoal fire" only. As to casehardening I would say, if a piece of gas-tubing is not to the fore, rivet up a box of sheet-iron, "fill it with hoof parings and any waste leather do."; rigidly exclude Messieurs Coal, Sulphur, and Co.; lute up the end with clay, and keep at a red heat for three or four hours; take out with a tongs, loosen the clay and plunge the whole concern quickly (before the air has time to act) into a tub of water. (Memo.—Prussiate of potash is the "thinnedest, skinnedest coverer conceivable").—J. J. A., Liverpool.

[47085.] —**Dynamo-Machine.** —To George

Tolman. — Your field-magnets are too small. What is the resistance of the wire on the ring? How many layers on each coil and rows of wire?—George Tolman.

[47086.]—**Picture-Frames.**—I fear that "Salt," page 315, is at sea and out of his latitude when he applies to an ordinary "picture-frame maker" as to matters of taste. I recently procured some mahogany board 1in. thick, sawed it up into strips of various breadths, planed out groove for glass, half-checked together, similar to an Oxford frame, average breadth being 1⅜in. for a picture of 20in. by 14in., got up smooth on front and sides; left some the natural colour; stained others with logwood, "Stephen's stains," then French polished; a gilt, ornamental brass nail (of cruciform shape), in the centre of each of the four intersections. This makes a nice, novel frame, and will last for ages. It is an improvement, then, to frame up the landscape, &c., in ordinary German moulding—viz., frame, glass, mount, and backboard, and then slip this into a frame of mahogany, a couple of sprigs keeping it in situ. I may say that I designed this specially for water-colour subjects provided with large, white mounts, and cannot say what would be the effect in contrast with "oils."—J. J. A., Liverpool.

[47087.]—**Small Launch.**—I would advise "Mariner" to have all his arrangements as to build of boat, boiler, machinery, &c., settled before commencing any one portion, as all depends on suitable combinations. Opinions will differ as to beam, &c. A boat of light build, 18ft. long, with 5ft. beam, should have a speed of 12 knots under favourable circumstances; of course, less in rough weather. I shall be constructing a boat of light draught of "Mariner's" proportions, and shall insure her to course 15 knots an hour. If "Mariner" will send me rough sketch of his lines, I will inform him how he may (with the assistance of any carpenter), quickly build his launch in the very best and cheapest manner; and with the Editor's permission, I will send simple diagrams, with brief description for publication in English Mechanic.—W. H. Phillips, Linden Grove, Nunhead, S.E.

[47090.]—**Tramway into Gravel-pit.**—What does Mr. Booker want to elevate the outer rail for? A horse condemned to walk up such an incline with a load behind him will not go at a dangerous speed, and there is no necessity, so far as I can see, to raise the outer rail at all. Still, it may ease the labour, if your correspondent raises the outer rail, say ½in. I shall watch the replies to this question with some attention, for I am not clear whether any advantage would be gained by elevating the outer rail.—Nun. Dor.

[47094.]—**Combustion of Coal.**—12 of carbon require 32 of oxygen for complete combustion, and 2 of hydrogen require 16 of oxygen—88·42 carbon require, therefore, 88·42 × 32 / 12 = 235·79, and 5·61 hydrogen require 24·88, or 260 67 in all. Since the coal contains 5 97 oxygen, we shall have to supply 260 67 − 5·97 or 254·7, which (since air contains 23 per cent. of oxygen by weight) is contained in 254·7 × 100 / 23 or 1107·4 of air. Consequently 20cwt. of coal will require 221·5cwt. of air.—X. N. X.

[47094.]—**Combustion of Coal.**—Dividing the quantities of C H and O by 5 to get the contents of 20 cwt. gives—

Carbon	17·684 cwt.
Hydrogen	1·122 ,,
Oxygen	1·194 ,,
	20·000

In complete combustion carbon burns to form CO_2—i.e., 12 C combine with 16 × 2 = 32O, so that 12 : 32 = 17·684 : 47·157 gives quantity of O required for the carbon. Air has 23 per cent. O by weight, thus 23 : 100 = 47·157 : 205 cwt. = weight of air required. In like manner we may find the air required for the H, remembering that this forms H_2O in burning completely, and that there is already some O combined in the coal.—Chromio.

[47094.]—**Combustion of Coal.**—The querist gives the assumed composition of a coal, and asks to have it explained to him in plain figures. Now, to find the amount of air needed for the combustion of one ton, I am not quite clear as to what he means by "plain figures," but will endeavour to make the calculation as simple as possible, at the same time telling my friend that he will certainly not understand it unless he knows a little elementary chemistry. One ton of the coal contains ·8842 ton of carbon, which burns to carbon dioxide as follows:—

$$\begin{array}{ccccc} C & + & O_2 & = & CO_2 \\ 12 & & 32 & & 44 \end{array}$$

from which we have 12 : 32 : : ·8842 : x = 2·3579 tons. One ton of the coal contains ·0597 ton oxygen, which may be taken as being in combination with ·0075 ton hydrogen, leaving ·0486 ton available. Hydrogen needs eight times its weight of oxygen for combustion, therefore we get ·0486 × 8 = ·3888 ton oxygen, which, added to the amount required for the carbon, gives a total of 2·7467 tons. In air, only 23 parts in every 100 are oxygen, so we get 23 : 100 : : 2·7467 : x = 11·94. We thus find that one ton of the proposed coal will need nearly twelve tons of air for its complete combustion.—Wm. John Grey, Elswick Science School.

[47100.]—**Loco. Valve-Setting.**—To begin, you will require a trammel, pair of spring dividers, centre-punch, a piece of tin, and a brass plate—but a piece of tin will do; it is to put the opening of ports on. We will suppose the loco. is an inside cylinder, and valves ready to be put in place. You will put one valve and spindle in coupling it to guide, leaving it free from eccentric rods, and, with the strip of tin in front port, draw the valve-edge to it; then with trammel on steam-chest back, on a part of guide which does not become covered in the traverse of valve, put a small dot on line, then place tin in back port, pushing the valve-edge back to it, and mark again on guide. In most inside-cylinder engines you will have to take out the first valve to mark No. 2, because you cannot get your hand between to do it. Well, having done the same with No. 2, you can box-up valve-chest and couple-up eccentric rods; then, with reversing-lever in the second notch (which is the one usually run in), from centre or out of gear, back or forward, as the case may be, pinch the engine (not yourself), but some labourers, while you, with trammel, as each line comes to trammel-point, scratch on guide until valve begins to close again, catching each four ports; then, with dividers, measure each port or opening, marking down front and back port, right-hand fore-gear, or otherwise, as case may be. Well, if the marks on guide are equal, your rods are right; but supposing your front port largest, then your rod is short, and requires lengthening half the difference of the two circles or opening of ports, or shortening the same if front port is the least. The brass plate referred to, if "Dome-Joint" will look at it, he will find is marked with letters—at one end, fore-gear; at other, back-gear; then R.F. and R.B. (right-front and right-back), and L.F. and L.B.; so with dividers and width of marking from centre-pop on guide, you mark quarter-circle, so then when your valves are right the whole will be a complete circle. Anything not plain will answer further.—J. O. E.

[47105.]—**Enamel for Silver Prints.**—The following formula for an encaustic paste is given in the *British Journal Photographic Almanac*:—Pure wax, 500 parts; gum elemi, 10 parts; benzol, 200 parts; essence of lavender, 300 parts; oil of spike, 15 parts. For varnish, mastic is about as good as any, the prints being first sized with a solution of gelatine. Enamelling with collodion, however, gives the finest glaze, and if you think you would like to try the process I will give you particulars. Mr. Newman will, I feel sure, readily answer any inquiries as to his encaustic paste.—W. Robinson, Jun.

[47106.]—**Dry-Plate Photography.**—1. The "simple lens" referred to, although generally called a "single" lens in order to distinguish it from the doublets and triplets also used in photography, is not simple in the sense of being a single piece of glass, but is an achromatic combination of two glasses, usually of a more or less meniscus form. If, therefore, "F. J. N." used a simple meniscus lens, the chemical and visual foci would, of course, not be coincident, and an indistinct image would be the result. Good photographs may, however, be taken with such lenses if, after ascertaining the visual focus, the back of the camera be pushed in a little, the chemical focus being shorter than the visual. The exact distance can, however, only be found by experiment. 2. An emulsion is a combination of bromide, or other haloid, salt of silver with collodion, gelatine, or other colloid body; the term being used because the silver salt is not dissolved, but only mechanically mixed with the gelatine, or other colloid substance used. The changes which take place in gelatine during the process of emulsification are not very well understood. There is usually more or less decomposition dependent upon the time of "cooking" and temperatures employed, and also (I think) a certain amount of chemical combination between the gelatine and nitrate of silver used. 3. Yes, or if common alum does not answer, try chrome alum.—W. Robinson, Jun.

[47110.]—**Template.**—To hammer a sheet of iron or steel, so as to remove all "buckles," is no easy job for an amateur to tackle. In the first place, if a large sheet, we must be provided with a smooth-faced anvil, and the face of the hammer should be slightly convex, or the plate will be shockingly "dinted" when done. Now, let us examine the worst "bulge" on the sheet, carefully study its boundaries, and strike gently all round in gradually widening circles (taking particular care not to strike on any neighbouring bulge, but nicely up to its edge.) Mem.—It is very good practice to try the 'prentice hand upon a buckled tenon saw, or an ordinary sheet of tinned iron.—J. J. A., Liverpool.

[47112.]—**Welding Cast Steel.**—Take the following articles by weight:—5lb. of silver-sand, ¼lb. of common blue, ¼lb. of common soda. Mix together and use as sand.—J. W. Wood.

[47113.]—**Moderator Lamp.**—If the overflow from the wick runs down the outside of the wick-tube and into the reservoir in more than just quick drops, then the oil is "supplied too fast," and this can be remedied by taking off first all the movable brass rings and fittings on the chimney and globe-rests. There will then be exposed two screws, which hold the head of the lamp to the body, take out these—don't drop them inside—the head can then be lifted off *upwards*, a wire will then be exposed. This wire regulates the supply. If too little oil comes the wire is too thick; if too much, too thin; file or exchange as required. If the overflow is not large, then the leather piston is like to be at fault. To get at this the bottom must be unsoldered; take care to wind up a little way first, and make fast the winder until you take the bottom off, or you may burn the leather. Having unsoldered carefully, let the spring down again, clean the leather or supply a new one as needed; you can see for yourself.—Hoinos.

[47117.]—**Tinning Steel Wire.**—The following, taken from Spon's "Workshop Receipts," will perhaps give you the information you require. "Iron which is to be tinned must first be steeped in some acid material. Then scoured and dipped in melted tin, having first been rubbed with sal-ammoniac."—J. R. E.

[47122.]—**Size of Battery.**—You do not say what power your steam-engine is. If above a man-power, better say no more on the subject.—George Tolman.

[47122.]—**Size of Battery.**—You may use a bichromate bottle battery of a pint capacity for each gallon of water you want to raise 3ft. in an hour, but a larger size would be preferable, as it would not require charging so often. You must immerse the least amount of zinc surface that will do the work required. A bichromate battery more suitable to your purpose, and very constant in action, can be made if you put a large piece of carbon into a glass jar, and fill the jar half-full of carbon in small pieces, place the zinc element at the top part of the jar, and use the ordinary bichromate solution. A battery of this kind will drive an engine for a long time, and give no smell if the zinc is amalgamated. I shall be glad to give you any further information on the matter.—J. Sutcliffe.

[47125.]—**Transmitter.**—Certainly you can alter how you think proper, after you have paid for the microphone—not the cases or switch.—George Tolman.

[47125.]—**Transmitter.**—The instrument you describe is what is known as the "combination" instrument, and was designed simply on account of its compactness; but, after a fair trial, its use was discontinued as unsuitable. It is not a patent, and you may alter it in any way you please.—Yoshi.

[47126.]—**Electrical.**—The frost will not affect the working—perhaps crack the cells, which should be placed on a dry floor.—George Tolman.

[47126.]—**Electrical.**—Frost has a decided influence on the working of batteries, reducing considerably the E.M.F. The temperature could be kept up by a petroleum lamp or greenhouse-stove.—Yoshi.

[47130.]—**Decorating Organ-Pipes.**—If "J. E. B." refers to No. 421 he will find several very ornamental designs for organ-pipes.—Cymro.

[47131.]—**Pedal-Pipes.**—Scales:—CCC, 4¼in. by 3¼in.; CC, 3in. by 2¼in. (inside measurement). Lengths:—CCC, 8ft.; CC, 4ft. 2in. The above are actual measurements from a pedal-stop of Bourdon; the pipes, as will be seen, are of very small scale, and are well suited for chamber use. The lengths are taken from the top of pipe to the bottom of the mouth, a short length for tuning being included.—Cymro.

[47132.]—**Hæmorrhoids.**—Gather a handful of crane's-bill, put the same in a pint pot, fill the pot full of boiling-water, cover over. Drink half of this at night; fill up your pot again with water, drink the lot the two following nights. Many ladies and gentlemen whom I know have been entirely cured by this simple herb. If you do not know the herb or cannot get it, and will advertise your address, I will send you a fresh-gathered supply gratis.—Tom B.

[47133.]—**Gold.**—When auriferous iron ore is smelted, all the gold should pass into the reduced iron, from which it can subsequently be separated by fusion with lead.—A. K. Huntington, King's College, London.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

QUERIES.

[47136.]—**Mellogen $C_{11}H_2O_4$.**—This substance is said (No. 897, p. 280) to be obtained from the electrolysis of water by carbon plates. What is the theory of action? Is the carbon from electrodes dissolved by the current, or is the carbonic acid attracted from the atmosphere by the electric current?—ZELIA NAIEN.

[47137.]—**Wood-splitting Machine.**—I want a quantity of thin wood about $^1/_{16}$in. thick, similar to what toy-boxes are made. Will any fellow-reader kindly give a description of a machine for making same?—EVERTON.

[47138.]—**Tapering.**—Will any fellow-reader inform me how to taper or point small circular pieces of soft wood, about the length and thickness of blacklead pencil, the taper to commence about 2in. from the end, and terminate in a sharp point.—EXPERIMENTER.

[47139.]—**Staircase.**—Would any reader of this paper inform me how to put a well in a flight of stairs with four winders in the quarter-space, the string to be cut?—A CONSTANT READER.

[47140.]—**Ampere.**—Will "E." (who has lately favoured us with some capital "Notes on Dynamo-machines") thoroughly explain the electrical measurement known as an ampère?—H. STOOKE.

[47141.]—**Notes on Dynamo-machines.**—May I be allowed to ask our friend "E." what we are to represent the resistance as, which we read off the tan / A e, &c.? Is it noted in ohms? If so, will the resistance read true in ohms, taking the same scale as was used for lines A e, A c (Fig 1). Suppose a machine rotating at a rate of n times, and at that rate I have a current of ten ampères (A e), and the E.M.F. (A C) gives seven volts. Should my resistance read ·35, as being the best resistance for n revolutions?—H. STOOKE.

[47142.]—**Marquetry.**—Would some kind reader inform me how the burning or shading is done in marquetry work? I have a little of it to do;—one portion of it is in the form of a fan, one side of each blade is shaded to give a hollowed-out appearance. It is a pattern very often seen in old work for corner-pieces, &c. The other portion is a bird let out into a sycamore ground stained green. How am I to stain the sycamore green? where can I obtain marquetry veneers ready done in pattern? Also, some narrow stringing in black and white diamonds ⅛in. wide, such as is seen in workboxes of Tunbridge work?—J. R., Liverpool.

[47143.]—**Aluminium.**—I have discovered a method for obtaining aluminium (as an impure alloy with zinc) by a very simple and inexpensive process, direct from the ore which I employ. Will some kind reader give me an easy process to purify it?—I wish to make the process perfect before taking a patent.—ZELIA NAIEN.

[47144.]—**Bending Wood.**—Can any reader tell me how to make an apparatus for steaming and bending sticks of wood, 3ft. long, 1in. thick, and the best wood for bending?—W. P.

[47145.]—**Oil.**—I should be much obliged for a receipt for preparing and purifying light drying oil and linseed oil for mixing with artists' colours.—ROSICRUCIAN.

[47146.]—**Tin Plates.**—Can anyone tell me the process used in tinning the usual sheet-tin plates, as by using spirits of salts I do not get a clean bright surface? What I want is a clean bright surface without having to wipe them while hot, such as you get on tin plates.—A. G.

[47147.]—**Photographic.**—In the picture by an ordinary ¼-plate lens, distant objects, such as a house across a river, are very small. Would a half-plate lens amend this? If so, could the necessary lengthening of the camera be effected at the front end? I see Messrs. Lancaster advertise in "ours" an "instantograph" lens. I purpose purchasing one of these if any of the kind instructors of photographical tyros would please say whether it is possible to adapt it to my existing camera, and so that it could be used at will with its own lens?—PYRO.

[47148.]—**Fogging.**—I took ten views at Keswick on Whit Monday, but they are all more outrageously fogged than any in my previous experience. I changed the plates in a double thick black twill calico sleeve, perfectly light-tight. I wonder, as the calico smells of the size, whether this adulterant chemically affected the film. I am awaiting ferric oxalate to redevelop.—PYRO.

[47149.]—**Changing Plates.**—If plates are slightly cemented together by the back with a piece of black paper intervening, the difficulty of changing them into the dark slides in the field is minimised. As dealers do not supply them thus cemented, I shall be glad if any of "ours" would suggest the best cement, so as not to endanger the sensitive film by damp in the drying. Would a very narrow band of thin French polish painted round near the edge of the glass answer? If so, could the plates be at once replaced in the box, so as to avoid danger from light?—TYRO.

[47150.]—**Steam-engines.**—Will some competent engineer kindly advise me which of the two following engines will work most economically, giving his reasons? Boiler at 50lb., main shaft to run at 120 revol.:—Compound engine, high and low-pressure cyls. 16in. and 28in. diam., 3ft. stroke, 60 revols. per min., driving main shaft off flywheel pulley two to one, with ropes; or, inverted engine, two cyls., each 15in. diam., high pressure, condensing, 22in. stroke, going 120 revols. per min., driving main shaft with equal pulleys.—QUOD DIXI DIXI.

[47151.]—**Washing-machine.**—I wish to know the proper manner of putting axles in washing-machine rollers, if any kind subscriber would kindly oblige—M. H., Hoyland.

[47152.]—**Field-glass.**—How can I separate the lenses of a binocular in order to remove spots which have appeared in the cement. Is it necessary to recement them? If so, is Canada balsam the right thing to use? I would rather not attempt it, than risk injury to the glass, and shall be obliged for instructions.—SPOT-LENS.

[47153.]—**Weston Dynamo-machine.**—Seeing one of the above described in Urquhart's book on "Electricity," will any reader kindly say if a machine constructed on the following principles would generate sufficient current to light an arc or several 20-candle Swan lamps?—A piece of soft iron tube 3⅜in. diam., 9in. long, ⅜in. thick; this to be divided into eight equal parts on the circumference, and at each division a piece of iron ½in. by ¾in. fastened on with screws; in each division No. 16 double cotton-covered wire is wound about 70 yards in each section, making, in the four sections, 280 yards. Also, would it be advisable to build the machine on the shunt principle, or take the current direct to the lamps?—Which is the best? What current (about), if well constructed, will it produce in webers?—ENGINEER.

[47154.]—**To Dr. Edmunds.**—Will you kindly say what is proper diet, &c., for Bright's disease? My wife is suffering from this complaint, and a local medical adviser recommends sedatives—no beer or spirits. Being anxious, I sent her to a West-end physician, who prescribed just the opposite: pint of stout per diem, and gin at bed-time. On stating that she could not take beer or spirits, he replied that she must. Being perplexed what to do, she has asked me to write to you. Her legs swell slightly, and are rather painful;—been so, more or less, about six months. Otherwise enjoys good health—age 40.—CARBON.

[47155.]—**Boehm System.**—Can any of "ours" tell me of a work which embodies the Boehm system for wind instruments? I have purchased Boehm's "Ueber den Flötenbau"; but modern flutes are evidently far advanced beyond his treatise. I want some practical details of the principles, so that I can apply them to a—BASSOON.

[47156.]—**Varnish.**—Please say what sort of varnish is used for dipping small articles, such as hair-pins, &c., that would dry on them without the time lost in heating stoves for that purpose.—W. R.

[47157.]—**Heat.**—Will any of "ours" kindly give the figure representing the ratio of heat lost (by contact with cool air) from substances, with various differences of temperature, according to the experiments and formula of Dulong, and how it is got?—WHEATLEY HILL.

[47158.]—**Oil Immersion Objectives.**—Will some microscopist please give his experience of above in resolving diatoms compared with water-imm. lenses of our best makers?—H. W.

[47159.]—**Heating Greenhouse.**—I have a greenhouse in hand at the present time, which is a source of no little anxiety. It is situate against the back of a very large house on rising ground, and is thus very open. It gets a fair share of S.S.E and S.W. wind. It is fitted up with hot-water pipes, and heated by one of Wright's gas-stoves, about 8in. diam. and 20in. high. All things seem to go well until a down-draught occurs, and then the fumes from the burnt gas become unbearable, as the greenhouse is built round the dining-room window, so as to get in from the house, &c. The vent-pipe from the gas-stove has been taken to the top of the house. This was a great improvement; but still, when a strong wind, the mischief still went on. If any of our readers who have had any experience in these matters will kindly give their assistance, they will be conferring a great favour on—W. R. S.

[47160.]—**Recovery of Silver.**—Will one of "ours" kindly say how the silver can be recovered out of the lead lining of tea-chests? I am sure there must be a good deal of silver in this class of lead, from its behaviour in a galvanic cell, where I have used it frequently instead of silver plates.—POROUS CELL.

[47161.]—**Sulphate of Alumina.**—Will someone kindly describe the process for making sulphate of alumina from bauxite (on a large scale), and also say whether this mineral can be dissolved in hydrochloric acid?—CHROMIO.

[47162.]—**Water Spiders.**—I want some information as to the habits of these interesting insects from one who has kept them. What do they feed on? One of mine once took a fly down into his den. Will they live on peaceable terms with fish, newts, tadpoles, &c., or which fares worst?—JOHN ALEX. OLLARD, F.R.M.S., Enfield.

[47163.]—**Preparation of Bone for Turning.**—What is the proper treatment for bone in order to make it suitable for turning? Is it artificially dried, or simply left in the sun to bleach? How long a time are bones subjected to the drying process, and what means have you of knowing when they are in a condition fit for use?—DRY BONES.

[47164.]—**Microscopic.**—I should be glad if T. J. Sturt, M.D. (letter 20096), or Mr. Lancaster, would give the number and page of the "E. M." in which Mr. Lancaster mentions using a concave lens to increase the magnifying-power of the object-glass, and also if bi-concave means a double concave, or a meniscus spectacle lens? Is the lens above mentioned attached to the eye-piece, or used as an extra object-glass? Please to say in what position in the ordinary student's compound microscope the lens should be placed?—HANDY-MAN.

[47165.]—**Casehardening.**—Many thanks to Mr. Paxton for his answer, but it does not quite explain all I want. He does not say whether I am to immerse box and all in the water, or take out bearings and cool separately. These collars for ball-bearings must be thoroughly hardened, and I want to know how I can harden them so that the casehardened part shall be more than skin deep. Can it be done by heating the collars and dipping into prussiate of potash several times? Also, will the collars scale much in casehardening? If these collars were made of steel, would they be liable to fly in hardening?—CYCLE.

[47166.]—**Glaziers' Diamond.**—Had misfortune to break the spark. Will any correspondent please say if it can be reset?—W. L. P. P.

[47167.]—**Floor.**—In excavating for stores and kitchens under a new shop-floor, I have met with an unexpected and insurmountable difficulty (on account of the great expense)—viz., a solid bed of rough hard stone, judged to be about 4 to 6ft. thick, about 4ft. below the ground-level. Will some correspondent kindly inform me if I could have the shop-floor 2½ to 3in. thick to bear a weight of 3 or 4cwt. being turned on it instead of joist? I think if I had T-iron joist, say about 2½ deep by 5in. wide, but about 4 or 5ft. apart, and filled in between with 2½in. battens tongued or dowelled together, and rest on the inside flange of the T-joist, and screwed from the under side with stout wood-screws. Is this practicable? If so, what thickness should the iron joist be—rolled or cast? Which would be the strongest—battens put straight across from joist to joist, or at an angle? Any hints for a sound thin floor will be thankfully received. Size of floor 28ft. by 20ft. supported under about 14ft. from the end. Will my old friend, "Jack of All Trades" give me advice on the matter?—W. L. P. P.

[47168.]—**Tinning Copper Sheets.**—Will some of our able correspondents inform me how to tin copper sheets on one side? It is required for both common and burnished copper. A sheet measures 4ft. by 2ft. Any information on the above will greatly oblige—COPPERY.

[47169.]—**Throttle-valve.**—I am substituting a small brass "turn-off cock" (about $^3/_{16}$in. bore) for a throttle-valve of my model engine. I mean to affix the lever of the governor to the handle of this cock. I will thank any of "ours" for saying if this will suit as well as the common throttle-valve.—S. MURRAY.

[47170.]—**Blast-Furnace.**—Wanted to know the best method of arranging the charge of ironstone, limestone, and (fuel) coal or coke in a blast furnace in a chemical arrangement, showing each in their chemical order.—BLAST-FURNACE.

[47171.]—**Action in Voltaic Cell.**—Will someone kindly favour me with chemical equations representing the action which goes on in the Bunsen and bichromate cells?—S. H. SALT.

[47172.]—**G.W.R. (B.G.) Engines.**—Will "Clyde," or other correspondent, please furnish dimensions of the following?—Fenton, Gooch, Stag, Sharp, and Dewrance.—J. L. F.

[47173.]—**M.R. Engines.**—Wanted the original dates of the following, also dates of rebuilding and principal dimensions:—2, 3, 7, 23, 29, 41, 110A, 155, 161, 192, 330, and 382A.—J. L. F.

[47174.]—**32ft. Pedal Reeds.**—Can anyone give dimensions of tube-board for 32ft. pedal reeds to be placed under the instrument, and supplied by a separate wind-chest? Could they be made to speak well without percussion?—ARIEL.

[47175.]—**Varnish.**—I shall be thankful for a simple receipt for making photographic varnish. Some of the recipes are too complicated; the ingredients are not procurable except in the largest cities. Nor can I think that there can be much use in such elaborate lists of gums which I find in our textbooks. I want something suitable for preserving gelatine negatives.—VARNISH.

[47176.]—**Broken Tracing-pen.**—My tracing-pen handle having broken off at the brass socket, could you inform me how to get the piece of bone out of the socket?—M. OLLINER.

[47177.]—**To "F.R.A.S."**—Does Loomis's "Practical Astronomy" give the means of finding the true time of new or full moon, together with the elements for projecting a solar eclipse approximately?—A. B.

[47178.]—**Dynamo.**—Will someone give particulars of the "Arago Disc Dynamo," exhibited at the Crystal Palace? Are the cores of armature bobbins wood or iron, and are the F.M.'s on one side of armature all same polarity, or are they alternately N. and S.? Mr. Geo. Tolman promised, a little time back, to give particulars of the little dynamo which he has constructed. I hope he will soon do so.- O.

[47179.]—**Magnets.**—In most of the textbooks the rule is given—the power of an electro-magnet is directly proportional to the strength of the current. Does this mean the intensity or the quantity of the current?—O.

[47180.]—**To "F.R.A.S."**—In Keith's "Use of the Globes," there is a statement that total darkness cannot last longer than 7 minutes 58 seconds; but Dr. Lardner, in his work on "Astronomy," says it cannot last longer than 4 minutes. Will you kindly tell me which is correct?—A. B.

[47181.]—**Boiler.**—I have a steam-engine 2in. cyls., 3½in. stroke. Will some brother-reader kindly inform me what size of boiler I shall require. Also, give me some instructions how to make same.—SLOCUM PODGER.

[47182.]—**G.W.R. Engines.**—Could someone give principal dimensions of No. 1445, wing tank?—N. W., Ealing.

[47183.]—**Brake Trials in Germany.**-Will someone oblige me with details of recent brake experiments near Stuttgart, Germany?—A DRIVER.

[47184.]—**Special Express Train on M.R.**—I shall be glad to know the number of the engine which ran the Prince of Wales special express on Whit-Monday, and the average speed attained.—A DRIVER.

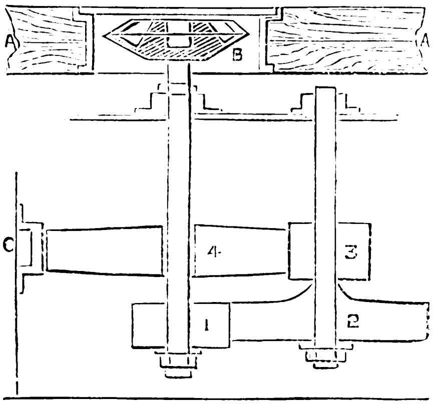
[47185.]—**Embossing Glass.**—To ALFRED W. SOWARD.—I have been trying to emboss glass, but without satisfactory results. I find the fluoric acid eats the glass when dipped in bodily, but can get the ground appearance by placing over the vapour only just sufficient to show the pattern and patchy. Does it matter how close (within an inch or two) it is placed over the acid? Is the common ground or matted glass made in this way, and does the acid lose its properties after using once?—C. W.

[47186.]—**Gum Paste.**—I should be glad of the following information:—1. Preparation of the paste; 2. Treatment when made; 3. Preparation of moulds. Any other information besides the above will oblige—GRECIAN.

[47187.]—**Bacteria.**—Referring to Mr. Thoms' very interesting letter on the above, will he kindly inform me what are the lowest temperatures that the different albuminoids in malt, &c., are coagulated? Also, if prolonged boiling does not take into solution again some of the coagulated albumen? If so, which kind? And also, if such albumen would not encourage the growth of bacteria? A short article on the above, in reference to bacterial life (if convenient), would prove very acceptable to many besides myself.—R. V.

[47188.]—**Medical.**—Will Dr. Edmunds, or some other medical correspondent, kindly inform me what is the handiest and most suitable form of "iron" to take regularly? Suffer from "poorness" of blood, and, as a consequence (I presume), extreme paleness. Digestion rather imperfect.—R. V.

[47189.]—**Bridge Opening.**—Can any reader help me with the following calculation? From the gearing of which I send sketch, I want to find how long it will take to open the bridge (swinging on its centre)—that is to say, how many revolutions of the capstan-head, B, will be required to open the bridge? The dimensions are as follows:—



Gearing: 1st Motion.

	Teeth.	Pitch.	Diameter.
Pinion	11	2¼in.	0ft. 7½in.
Wheel	57	2¼in.	3ft. 4½in.

2nd Motion.

	Teeth.	Pitch.	Diameter.
Pinion	11	3½in.	1ft. 3/16in.
Wheel	33	3½in.	3ft. 9/16in.

Rack:—

Radius	20ft.
Length	40ft.
Pitch	3½in.

In the drawing, A A is a portion of the bridge flooring; B is a capstan-head, and C the rack. The wheels are numbered in the order in which they gear—i.e., 1 gears with 2, 3 (on same shaft as 2) with 4, and 4 with the rack; 4 runs loose on the shaft. The bridge turns on a central pivot, has the gearing in the centre, and is 142ft 8in. long, and 40ft. wide.—RUSSELL.

[47190.]—**Fernery.**—Would somebody give me full instructions for making a small indoor fernery? and oblige—A. HALLETT.

[47191.]—**Loco. Building Shops.**—Will some reader inform me as to whether there are any loco. building establishments at Liverpool or Earlestown?—H. S. P.

[47192.]—**Locomotive Engines.**—I have to thank "Clyde" for drawings and details of L. and N.W. and B.E.R. given by him at my request. I have been noticing lately some of the locos. used on the L. C. D., L. B. S. C., L.S.W., and S.E Railways. The S.E.R. have had some nice bogie-tanks built within the last year or two—Nos. 303-312, 162, 181, &c. Can anyone give details? Also of bogie engines Nos. 19, 36, 176, &c. The small tank locos. built by Mr. Beattie for the South Western are still to the fore. Notwithstanding their low cylinder power, they take seven or eight carriages up Snow Hill in very good style. I notice in my reply to "Netherby" on Caledonian Engines, in No. 890, one or two misprints—e g, "Gamkirk" is printed for "Garnkirk," and "running home" for "running time."—CARSTAIRS, London, S.E.

[47193.]—**Nitrate of Lead.**—What are the most suitable apparatus (and generally adopted) in the trade for the manufacture of nitrate of lead and commercial stannate of soda on a large scale?—LEAD.

[47194.]—**Organ Tremulant.**—Would any correspondent be good enough to give me a description of above, so as to be able to make one and fit it to an organ?—CYMRO.

[47195.]—**Telescope Object-glass Making and Correcting.**—In Vol. XXVI. will be found two interesting letters by Mr. Godfrey on the above subject, and they prompt me to put the following query:—Suppose I buy an o.g. of 3in. or 4in. diameter of the usual focus (say, up to 16 dia.), and on mounting and testing in the manner advocated in back vols. of "ours," I find it not entirely free from spherical aberration. Can this be reduced or eradicated by suitable polishing? and, can it be freed in a similar manner from a slight amount of chromatic aberration? I am led to suppose so from the tentative process employed by Mr. Godfrey as above, and if "Orderic Vital" will kindly read Mr. G.'s letters on page 139, Vol. XXVI., and page 639, Vol. XXV., he will better understand my meaning. I am used to glass grinding, polishing, and correcting, having made a 6in. reflector on equatorial stand, but my terrestrial position is so bad that I am quite shut out from many interesting astronomical phenomena which I could have the pleasure of observing with a smaller telescope on a portable stand used in a front room. My speculum-grinding machine would be useful in the process.—J. C. L.

[47196.]—**Electricity v. Gas.**—Can't you manufacture gas by the action of electricity, and burn the two together in one combination of elements?—FIDDLER.

[47197.]—**Stamping Brass Discs.**—I want a lettered inscription impressed on the edge of brass discs leaving a small space on the circumference to insert small variable device, to be included at one operation. Discs ¾in. diameter, ⅛in. thick.—BARODIS.

[47198.]—**Wet-Bulb Thermometer.**—Having been troubled for a month or so with finding the water evaporated out of the vessel, and the threads and muslin dry in my wet-bulb thermometer, when I went to take my morning observations (the only one my business permits me taking), I have arranged inside the screen a test-tube full 1in. diameter, which is filled with water, having a perforated bung in, through which passes a short piece of glass tube not less than a ¼in. diameter. I tried ⅛in., but it refused to act at all. If the end of the glass tube just passes into the vessel, as soon as the water has evaporated below the level of the mouth of the tube, a bubble of air will enter the test-tube and the water will flow down, restoring the original level. An inverted flask is easier to fix than the test-tube, needing only the ring of a laboratory retort stand, but it has the disadvantage of occupying too much of the air space within the screen. The idea was suggested to me by using the balloon battery—a modification of the Daniell.—JOHN J. GILBERT, F.M.S., &c.

[47199.]—**Winds.**—The usual explanation of wind is that it is the atmosphere rushing from a place of high barometer to one of low barometer, which is so far satisfactory; but what is the explanation of (1) those long howling gusts, and (2) the short chopping gusts which appear to come in turn from all points of the compass? We have had too many lately.—F. M. S.

[47200.]—**Indurated Liver.**—Can Dr. Edmunds or any reader tell me if there is a cure for induration of the liver? I have a relative aged seventy, but of a sound vigorous constitution, who is now suffering from it, and one medical man who has been attending him some time, holds out no hope of his recovery, whilst another who has recently been called in considers he can cure him. Which of them is right? An assurance one way or the other would be esteemed by—AN ANXIOUS ONE.

[47201.]—**Instantaneous Photography.**—I have an apparatus which is said to be specially made for the most rapid work, objects in motion, &c. I have tried it with the instantaneous shutter on some clouds, but the plates were not acted upon at all. I was advised to make a longer exposure; but, as I expected, the movement of the clouds made them almost shapeless in the photograph. Any information will greatly oblige—TYRO.

[47202.]—**Extraordinary v. Otto.**—Will anyone say which is best and safest for a hilly country and rather rough roads?—W. L.

[47203.]—**N.E.R. Locos.**—Can "Meteor" or others give us a sketch and principal dimensions of the passenger engines (Nos. 1160 and 1161) built at Darlington about 1875? They are commonly called Quakers, having square cabs.—CLEANER, York.

[47204.]—**L. and N.W.R.**—Can any readers of "E.M." tell me why the engines on some of the local lines (Stafford to Rugby) have two throttle-valves or starting-levers? An explanation will oblige—CLEANER, York.

[47205.]—**Anemometer Indications.**—What is the meaning of the following passage in the Greenwich Visitation Report?—"The vane of Osler's anemometer made in the year 1881, fourteen revolutions in the positive direction N.E.S.W.N." I understand it that the wind, instead of changing from N. to S., say, went steadily round the compass, and did that fourteen times in the year.—F. M. S.

[47206.]—**Dry Plate Developer**—Will Mr. Parkinson say whether the addition of citric acid added to the pyrogallic acid and water will make the solution keep some time? I prepare a quantity of ammonia solution, and always have to weigh my pyro and mix just before use, and I should like to prepare a similar quantity of the pyro always ready, and Swan's formulæ now adds citric acid. And, how can I make my gelatine so that it will keep for mounting prints?—F.

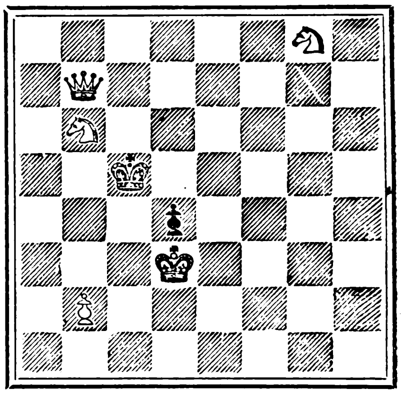
[47207.]—**To "Ll. B. A."**—In letter 20130 you do not say what size the German silver wire which is stretched on Fig. 2 is, and how many ohms resistance. Also, what purpose will the excess of wire on the frames (Fig. 1) which is beyond the point where the copper wire is soldered be for? Am I right to assume that one end of coil and the copper wire connected to same are to be joined as at Fig. 5?—NOSBEDNA.

CHESS.

ALL Communications for this department must be addressed to the Chess Editor, at the office of the ENGLISH MECHANIC, 31, Tavistock-street, Covent-garden, W.C.

PROBLEM DCCLV.—By W. COATES.

Black.



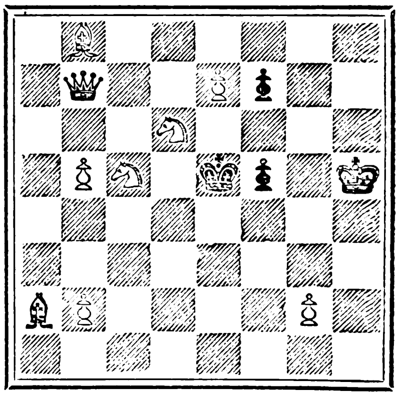
White.

White to play and mate in three moves.

PROBLEM DCCLVI.—By "NUT-SHELL."

From the *Chichester Parochial Magazine.*

Black.



White.

White to play and mate in two moves.

Solutions to above problems are invited.

SOLUTION TO 751.

White.	*Black.*
1. Q to Q Kt 6	1. R or B takes Q (a)
2. Kt takes P	2. Anything
3. Mates	
	(a) 1. Kt takes P, &c.
2. Q to K Kt sq	2. P or K takes Q
3. Kt mates	

This admits of a second solution beginning 1. Kt takes K B P.

SOLUTION TO 752.

White.	*Black.*
1. B to Q B 4	1. K to B 6 (a)
2. Q to Q B 5	2. Anything
3. Q or B mates	
	(a) 1. K to K 5 (b)
2. Q to Kt 4 (ch)	2. K moves
3. Q mates	
	(b) 1. K to K 4
2. Q to Q B 5 (ch)	2. Moves
3. Q mates	

If 1. $\frac{\text{Q to K R 5}}{\text{K to B 6}}$ 2. $\frac{\text{B-K B 8}}{\text{P moves}}$.

WE have been informed that this problem is by Mr. F. Arthur Hill. It was his first composition, and appeared in *La Semaine Française*, the *Illustrated Sporting and Dramatic News*, in Italy, and America.

NOTICES TO CORRESPONDENTS.

Schmucke.—Thanks for the problem, which, if up to the mark, shall be inserted. Your solutions are generally very accurate. Those to 751 and 752 are correct, though that to the former is not the author's.

The following epigrams on "a cooked problem" have won the prize in the *British Chess Magazine* Competition :—

No. 1.—By Mr. W. F. Payne, Abingdon :—

Behold, disastrous fate—a problem cook'd !
'Tis like some castle safe from front attack,
To which, a little loophole overlook'd,
A knight gains fatal entrance at the back.

No. 2.—By Mr. J. A. Miles, Fakenham :—

Like new-laid eggs, Chess Problems are :
Though very good, they may be beaten ;
And yet, though like, they're different far—
They may be cook'd, but never eaten.

ANSWERS TO CORRESPONDENTS.

◆◆◆

*** *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded ; and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, June 14, and unacknowledged elsewhere :—

Prof. Larmor.—G. Bower.—J. Parnell.—J. Robinson.—H. Harris.—Chance Bros.—A. Forster.—R. Lewis.—T. McNally.—F. d'Alquen.—C. Birchall.—Gereb Admi.—Don Carlos.—H. S.—Burette.—Rev. J. J. M. Perry.—A Poor Irish Boy.—J. H. Evans.—G. J. C. E.—Brick Kiln.—Phonetic.—Frank Smith.—Mide.—A. J. Smith.—An Experienced Old Hand.—J. H. A.—Amateur.—Old R'way Grease.—H. Painter.—C. H.—Adonis.—Beta.—J. H. W.—E. Thomas.—R. Kanthack.—Ligurian.—E. L. P.—Orderic Vital.—G. Tolman.—E. W.

W. E. H. (The question was answered with illustrations in Nos. 818, 819.)—D. Packer. (Thanks. Scarcely of sufficient interest to occupy space in our columns.)—Wheatley Hill. (In Vol. XVIII. you will find a series of articles on the Theory and Practice of Coal-Mine Ventilation, which may give you the desired information.)—C. W. (You will find replies to definite questions in back volumes ; but we should recommend you to procure one of the handbooks—say, Gedney's "Parrakeets, Parrots," &c., published at 170, Strand, W.C.)—N. W. Ealing. (The second query is beyond us ; it has nothing to do with the merits of the brakes.)—New Reader. (There are many in back numbers, some even in present volume ; but possibly the best for you was that described on p. 332, No. 846.)—East Anglian. (You understand that much depends on the nature of the ink. Cyanide of potassium will remove the ordinary make, but that is very poisonous. You can try soaking well in permanganate of potash, Condy's fluid, and then go over with hot solution of oxalic acid.)—Handy Man. (Instructions for binding periodicals on p. 377, No. 770.)—Matthew Olliner. (You can only make it thicker. 2. Liquids : all chemists and druggists sell them. Get Valentin's "Lessons in Inorganic Chemistry," Collins, Sons, and Co. ; but if you wish for experimental chemistry, you can have nothing better than Prof. Reynolds's little book, published by Longmans. You will find out about old and new as you go along. It has nothing to do with practical chemistry.)—Stick in the Mud. (Any of the electrical dealers will supply you with the proper covered line wire. The method of connecting up circuits and bells or "calls," was fully described and illustrated on pp. 67, 87, 111, of this volume.)—F. J. A. (We gave the description on p. 77 of this volume. The invention consists in the "solution," which is presumably used in the Bunsen cell. It is doubtful whether it is better than the ordinary solution, and the use of the battery will be attended with considerable expense.) — W. Wright. (If none of those described in back numbers will suit, we are afraid we cannot help you.)—Novice. (If you are to study it for its own sake, get Sprague's "Electricity," published by E. and F. N. Spon, Charing-cross ; if to pass an examination of the Science and Art Department, procure Guthrie's "Electricity," published by Collins, Sons, and Co.)—F. C. (A paper was read last year at the Musical Association, we believe, which was followed by a discussion ; but the general opinion was "both." As to the character of the pieces, that is immaterial.)—One who Wants to Excel. (Apparently a modification of the Daniell, but not an improvement. If you want to make a cheap battery for ringing bells, see p. 308, in last week's number, or p. 5 of this volume.)—Musical. (Both have their appropriate places, but the flute is no doubt the easiest. You should procure a good instrument, not necessarily a high-priced one. See the indices for a full discussion of the subject.)—Core Boy. (Your first query was answered so recently as May 12, and the others in back numbers. See p. 140, No. 864.)—A. E. C. (We do not understand what you mean by "analysis." We know of no book devoted to the branch.)—Agent. (The doctors are right—Dr. Edmunds could tell you no more.)—Wm. Johnstone. (We fear we can give no advice worth taking. Probably you might do well at Sydney, if possessed of capital ; but we hardly think you would much better yourself if a workman.)—Theta. (We never heard of it. There is the *Chemical News*, a small weekly paper, which can be ordered through any newsagent.)—Geo. Powell. (We have a letter in type from Mr. Tolman, giving instructions for the construction of a small dynamo-machine. It anticipates most of your queries.)—Jimbo. (Both queries had been answered in back volumes. Nobody can answer such a vague question as that about the Smoke Abatement Exhibition. The awards were made in different classes, and were duly published at the time.)—A New Subscriber. (Probably rheumatism.)—Electrician. (Pack a carbon plate in a porous pot with equal parts of well mixed gas carbon and binoxide of manganese both about the size of hempseed or peas, but free from dust. It is usual to seal the cells with pitch. Place it in a jar of less height than the porous cell, and pour into the jar a solution of sal-ammoniac, to about two-thirds fill the outer vessel. In that place a zinc rod, and the cell is ready for action. 2. As we do not know the lamp referred to, we can say no more, except that you have decided on very insufficient evidence. 3. How can any one tell the cause of your failure without examining the coil? You say that everything is all right, and yet you get no result. Try again, reading up the directions. See p. 313, last number.)—G. P. Renshaw. (Thanks, but we fail to understand how the brake has been rendered more efficient by the use of a tell-tale gauge : that such a device should be thought necessary is a practical confession that the brake is not altogether satisfactory.)—John Norman. (The best made in this country are composed of emery and water-glass—silicate of potash,—cast in moulds and subjected to pressure, we believe. Never heard of them being used for the purpose, and think them scarcely suited.)—E. Hardcastle. (We believe we have given every tried or proposed process for silvering specula—in some cases many times. See p. 111, No. 863, and the index of the last volume, or any other you have.)—L. H. Jacobsen. (It is not clear what the new discovery is, for the grain of wheat, if there is one, is hidden in a bushel of chaff. We have not space for matter of that kind.)—Ariel. (Castile soap and cuttle-fish bone of each 2oz. in fine powder ; honey of roses, 5oz. Make as liquid as you please.)—Z. 99. (Next time kill the spirits of salts with zinc. It is only of use in its simple state when zinc has to be soldered ; but for the present purpose use rosin, as acid should never be used in soldering electrical connections.)—Heywood. (Ask for dextrin, and dissolve it in water.)—Gilbert. (Carbons for batteries should be cut from the "scurf." It is laborious work, as you say ; but there is no help for it. We believe sticks of the size you mention can be bought for about 9d. each. You can cut them with notched hoop-iron and sharp sand or emery. All this has been stated many times in our columns.)—J. W. Wood. (The carbons used in electric arc lamps are compressed by very powerful machinery. The "ends" you have may be utilised when crushed for battery purposes, or possibly for remoulding, but it depends upon the material to a certain extent.)—Amateur Tinker. (Both queries answered very recently. For japanning tin, see p. 238, No. 868 ; cold soldering, p. 81, present volume.)—R. H. H. (Yes, it will do, the wires as large as you please. See p. 308. You know that you will want a coil. See p. 313, last week.)—Yankee Doodle. (You can easily contrive to see one of the lamps ; but our readers would not thank us for illustrations and descriptions of such well known devices. If you want to make a simple lamp, look through the last four or five volumes, and you can take your choice.)—J. J. W. H. (Dr. Edmunds has answered both questions very fully ; varicose veins on p. 211, No. 867, and indigestion in many numbers.)—H. W. (Only the man who has left the country, according to your account of the case, could bring any action against you ; but you are, of course, liable at any time to interference by him should he return.)—An Old Reader. (The strong probability is that your unfortunate relative is *really* insane, and that you will go mad, too, if you pursue such practices. If your other relatives choose to fill the pockets of "mediums" and other impostors they must ; but surely your Scotch common sense should tell you that you are all being humbugged or swindled.)—H. Lawes. (We replied to you last week on p. 317 under the signature of "Beginner," which was appended to your first letter.)—A Constant Reader. (A fatty tumour, which any surgeon will remove, if necessary—probably its removal is not necessary.)—A Would-be Artist. (Do not attempt it : all necessary for your present requirements can be procured at the colour-shops ; by-and-by, perhaps the merits of your works, like those of the old masters, may partially depend on your colour-mixing.)—C. H. (Mr. Wetherfield is good enough to reply to questions, but we cannot ask him to waste his time and our space with extracts of evidence, &c., which you would probably misunderstand, and which could certainly interest no one else ; (2) query next week.)—Ignorance. (Scores of recipes have been given from time to time in back vols.)—Carino. (We really cannot trace the query to which you send the reply. You give the wrong number, and no heading, and it is evidently some time back.)—A. J. C., E. L. P., C. H. Domaille, J. H. Huxley. (In type.)

Every Workman connected with the Building Trades requiring a situation should advertise in "THE BUILDING NEWS," published every FRIDAY, price Fourpence, at 31, Tavistock-street, Covent-garden London, W.C.

"THE BUILDING NEWS" is the Principal Journal, representing Architects and Builders, and has the largest circulation of any Professional Journal in the kingdom.

Every Workman should insist on seeing "THE BUILDING NEWS" every week at his Club or Coffee House. He will find more "Lists of Tenders" for new work in it every week than in any similar paper, and can thus judge where work is likely to be had. He is also specially invited to make use of "Intercommunication" if he wants to know anything about his trade ; to write to the Editor if he has any suggestions to make and to advertise in the paper when wants work.

The charge for Advertisements for Situations is One Shilling or Twenty Words, and Sixpence for every Eight Words after.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post-free to any part of the United Kingdom. For the United States, 13s., or 3 dols. 25c. gold, to France or Belgium, 13s., or 16f. 50c. ; to India (via Brindisi), 15s. 2d. ; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 3d. each to cover extra postage.

Messrs. James W. Queen and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post-free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. XXIV., XXVI., XXVII., XXVIII., XXIX., XXX., XXXI., XXXII., and XXXIII., bound in cloth, 7s. each.
[Vol. XXXIV. Now ready.]

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in March and September, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or 2½d. each, post-free from the office (except index numbers, which are 3d. each, or post-free, 3½d.)

Indexes for each half-yearly volume up to Vol. X. (except Vols. II., III., IV., V., and X.) inclusive. 2d. each. Post free 2½d. each. Indexes to subsequent vols., 3d. each, or post-free, 3½d. Cases for binding, 1s. 6d. each.

*** Subscribers are requested to order Cases and Vols. through their booksellers, and not to send direct. The regulations of the post-office prevent their transmission through the Post.

CHARGES FOR ADVERTISING.

	s.	d.
Thirty Words	2	6
Every additional eight words..	0	6

Front Page Advertisements Five Shillings for the first 40 words afterwards 9d. per line. Paragraph Advertisements One Shilling per line. No front page or paragraph advertisement inserted for less than Five Shillings. Reduced terms for series of more than 6 insertions may be ascertained on application to the Publisher.

For every succeeding Eight words..	0	3

ADVERTISEMENTS in the SIXPENNY SALE COLUMN:

	s.	d.
Sixteen Words	0	6
For every succeeding Eight Words	0	6

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid ; no reduction is made on repeated insertions ; and in cases where the amount sent exceeds One Shilling the publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement and charged for.

Advertisements *must* reach the office by 3 p.m on Wednesday to insure insertion in the following Friday's number.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a Pink Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

Holloway's Ointment not only heals sores, wounds, and relieves external ailments, but, rubbed upon the abdomen, it acts as a derivative, and thus displays the utmost salutary influence over stomachic disorders, derangements of the liver, irregularity of the bowels, and other intestine inconveniences which mar man's comfort.

OUR EXCHANGE COLUMN.

◆◆◆

Minerals, 100 good specimens, including sapphire, ruby, topaz, emerald, opal, all named, different, 10s. Apply for list. Also many finer, rarer specimens.—Collector, Richard's Library, 42, Tachbrook-street, Pimlico.

The best **Ebony Stain** for wood, sample bottle 6d. —R. M. Hands, Westbourne, Bournemouth.

Tourist ½ **Camera**, slides, lens, shutter, tripod, chemicals, &c., all perfect, £3 10s.—Photo, 51, Legh-street, Warrington.

Metallic "E" **Violin Strings**. Infinitely superior to gut. Four post free 1s.—Smith, 2, Bedford-street, Plymouth

Metallic "A" and "E" **Violin Strings**, acknowledged success. Six, post free, 1s.—John Elarco, 36, Kelvin-grove, Liverpool.

Micro. Photos.—List of 350 one penny stamp.—E. and A. Dancer, 436, Stockport-road, Manchester.

New loud **Violins**. No back or soundpost, 15s., 20s., by "Fiddler," 19, Edward street, Burdett-road, E.

Lathes, Lathes, cheap good screw-cutting, from £10. Easy payments. Hire system. First-class tools.—Makin, Cupola, Sheffield.

Electrical Depot and Manufactory.—Millar's, 126, Chapel-street, Salford. Handiest shop in the trade for amateurs.

Electric Lamps, 5s.; Bells, 5s.; Batteries, 2s. None better or cheaper. Instruments repaired.—Millar, as above.

Slide-rest, 10in., 40s. Engine, about 1-horse, 45s. —231, Swan-road, West Bromwich.

Combined **Engine and Boiler**, cylinder 5in. dia. y 10in. stroke, £19.—231, Swan-road, West Bromwich.

Superior 4½in. **Slide-Rest**, good design, quite new, remarkably cheap.—F. Hodges, 186, St. James-crescent, Gloucester.

Handy Bench Vertical **Drilling Machine** (to ¾in.), hand or power.—F. Hodges, 186, St. James-crescent, Gloucester.

6in. single **Headstock and Poppet**, superior make, new. Cheap.—F. Hodges, 186, St. James-crescent, Gloucester.

Watches! Watches!! Watches!!! 7s. 6d. each, sent free per post.—J. Dalby, 6, Albion Hill, Leicester.

Second-hand **Model Steam Engines**, Scientific Instruments. Catalogue 2d. post free.—John Bateman, 131, High Holborn.

Splendid set of **Gas-Engine Castings**, cylinder 2¼ bore, 4½ stroke, cheap.—T. Warsop, Patterdale, Penrith.

Astronomical Telescope. I will take £1 for a Telescope of great power, 5ft long, with garden stand, made by my late husband.—M., 35, Euston-grove, Claughton, Birkenhead.

Beautiful Instantaneous **Photograph** of Swarm of Bees, 8 by 6, mounted, 2s.; unmounted, 1s.—C. Woodhead, Hitchin.

Safe for Sale, fireproof, 30 by 20 by 18in. outside, cash drawer, patent lever lock, perfect condition, 2 sets keys, price £5, delivered.—Richard M. Lord, Wolverhampton.

Corn Bin, galvanised iron, holds 8 bushels, price 35s. delivered.—Richard M. Lord, Wolverhampton.

A Dallmeyer Triplet **Photo. Lens**, No. 1 by 7in. focus, equal to new, price £2 10s.—F. Clark, Slip End, Luton, Beds.

English **Concertina**, splendid condition, cost seven guineas, for £4. Send for particulars.—Hallett, Sturminster, Newton, Blandford.

Hæmorrhoids.—Internal Piles. Spencer's carefully prepared Pills give immediate and permanent relief from this distressing complaint.

Piles.—Spencer's Pills cure when all other remedies (so-called) have failed. They contain nothing dangerous.

Hæmorrhoids.—Spencer's Pills, 2s. 1½d. per large box post free.—S. Spencer, 26, Dysart-road, Grantham.

Photographs, Scottish Scenery (extraordinary value), 7in. by 4in., price 4d. each.—Finlay, 135, Renfrew-street, Glasgow.

Wonderful **Luminous Watch Box**, 12 stamps. Luminous Stars, 4 stamps post free.—"Photo," 182, Trongate, Glasgow.

Jet Black Quick-drying **Endorsing Ink**, for numbering machines, rubber and other stamps. An excellent article. Sample bottle eight stamps.—William Guest, Ormskirk, Lancashire.

Hydraulic Organ Blower, worth £10, will take £4 10s.—C. Bayley, Cyprus House, Parkstone, Dorset.

Photographic.—Negatives developed, intensified, retouched or printed, or work of any kind done for amateurs on very reasonable terms for good work.—N. Mackie, 2, Derby Houses, West Croydon.

Britannia No. 1 **Lathe and Fretsaw**, with all accessories, £5 10s. Cradle Spring, 10s.—Walters, 50, Watlington-street, Reading.

Microscopic Objects.—Diatomaceæ arranged in groups. Arachnoidiscus Japonica, Heliopeltæ Melli, Ithemia Enervis, and Autacoidiscus, 4 slides best mounts, 3s.—W. White, Warden-place, Nottingham.

6in. Slide and Screw-cutting Treadle **Lathe**, 6ft. gap bed, 6in. Self-acting Treadle Lathe, 4ft bed, 12in. by 14in. Planing Machine with shafting, slotting, and drilling combined; chucks for all. Also one-horse oscillating Engine and Boiler. Lot £80.—C. W., Castle House, Epsom-common.

48in. **Bicycle**, roller bearings, lamp, oilcan, spanner, &c., £3. A bargain.—H. Miller, 1, Manor Villas, Great Berkhamsted, Herts.

48in. **Bicycle** for Sale, cheap, good as new.—Apply (after 7 in evening) at 1, Newlands Cottages, Newlands, Peckham Rye. No dealers.

8in. **Protractor**, with Vernier, in case, 20s.—Grocer, 51, High-street, Stoke Newington, London, N.

Equatorial Telescope, advertised in previous numbers. 9½ Silver Mirror, With-Browning, driving clock, costing over £100, will be sold at Stevens' Sale Room, Covent-garden, this day, Friday, June 16th.

Excelsior **Tricycle**, 52in. driving wheel, cost £14 10s. Easy runner. £5 cash.—Wright, Mercer's-row, Northampton.

Important to Violinists.—Improved **Violin Chin** Holders. List, with engravings, one stamp.—Nicholson, 35, Victoria-street, Sheffield.

Finished steel **Piston Rings** for cylinders, 2½in. to 4in., 3s. to 5s. per set.—"Alpha," Dover.

Propellors, 18in. dia., 7s. Other sizes up to 6ft. dia., equally reasonable.—"Alpha," Dover.

Handsome 3½in. by 4in. **Launch Engine**, £18. Sets of Materials, 90s. Other sizes equally cheap.—"Alpha," Dover.

New 3½in. by 4in. **Launch Engine**, with boiler, shafting, pipings, &c., complete, £41.—"Alpha," Dover.

5in. by 5in. **Launch Engine**, first-class engine, by Yarrow, £18.—"Alpha," Dover.

New 2 H.-P. and 3 H.-P. Cochrane **Launch** Boilers for Sale, cheap.—"Alpha," Dover.

To Electricians.—Quantity of superior thick Gutta-percha Covered Wires, about Half Cost.—"Alpha," Dover.

Three-jaw **Chuck**, suit 4in. to 6in. lathe, Castings 2s. 6d. Drawing, six stamps.—A. Dorrington, West Gorton, Manchester.

Amateur's **Drilling Machine Castings**, 3s. 6d. per set. Working Drawing, eight stamps.—A. Dorrington, West Gorton, Manchester.

Lathe Planing Machine Attachment **Castings**, 12s 6d. Working Drawing, 14 stamps.—A. Dorrington, West Gorton, Manchester.

Half Horse-power Horizontal **Engine Castings**, 32 parts, ports cast in, 12s. 6d. Design.—A. Dorrington, West Gorton, Manchester.

Amateurs and others before wasting money on inferior articles should send for my Lists and Testimonials. All Castings of best quality.—A. Dorrington, West Gorton, Manchester.

½ Horse-power Horizontal **Gas-Engine Castings** and Forgings. Lithograph, three stamps.—A. Dorrington, West Gorton, Manchester.

Blecnum Spicant and Parsley **Ferns**, 1s. per dozen free.—James Dove, Low Fold, Ambleside, Westmoreland.

Organ, 3 stops, mahogany case, pedals; supposed age 100 years.—Hill-top, Walwood road, Leytonstone.

A. **François'** List of Aneroid Barometers, Field-glasses, Model Engines, Steam Boats, &c., will be forwarded free.

Readers of the "**Mechanic,**" will do well to send for François list and compare with others.

A. **François**, while thanking those who have honoured him with their patronage, beg to say he will forward list to them.

François, Devonshire-place, Ryland-road, Birmingham, has articles on his list at half usual price Fact!

Physics.—All Lecture Requisites for Mechanics, Magnetism, Heat, Light, Sound, Water, Air, Chemistry, Geology, &c.—Caplatzi.

Electric Stores.—Unapproached for quantity, variety, and cheapness especially. Frictional Machines, Coils, Batteries, Motors, Telegraphs, Bells, Wires, Fittings.—Caplatzi

Musical.—Five-stop oak case Harmonium, £5. Ditto, portable, £3, £4, £5. Splendid new Baritone English Concertina; Reeds, Pans, Keyboards, Bellows, for harmonium, cheap.—Caplatzi.

Best Air-Cane **Revolvers**, Guns. All kinds of Fittings, Cases. Also some Fishing Tackle, cheap.—Caplatzi.

Electro-Motors for Rails, Boats, Pumps, Vacuum Tools, &c., 20s. to 30s. 9in. Armature, Wheels, Axis, Commutator, 10s. Magnets, 3s., 5s.—Caplatzi.

Lantern Slides, Photos, hand-painted. Fine sets of Astronomical, Botanical, Geological, Zoological, Scriptural, Scenery, Effects, and Comical very cheap.—Caplatzi.

Dynamo Machines, Castings, and all parts for making same. Two large Patent Lamps. Incandescent, 5,000-candle Dynamos. Half ton of permanent Magnets.—Caplatzi.

Batteries.—Grove's, Bunsen, bichromates, Daniell, Leclanche's, Plante's, Smee's, Medical, and a dozen others, in great quantities. All Materials and Fittings.—Caplatzi.

Electric Light Batteries, lamps and fittings, specially constructed to save labour and expense. Large number very cheap.—Caplatzi.

A splendid £150 set of **Dissolving Apparatus** and 150 Slides, all works of art, mostly Indian. Astronomical, &c., from an officer.—Caplatzi.

For Lectures and Soirées.—All kinds of **Apparatus** on Hire at 2s. 3d. per £ value. Advice to customers free, saving labour, care, and money.—Caplatzi.

Cables, covered wires, copper, German silver platinum. Several hundred pounds, very cheap. Telephone Handle Cord &c.—Caplatzi.

Cheap Photography. 50 good second-hand Apparatus, for pictures 4, 5, 6, 8, 10, 12, 15in. Cameras about same price as lenses; each from 5s., 8s., 10s., 12s., 20s., 30s., 40s., 60s., 80s., 100s.—Caplatzi.

Folding **Cameras**, Landscape Lenses, 15 various sizes, one with 9-cameo lenses, 40s.; ditto, with four ¼-plate, 70s.; with two, 40s. and 60s. All necessaries.—Caplatzi.

A 6-guinea Dubroni's **Complete Set**, 50s. Fine 8 and 10in folding, wet or dry sets, 60s., 80s., very portable; all kinds of Stands, Baths, equally cheap.—Caplatzi.

C. Backs, single and double, best make, less than half price. New Bellows, Printing and Rolling Presses, and multiplicity of dark-room fitting.—Caplatzi.

Particulars Weekly. Catalogues 2d. Dr. Caplatzi, Science Depot, Hire and Exchange, Chenies-street, Tottenham Court-road. Near University College, British Museum, and five stations.

2½-horse **Vertical Engine**, Pump, &c., £10, or exchange small Screw-Cutting Lathe.—33, Victoria-street, Sheffield.

Ferns.—Hardy Dorsetshire Ferns, ten varieties sent free, 1s. 2d. 2 dozen, 2s. 2d.—A Hallett.

Large Dorsetshire **Ferns**, many varieties, 100 5s.; 50 3s., packed in box.—A. Hallett.

Hartstongue **Ferns**, 12 good strong plants sent free for 1s.—A. Hallett, Sturminster, Blandford.

Your **Photograph Enlarged** to 15 inches in crayons, 3s. Numerous testimonials.—H. Wright, Artist, 55, Parkstone-road, Peckham.

Eight horse-power Vertical **Engine and Boiler.** Can be seen working. Not large enough for owner. Price £60. —Herbert, 77, Old-street, Ludlow.

One H.-P. **Vertical Boiler**, quite new, complete, £9 10s. Two ½ H.P. Boilers, quite new, each, £5 10s.—H. May, New-street, Chelmsford.

One 4 H.-P. **Vertical Engine** and Cornish Boiler, good condition, £36.—H. May, New-street, Chelmsford.

Combined Vertical **Engine and Boiler**, 2 H.-P., equal to new, £18.—H. May, New-street, Chelmsford.

Electro-Plating Apparatus, complete sets, 5s. 6d. to £10. Price Lists, one stamp.—H. Mills, Eastern Counties Plating Works, Ipswich.

Photographic Printing. The best results, including touching and finishing, on cards, 1s. 6d. dozen.—Mitchell and Co., Artists, Sydenham.

Luminous Paint. A few bottles for sale, price 1s. 9d. each.—H. Johnson, 3, North Hill-road, Ipswich.

Waterlow's **Stylographic Pen**, splendid condition, cost 12s. 6d. Price 3s. 6d.—H. Johnson, 3, North Hill-road, Ipswich.

Dynamo Machines, for nickel-plating, &c., 5, 10, 15, 20, £25.—George Tolman, Dynamo Machine Maker, Wolverhampton.

Dynamo Machines, heats to redness, two, four, six, twelve inches Platinum Wire.—George Tolman, Wolverhampton.

3½in. **Bar Lathe**, good as new, chucks, complete, 65s.—W. Browning, Union-street, St. Thomas, Exeter.

Fan (patent) for four fires, by W. Gunther, complete, hand or power.—49, Graham-street, Derby.

3in. back-geared **Lathe**, with slide-rest, by Britannia Company, nearly new.—A. Kendall, Brackley.

Twenty-horse, Seven, Four, Two, and one-hore **Engines**.—James Sutcliffe, Princess street, Granby row, Manchester.

"**Carpenter and Joiner's Assistant,**" by James Newland; uncut, 15s.—H. Newberry, Fisherman Cottage, Kennetside, Reading.

Plate.—12 Table Forks, 12 Dessert Forks, 12 Dessert Spoons, 12 Tea Spoons, 6 Table Spoons, stamped A 1 quality, quite new, 39s. Sample forwarded.—Mrs. Brown, Denmark House, Queen's-terrace, Southampton.

Dynamo Castings and Wire for Machine for Six 10-candle Incandescent, or one Arc, 30s.—Patrick.

Incandescent Lamps, Batteries, Wire, and all apparatus and parts.—Patrick, 15a, White Lion-street, Chelsea, S.W.

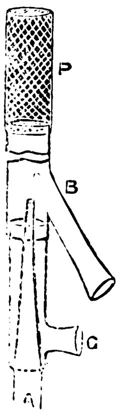
LEWIS'S INCANDESCENT GAS-LIGHT.

By J. T. SPRAGUE.

THIS light, mentioned in "Scientific News," p. 324, was the subject of an article in the *Times* a few days ago which has brought it into considerable notice, and as I have had the opportunity of a complete examination of the apparatus, I propose to give "our" readers full information thereon before the world at large knows anything about the matter. When the experimental exhibition, now preparing, is actually presented to the public between Clerkenwell-green and the "Angel" at Islington, no one who sees the light will believe it is a gas-burner at all, so utterly unlike is it to any gas-light ever yet seen. The burner is not correctly described (as in the *Times*) as a Bunsen burner with a gauze cap. It is a true Herapath's blowpipe, to which air is supplied under a pressure of 6in. or 7in. of water, and which is caused to act also like an injector, so that it induces a stream of air in addition to the supply sent in. The figure will explain the construction.



A is a tube connected to the air-supply, which gradually tapers, and terminates in an opening adapted to the size of burner and air-pressure.
G is a tube connected to the gas-supply, which, together with A, forms an ordinary Herapath blowpipe.
B is a tube which fits on to the blowpipe, and has a side tube and mouthpiece, up which the induction air-current passes, and in the upper part of which the air and gas mingle.
P is a tube half an inch wide, and one and a half high, formed of a gauze of platinum wire of about 35 gauge, and closed at the top with a similar gauze.

When the gas and air are turned on and a light applied, an extraordinary effect is produced; at first there is a roaring flickering blue flame, which in a few seconds disappears, the platinum glows with intense lustre, and appears to enlarge (this being, however, only an optical illusion) and we have a glowing pillar of solid light without a sign of flame.

The light is, in fact, an incandescent one, just like the electric incandescent lights, derived, not from actual combustion directly, but simply from the high temperature of a solid unchanged body. The combustion produces no light itself, but simply heats the platinum, just as the electric current heats the carbon thread.

The burner, as at present arranged, consumes about ten feet of gas per hour, giving a light of over 50 candles. But light is a function of temperature, and, therefore, by increasing the pressure of air and the consumption of gas, a much larger ratio of light can be obtained, and it is said that in this way 20 feet will give 180 candles.

In the pamphlet which I published on the electric light in 1878, I suggested the probability that the time would come when, owing to the demand for heating, cooking, and engines, the gas companies would "undertake the making of a much cheaper heating gas, and trust to a carburetting process at the point of combustion to render it illuminating." This new gas-burner, if largely adopted, would bring this about, because it does not require illuminating gas to furnish light. Now, ordinary gas only contains about 4 per cent. of illuminating materials, rich hydro-carbons whose office it is to decompose and charge the flame with particles of carbon, which become incandescent while they are being consumed. But this 4 per cent. is the great element of cost in gas. To get it, cannel-coal has to be used, and the retorts drawn when only 8 or 9,000ft. of gas are extracted. To obtain heating-gas only ordinary coal need be used, and that need not be drawn from the retorts until some 15,000ft. of gas are produced per ton; this, in itself, is an important saving in fuel, as well as increase of gas, but even then the coke need not be drawn at a white heat, but by passing superheated steam, it can be cooled, and a large further production of gas obtained.

As a set-off to this and to the increased light, however, the new system will involve either a second set of mains and services to supply the compressed air, or else local mechanism to compress it on the spot. In the burners, as at present arranged, about four volumes of air are supplied, and the induction effect brings in the other four or five volumes needed for perfect combustion; but this is with a pressure of 6in. By increasing pressure and diminishing the orifice, the proportions may be largely modified, so that only two volumes need to be supplied; this is, of course, simply a question of mechanics and relative convenience and economy, as to which practice will determine.

The light itself is very pleasant; it is perfectly steady, and without any of the flickering of ordinary gas-burners. It is whiter than ordinary gaslight, owing to the higher temperature, and this whiteness can be carried much further than it is. It is more penetrating than the electric lights, because its quantity is greater, and its intensity less; that is to say if equal lights were given, according to the photometer, by the two lights, the gaslight issuing from a larger surface than that of the carbon thread which furnishes the electric light, would be more practically useful, and the difference would become more evident as distance from the light increased. For the same reasons the light is less trying to the eyes.

There is no smoke arising from the burner, because the gas is perfectly burnt; and, of course, there is less heat for a given quantity of light, because less gas is consumed.

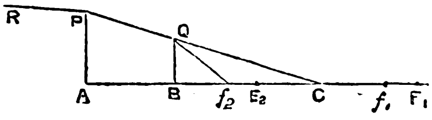
It is evident that gas does not mean to be blown out yet, and that the electricians will, by their exertions, stimulate those concerned in gas, and it is to be hoped that both will succeed and contribute to the public benefit.

A CROWN GLASS ACHROMATIC TELESCOPE.—II.

Spherical Aberration.

BEFORE proposing a pair of lenses which will diminish the spherical aberration, it will be well to explain the method which I have used for finding the aberration of the pair, since, in Dr. Parkinson's "Optics," the book chiefly in use, nothing is said upon the subject, except a few words when the lenses are in contact.

I suppose, then, a pair to be aplanatic when all rays, after emergence, converge to the same point. Let a ray RP be incident upon the first lens at P, and suppose that F_1 is the geometrical focus to which it would be refracted if there were no aberration, and suppose that it is actually refracted so as to meet the axis in C, so that F_1C is its aberration. Suppose, also, that after the second Refraction, it is refracted in direction Qf_2; then if F_2 is the conjugate focus of F_1, it is the point to which all rays would be refracted if there were no aberration, so that the aberration of the pair is F_2f_2.



If now, we suppose, as is often done in optics, the course of the rays to be reversed, a ray from f_2 to Q would, when produced backwards, coincide with QC; and if f_1 is the geometrical focus of f_2, f_1C is the aberration of the reversed ray.

Now, it is easily seen by the formula for congugate foci that approximately $BF_1 - BF_2 = Bf_1 - Bf_2$, or $BF_1 - Bf_1 = BF_2 - Bf_2$, that is, $f_2F_2 = f_1F_1$. In other words, the aberration of the pair is equal to the difference of the aberration of the first lens, and the second when the rays are reversed; but if we neglect products of aberration we might suppose the reversed ray to start from F_2 instead of f_2.

The rule, therefore, for finding the aberrations of the pair is this—Find the aberration of the incident ray for the first lens, and then that of a ray starting from the conjugate focus of the second towards it, and the difference of the two aberrations will be the aberration of the pair, taking care of the proper signs.

Suppose, for instance, that we had a plano-convex and a plano-concave of equal focal length, and their curved surfaces in contact. Then parallel rays incident upon the first emerge parallel from the second, and there is no aberration; but the aberration of a ray upon the first is toward the lens. Also, if the emergent rays be reversed, their aberration is also towards the lenses, and, being equal to the former, satisfies the condition of aplanation.

Again, suppose the rays emerge parallel from the second of any two lenses (convex), the aberration of the reversed rays is towards the lens, hence, also the aberration point, as we may call it, of the first lens must coincide with the second, that they may be aplanatic. In fact, the first lens must bring a ray to that point from which it would be refracted parallel to the axis by the second. One more example: It is well known that Mr. Wray's glasses are admirably corrected. If I have rightly estimated the curves and refractive indices which he has used, the aberration, according to the method here proposed, amounts only to $\cdot 0076\ y^2 / f$, and is less than a 200th part of the convex lens alone.

Proposed Telescope.

We may now propose an arrangement of glasses. The first thing to be done is to find a convenient relation between the focal lengths of the two, and in doing so we may distinguish between the two cases of achromatism mentioned in the last number—namely, when it is supposed to mean the making rays emerge parallel, or the bringing them to the same point, and thus destroying the chromatic aberration. I shall confine myself at present to the former, which is the idea of achromatism to which alone we have been accustomed, and which will, perhaps, therefore, be generally preferred, though I confess I do not do so myself.

The focal length, then, of the concave must be greater than that of the other, and not in a much greater ratio than 3 : 2, or in a much less than 4 : 3. For, in the former case the spherical aberrations would be extremely intractable, and in the latter there would be loss of magnifying power.

These two ratios, therefore, are the ones to which I shall confine myself, and each of them will give admirable combinations for aplanatism, and there is a very curious relation between the best forms of lenses to be used in the two cases. Thus, if we take the ratio 3 : 2, the best form will be a plano-concave, flat side outwards for the second lens, and a convex with radii in proportion of 11 : 4, the flatter side being inwards; but if we take the ratio 4 : 3, the first lens will be plano-convex, curved side outwards, and it will be the concave one which has its radii as 11 : 4, the flatter side being turned outwards; the ratio 11 : 4 appears in both of them, as it does also in one of Coddington's combinations.

For the first ratio, then, we have as follows:—Distance between optical centres of lenses = $\frac{1}{4}$ focal length of first lens.

Magnifying power or focal length twice that of first lens alone.

Length of instrument, or distance of the image from first lens = $7/4 f_1$; radius of first surface = $15/22\,f$, of second $15/8\,f$.

Aberration of ray incident on first lens = 1·1429 t, and of reversed ray incident upon second 1·1406 t difference, or aberration of pair = ·0023t. The pair, therefore, is highly aplanatic. The value of μ used in finding the above was 1·5, but if we put it at 1·5330, the value for the mean, say, in Parkinson, it becomes very much smaller even than this.

A plano-convex lens will give a respectable correction, though not near so exact as the above, giving an aberration of less than 1-62nd part of the front lens alone.

We need say nothing about the other ratio further than this: that the distance between the lenses being smaller, the red and blue rays will not have diverged so far before they meet the second lens; consequently the converging parallel rays will be closer, and the objectionable quantity mentioned in No. 1 will be smaller; but, on the other hand, when the first ratio is that used, the instrument, as I shall try to show, will bear a larger aperture in proportion to its length.

I may mention that I have found some most excellent combinations, as it would seem, for a telescope made upon the other plan mentioned in No. 1, but these I do not purpose at present to publish.

W. G. Penny.

(*To be continued.*)

THE ACHROMATIC OBJECT-GLASS.—II.*

By W. Bradbury ("Orderic Vital").

(*Continued from page* 298.)

HAVING thus indicated the object of these papers, and of those more important ones which will emanate from another pen in connection with them, I proceed to consider the development of the object-glass.

In the earliest instruments, the object-glass was a simple double convex lens. It was found, by making a metal tool of a concavity equal to a portion of a sphere of given radius, and working both sides of a piece of glass in it until they fitted, that such a lens formed an inverted image behind it, somewhere about the centre of the sphere of which its surfaces were parts. This image was defective in many respects, which became much more apparent when the instrument was used on celestial rather than terrestrial objects. The light from a bright object was not accurately condensed in one focus, but more or less scattered; and the image, instead of being one distinct formation, was really the result of the superposition of a multitude of images, and consequently wanting in sharpness. Also, instead of there being a bright image on a dark background, it was surrounded with a halo of colour.

But as the study of optics became extended, various minds were exercised in the attempt to remove or lessen these troublesome deficiencies. The laws of optics were brought under mathematic treatment; Snel discovered that the sine of the angle of incidence bore a constant ratio to that of the angle of refraction. To a mind of the calibre of Huyghens, it was at once obvious that under this law a spherical surface must act unequally on different rays of light, and that an aberration or diffusion must take place whenever it was employed. Possessed of high mathematical abilities, he deduced an equation by which the amount of this aberration might be calculated, and showed that an equi-convex was not the best form of lens to use as object-glass. To give the least possible aberration with spherical surfaces required a lens whose back radius was six times as long as its front one; but to rid it entirely of that error required the curves of its surfaces to somewhat approach those known as the conic sections. Finding that the aberration increased as the square of the diameter of the lens, he recommended the use of object-glasses of long focus and small aperture, thereby increasing the magnifying power without largely increasing the aberration. Such instruments were denominated aërial telescopes, and though a tolerably distinct image might be obtained, it was faint from loss of light, and there still remained the troublesome halo of colour, which no alteration of form could destroy.

It was left for the illustrious Newton to explain how this outstanding colour was caused. He discovered that a ray of white light, instead of being simple, was really compound, and resulted from the union of a number of coloured rays. A prism of glass acted as an analyser, and a ray of white light entering it was, during its passage, split up into its constituent colours. The ray as a whole was refracted or bent in accordance with the law of Snel, though each colour was differently affected, in regular order, but not in a regular degree. Violet was the most deflected, and red the least; while the other colours were intermediate between these extremes. When two similar prisms were fixed with their bases in contact, rays through each were bent in opposite directions, and by their intermixture, a partial reunion was effected. But the extreme colours were not wholly combined, for the colourless image was the result of the overlap of the greatest number of coloured rays. Similarly a convex lens, being a circular prism with an infinite number of plane faces, formed a colourless image by the condensation of the greatest number of coloured rays.

Finding that dispersion always accompanied refraction through a transparent medium, there seemed no possibility of producing a pure image by such means, and Newton turned his thoughts in another direction. A ray of light, reflected from a mirror, is not chromatised; and as the same effect can be produced by either a convex lens or a concave mirror, the latter offered several advantages in the construction of a telescope. Besides the freedom from colour, there was only one surface to fashion, and the instrument could be made very short and compact, and of any desired aperture.

But while the development of the reflecting telescope proceeded rapidly, the refracting instrument was not allowed to remain stationary; acute minds were at work endeavouring to solve the problem of producing a pure image by refraction. Newton concluded that a certain amount of dispersion always attended a certain amount of refraction, and that consequently the one could not be destroyed without destroying the other also. For if the two were in a definite proportion, action and counter-action would be equal, and the course of the ray, in the end, would not be altered.

This was a natural conclusion to arrive at, for at this early period the number of translucent substances was not large, and attention was directed more to the phenomena of dispersion in its relation to the nature of light than to the means by which it was made visible. The manufacture of glass was then in its infancy, and though we read of several kinds, they were chiefly of one species—viz., crown or plate glass, and were tinged with colour, green, blue, pink, or straw colour. The manufacture of flint-glass appears to have been little understood; the firm now known as Powell, of Whitefriars, was apparently the most advanced in the art. But the action of all kinds of glass on light was similar, and it was not till many years after Newton's time, that the discovery was made that it differed in degree. The ratio of the sines of incidence and refraction had been found to be, as nearly as possible, 3 to 2; and this, though correct for the species of glass then in common use, was erroneously supposed to apply to all kinds. Even after it had been found out that the refractive power varied with the density of the glass, this simple but confusing number continued to be employed in optical formulæ.

In 1747 the giant intellect of Euler was employed in optical investigations. His experiments and deductions led him to doubt the truth of Newton's dictum regarding dispersion; and though he could not enunciate a satisfactory theory, he saw that a certain amount of refraction was not attended with equal dispersion in all substances, and suggested the possibility of counteracting dispersion by means of two media of unlike refractive powers.

His memoir met the eye of John Dollond, who resolved to put the theories of the great mathematician to the test of experiment, in order to ascertain their practical value. First, he tried whether equal refractions produced equal dispersions. By arranging a prism of glass to act in opposition to a variable prism of water, he adjusted them so as to make the emergent ray fall in a line with the incident one. In this position refraction was balanced; but he was surprised to find that the colour was not at the same time subdued. Such a result made it very evident that one of the media had a greater dispersive power than the other; but, as the opposing prismatic angles were not equal, there was also a difference in refractive power. The prism of glass could produce the same deviation as its neighbour by a much more acute angle. Continuing his experiments, Dollond found that when refraction was balanced, the dispersion of the glass overpowered that of the prism of water. By increasing the refracting angle of the latter, the outstanding colour was reduced; and, eventually, a position was reached, in which the emergent ray was practically free from colour or achromatised. When this took place, the deviation due to the first refraction, was very far from being wholly destroyed; and the persevering artist saw that the action could be imitated, by means of a double convex water lens and a double concave of glass. Such a telescope was made in 1757, which gave an achromatic image.

Dollond continued his experiments with the object of finding a suitable medium, less unstable than water. On making a trial with some flint-glass, he discovered that a similar relation existed between it and crown glass, as he had previously found between crown glass and water. It was superior to either in refractive and dispersive power. A prism of this material was able to correct the chromatism of one nearly double the size of crown glass. This discovery was the foundation of the achromatic telescope, and Dollond constructed an instrument, giving a colourless image by correcting a double-convex crown lens by means of a double-concave flint lens, in 1758.

Dollond protected his invention by letters patent, and the Royal Society, in acknowledgement of the eminent services he had rendered to science, bestowed on him their Copley Medal.

When the principle of construction became known, it appeared that another investigator had been working on the same lines, even earlier than John Dollond. This was Chester More Hall, an Essex gentleman, who had undertaken experiments in correcting dispersion about the year 1729. He appears to have actually constructed an instrument similar to Dollond's, but no account of it was published at the time of the discovery.

THE ORGAN: A COMPREHENSIVE TREATISE ON ITS MANUFACTURE, PROCURAL, AND LODGMENT.[*]

By John Watson Warman,

Associate of the College of Organists, London.

f. HAVING done the preceding, see what is said (at *q q q q*, next) with respect to the Coupler Swell to Pedale's being made of the *Part* kind.

g. The only Defects which the Faringdon Treatment can be said to possess are the following:—(1) There is a slight Friction at the contact of the Square-Nose with the Key-Tail, such friction being caused by the lateral Traverse of the one across the other. (2) The Keys of the Swell-Section cannot be regulated from the front or outside of the Organ. (3) The Removal of the Great-Section Stickers is rendered a little less easy. (4) There is possibility of a "sticking", through the casting of a Backfall of the Great-Section, or of a Coupling Backfall, or of a Great-Section Sticker, or of two or more of these in contrary directions as one time. (5) A Clear Coupler Man.-to-Man. (see *r* next, 2nd parag. and on) is rendered less practicable, by reason of the non-correspondence laterally between the two sets of Keys, and because of the Fanning and Raised position of the Great-Org. Backfalls. (6) There is, at the fore Nose of the Coupling Backfall, a Friction, not only by its legitimate Traverse, but possibly also against its own or its adjoining Sticker. (7) The Coupling Action Man.-to-Man. cannot be Regulated from the front of the Organ. (8) There is no Participation (see *n*, ante) of the Swell-Org. Key-Tails when the Great is played upon with the Swell Coupled to it. (9) It is exceedingly difficult to Remove those Swell-Org. Keys which are Couple-able to the Pedals, because the Noses of the Action-Squares—not detachable like Stickers—placed on the Tails of such Keys, prevent the latter from being lifted free of the [long] Wires of the Stickers of the Action Swell to Pedale.

The foregoing have been stated in regular order of their importance, the *least* weighty being placed *first*. A few additional Remarks are, however, necessary.—No. 1 is of no real consequence whatever, for the very slight friction existent is much more than counterbalanced by the facility gained (with a proper treatment in the Contact of the Coupling to Pedals; see at *p*, ante) for the taking out of the Key, and because there is thus no Sticker,—the latter not only adding to the cost, but rendering Key-Participation less easy: see here at *s*, next, 1st parag.; at *o*, ante; and also again at *p*, ante, for other points there mentioned. No 2 also cannot be regarded as a fair objection. See now first at *h*, next (9th parag. and on) for a method of Front Regulation: to this it is to be added that the writer's *Cranked Sticker* (see *z*, ante) favours such a Regulation; but that such Cranking was not at that time known, and is also never required for the Skewed Key. There is, in the present Instrument, no difficulty whatever in Regulating the *Swell* Manual from the Organ interior, because the Pulls of this Section are close to the space between the two Manual Wind-chests (see at *d*, ante, 1st parag., for the posit of the *Great*-Section Pulls). No 3 also is of little moment, for, provided the Great Section Stickers be long enough, and the Coupling Backfalls be set sufficiently high (both of which points are properly observed in the Faringdon Organ), there can exist little difficulty in Removing such Stickers quite as freely as there is ever likely to be occasion for. No. 4 is of course of more weight in the abstract; but with properly seasoned material, and the Coupling Backfalls not too long (they are correct in such respects in the present Instance), the risk may be considered almost non-existent. Here see what is said at *k*, next, as to not having these Backfalls too *short*. No 5, though important in itself, is also not a fair objection: the writer's Clear Coupler was not invented at the time when the Faringdon Instrument was constructed; and in addition to this the comparatively ample size of its Pedale Section—*i.e.*, two 16ft. Registers and a Super-Octave Coupler to them—materially lessened the need for any supplementation of the Bass by aid from the Great-Organ. No. 6 is of course real. The Transverse of the Block-top must be tolerated, but it is too slight in amount to be of any practical importance whatever: any friction of the [Coupling] Backfall Nose against its own Sticker can be avoided by the simple expedient of slightly Bevelling the side of the said Nose: and the remaining risk—that of friction against the neighbouring sticker—can be got rid of by very slightly Sloping both the under side of the [Coupling] Backfall Nose and the [upper] face of the Driving-Block,—so that the tendency in the said Nose is to continually slide towards its own Sticker. No. 7 is the first real defect that presents itself. There is some difficulty in gaining access to the Regulating Buttons with which the Coupling Stickers are provided,—such difficulty arising from the fact of the Great-Organ Pulls being set at the front of the Instrument (see again at *d*, ante, 1st parag.), and, therefore, causing the rear ends of the Swell-Organ T-Squares to be at some little distance from the accessible space between the two Manual Windchests (see *Summary*, at *l*, next, 3rd parag.). And although it is quite practicable to employ a form of Regulating Mechanism for this type of Coupler which shall be properly workable at the Organ Front (see *h*, next, 3rd parag.), such working will require the aid of a regular Tool. No. 8 is a real, though easily remediable (see *o*, ante) blemish, but there is here this to be said in defence,—viz., that no other Organ-Builder, not even excepting Willis himself, seems so far to have realised this. No 9 is the most serious point of all, because the Removal of a Key, or even of an entire Keyboard, is liable to be urgently required at any moment, and in any Manual which has another Manual beneath it there is obviously the additional requirement of access to this latter as well. There exists also the consideration that whenever (as has already been seen to be the case here) such Wired-Sticker-driven Key-tails have Action Noses resting on them, and such Noses are set behind such Sticker-Wires, then the Actuation by the Pedal Key of such Manual Key has a tendency to tilt up the fore end of the latter (see *r r*, *Bis*, ante). This No. 9 Defect is the more unhappy because it is one so easily to be avoided (see *h*, next, 5th parag.), and this, too, *without* sacrificing that Participation (see *h*, next, 4th parag.) which constitutes the only merit of having the impulse of the Man.-to-Ped. Coupling to be given directly against the Key-Tail.

[It should be here observed that the writer is not absolutely, though being all but absolutely, certain that the last-named defect actually exists in the Faringdon Organ: a letter to Mr. Nicholson has elicited no reply.]

Here again collate the present with the Hoddesdon Design (comm. at *m*, next).

As a *Summary* of this No. 1 Treatment we may say that although it is, considered as a whole, a good one, yet that the presence of the three last named Defects should prevent its *literal* adoption under any circumstances whatever. For the corrections desirable we now proceed to the next.

h. *No. 2 Treatment.*—This virtually consists, as just intimated, in a Correction of the preceding Three last-named Defects, the Six first-named being generally inevitable with such particular [No. 1] Treatment (see, however, what follows at a little on, commencing two paragı. before *i*, next).

With the present Treatment the Arrangement and Structure of the Clavier-Involved portions of the Organ, and of the Manuals themselves (see, however, as regards latter, at *k k*, next) are assumed to be exactly as in Treatment No. 1.

Seventh Defect (stated at *g*, ante, 1st parag.). This may be obviated by applying a Regulating Button to the fore end of the Coupling Backfall, such Button being affixed on the lower end of a Screw-Wire, which passes vertically downward through such Backfall Nose. By simply Turning this Wire the desired Regulation can obviously be at once obtained. The [Coupling] Backfall itself should always, when it carries such Button, be so modified in its general form as to still ensure the proper Crossing of the Line of *Centers* (see on this matter in *Departments* Coupling - Action, and Key - Action). The Driving-Block will be Buffed, and also slightly Sloped as previously directed (see *g*, ante, 2nd parag.). The Button should be large enough in its [area] diameter to keep its Backfall-Nose clear of its own Sticker—thus avoiding the having to Bevel the *side* of the said Nose (see again *g*, ante, 2nd parag.)—, and will also be made convex at its bottom face in order that it may, as when *non* Regulating,—*draw* itself towards its said own Sticker; and the Regulating Wire will be formed at its top end into an Eye suitable for being clutched by a proper Regulating Tool. Of course the *Coupling Sticker* will not now receive any Regulating appliance. An easier way of obtaining Front Regulation of the present Coupler, so far as the making of the Backfalls is concerned, consists in applying the Regulating Button—in such cases Convexed at its *top* face—to the *Driving Block* attached to the Sticker,—the Screw-Wire of course then passing *up* through such Block, and having its clutching Eye coming below the latter, and its Button turned upwards and carrying the Backfall-Nose (see again *Departments* Coupling-Action and Key-Action). But remember that this last arrangement will probably be not quite so favourable to the Regulating—even with the said Backfalls set as *high* as possible (see *d*, ante, 5th parag.)—, because the Tool cannot be so easily inserted.

—*Eighth* Defect (also stated at *g*, ante, 1st parag.). This is easily and effectually got rid of by the method already given (at *o*, ante) of cutting each Key-tail of the *Coupled* Manual (here, the Swell) into a Fork, and inserting into latter the Nose of its Action Square.

—*Ninth* Defect (also stated at *g*, ante, 1st parag.). The method of remedying this also has been already described (at *p*, ante), as consisting in simply Wiring the Man.-to-Peds. Sticker-Head into the Square-Nose instead of into the Key-Tail,—of course securing *Participation* (see *n*, ante) either by the Nose-in-Tail-fork treatment (see *o*, ante), or, if the *Front Regulation* of the Swell-Org. Keys be insisted on (see next parag. but two), by the *Clip* device to be directly described (at *j*, next). It is, remember, only the *Swell* Org. Keys which will thus have the aforesaid Wiring entered into their Action instead of into their Tails. For the exact treatment of the Key-Tails and Square-Noses see as given in the shortly following Design (at *m*, next, 2nd parag.).

See at this point with respect to the Coupler Swell to Pedale being made of the *Part* kind (ref. *q q q q*, next);—in which event the just-mentioned entering of the Coupling-Sticker of course becomes *inevitable* for and in *one* of the two Noses which rest on the single Key-tail of such Swell Manual.

Before speaking of the Front-Regulation just indicated, it is as well to observe that it may be considered best, on the whole, to here keep each Great-Org. Sticker of one same *width* throughout its whole length (see now at *m*, next), because of the presence of the Coupling Backfalls between such Stickers, and of the consequent Blocks attached to the side-faces of the latter. But be careful that such width actually adopted be really sufficient to prevent the possibility of an unbidden sounding through any Sticker's becoming turned askew or across in the Cutting in in such a way as to be *jammed*. Here see (at *zz*, ante) how that the *Cranked* Sticker—described at *z*, ante—renders absolutely impossible any such jamming,—of whatever form the Sticker be.

It is now desirable to explain the manner of the said Front Regulation of the Swell-Org. Keys;—although it is to be distinctly understood that such Regulation is not, by the writer, advocated for the present Treatment, and has, therefore, *not* been included in the regular Defect just Corrected, but added here instead,—as a point of additional or extra information.

The most simple method of Front Regulation for a Manual, when its Action Noses—whether of Backfalls, Levers, or Squares—are in direct contact with its Key-tails, consists in providing each such Nose with a *Screw-Wire and Button*, of the kind which has just been described in connection with the Coupler Swell to Great. Here, see the description given with latter (at *h*, ante, 3rd parag.), the *first* form of which Regulation may be faithfully copied for the present Key Regulation, *excepting* that now the Button needs not to be convex at its under face, and that such *face* should here preferably receive the Buffing,—in the form of a little circular disc of soft Cloth glued thereto, so that the Key-tail (on which such Clothed face, of course, rests) shall not itself require such Buffing.

---

[*] All rights reserved.

In the present Treatment No. 2 it will, remember, be necessary that the said Action Noses do extend far enough forward for their Regulating Wires to be at any rate not in *rear* of the line of the Great-Org. Stickers, or else the Regulating Tool will not be able to properly operate between these last. It is required here only to add that in all cases where (as in Treatment No. $5\frac{1}{2}$; see at *u u*, next, 4th parag.) there exist *no* Stickers or other obstructing portions in front of the point of such Regulating Wires, the Clutching-eyes of the latter should preferably be made large enough to allow of being Turned by the Finger and Thumb.

(*To be continued.*)

PRACTICAL NOTES ON PLUMBING.—XXXVII.*

By P. J. DAVIES, H.M.A.S.P., &c.

(*Continued from page* 322.)

FIG. 220 A is a small diaphragm basin bib valve-cock, generally silvered; it is made in sizes from $\frac{1}{4}$in. upwards, $\frac{3}{8}$in. being generally use, and is one of the neatest designs yet introduced. For rerubbering the valve unscrew to top *b*. B is an end horizontal screw-down diaphragm basin valve-cock, also suitable for urinals, butler's pantry, sinks, &c.; C is the ordinary spring-valve, generally made to close with the stream; when such is the case a water cushion should be formed at the back of the valve to prevent concussion (see Closet Valves). D is the ordinary standard for screwing the basin-cock A into where the pipe passes through the slab, this is very handy when the basin-cock has no other fixing; F is the ordinary lengthening piece for bringing the nose of the cock forward, and over the basin when the cock is too short.

FIG. 220.

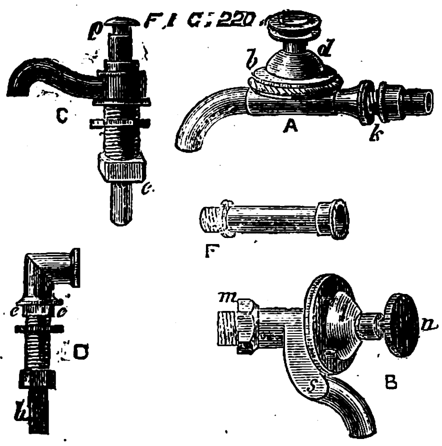

Fig. 221 is a diaphragm waste preventing basin-cock, suitable for schools, &c. For the action of this cock see valve 161.

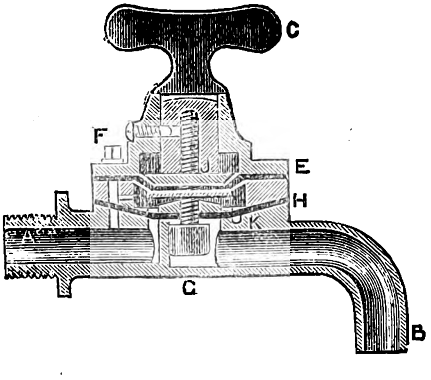
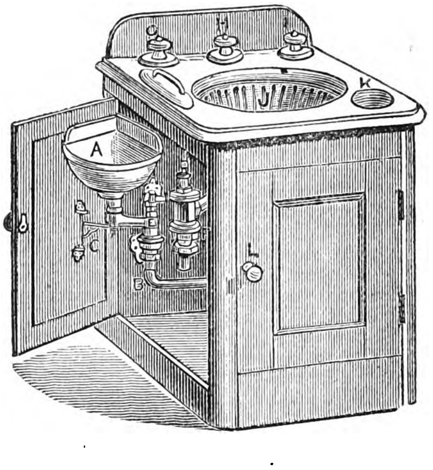
FIG. 221.



Lavatory and Urinal.

Fig. 222 is a lavatory basin and urinal combined. The basin has the usual pull-up knobs for actuating the valves from below; the urinal is made to swing with the door, and in such a manner that by the action of opening the door the water supply is opened, when the water runs full-bore to flush out the urinal.

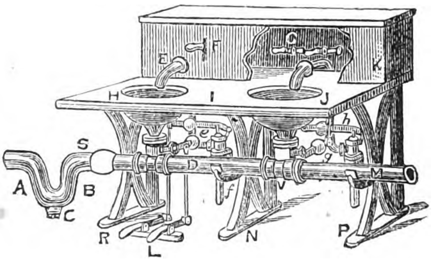
FIG. 222.



Lavatory Range.

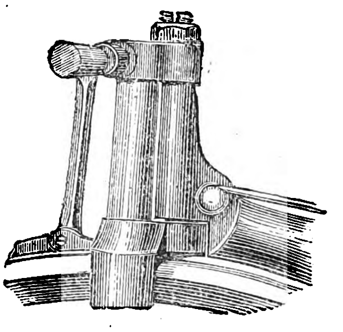
Fig. 223. This is nothing more than a number of lavatory basins, such as before described, fitted in a line; most of the preceding fittings may be used. This range is fitted up as follows:—First decide upon the number of basins, then have the top I.J, in which make the holes for the basins so that the rims will be flush with the slab, or if the basins are to be supported on a separate top (generally made of wood) then the rims must be let flush into the wooden top, and the slab bedded down with red-lead upon the rims of the basins, so that the water cannot get between, for if it does these basins will be a continual nuisance. In this diagram (223) the top slab is shown, supported upon three standards R, L, P; but it is not always necessary, for the slab J may be supported by letting it into the brick-work, say $4\frac{1}{2}$in., and making it good with Portland cement, or the slab may rest on wooden bearer, say of $4\frac{1}{2}$in. quartering, let into the wall between each basin or allowed to rest upon a frame, as shown at Fig. 222. Having all this settled, see about the waste M D S A. Sometimes this is done as shown in the diagram before us, that is, a pipe running along the entire length of the range, with lever-valves *g*, *h*, *e* discharging direct into the large waste-pipe, or instead of lever-valves, simple washers and plugs will answer; but when the washers and plugs are used, fix a trap below, because the plugs are nearly always left open, and the stink from the waste has every chance to come up; this not so much the case with the lever arrangement, because the valves are nearly always closed. Of course, I do not say that the waste-pipe A S D N is to be fixed of such large size or in such a manner that it will contain a lot of dirt; but, on the contrary, it must be constructed to be as self-cleansing as possible; but with every care there is sure to be filth collected in these long ranges of horizontal pipes. Lately, I have met with several fitted up with 4in. iron waste-pipe, this, for the small-waste generally fitted to wash-basins, is a mistake, for such large pipes cannot be expected to be washed out. In reason, the smaller this pipe the better. Say the outlet-valve from the basin is $1\frac{1}{4}$in., then the horizontal pipe should not exceed a $1\frac{1}{2}$in. smooth leaden pipe, with a fall of at least 1ft. in 10ft.; the trap A, should be fixed as near the end basin H as possible, with a pipe to insure fresh air from the outside of the building, but keep its end above the tops of the basins, or this pipe may some day act as an overflow pipe—that is, when the trap A becomes blocked. I have fixed such pipes to act as warming and fresh air inlet; but it must not be done so as to become a nuisance. Of course, from the other or top end of the waste pipe at Q, a ventilating pipe must, or at least should, be taken to above the level of the first air inlet, so as to induce the fresh air to be siphoned through the waste-pipe.

FIG. 223.



A SELF-STEERING BICYCLE-HEAD.

IN the accompanying engraving, we illustrate a new form of bicycle head, which possesses several novel features, which render it superior to other forms, as our readers—especially bicyclists—will readily perceive, one great point being that it is self-steering. In this head the centre of the neck is removed back from the centre of the head, and is held at the top and bottom in snugs. When a bicycle is ridden, the alternate pressure upon the pedals causes the front wheel and, necessarily, the head and handle-bar, to oscillate, and with the ordinary head, if the rider wishes to move in a straight line, and not follow a serpentine course, he must hold the handles quite rigid, and keep them square. With the new head the front wheel and head are kept straight and square by the pressure of the neck upon the snugs. The slightest swerving of the front wheel out of line with the backbone, throws the centres out of line with centre of the head and the back wheel, which causes the spring of the backbone to be exerted to pull into the line again, and so keeps the front wheel perfectly straight.



Again, when turning, the action of the centres throws the back wheel in a circle, and thus prevents the side-slipping always observed when commencing to turn a corner, which is the cause of the back tire wearing away so soon. This head is much longer than ordinary from centre to centre of neck. The usual length is 3in.; but this is $5\frac{1}{2}$in., at the same time the head in itself is no longer over all. It is also stronger, on account of the head being a perfect tube, which in ordinary heads is half cut away to allow the neck to enter, thus frequently causing the tube to break: it is also much lighter, as the barrel is hollow and thinner. This head permits the machine to turn in a small circle, and it cannot lock. The neck not being confined inside the barrel of the head, can revolve two thirds of the circle, whilst ordinary heads only revolve about one fourth of the circle. It can be taken to pieces very quickly, and, being made of hardened steel, the wear of the parts is greatly reduced. This head is the invention of Messrs. W. Gorse and Son, of the American Works, Icknield-square, Birmingham, by whom it is applied to the bicycles manufactured by them.

ELECTRICAL ACCUMULATORS OR SECONDARY BATTERIES.*

By Prof. OLIVER J. LODGE, D.Sc.

(*Continued from p.* 279.)

TO understand fully the action going on in a Faure cell it is necessary to know something about the salts of lead; for at the present time lead seems by far the most suitable material for secondary batteries. The protoxide of lead is called litharge, and is of a yellow or puce colour. Its constitution is PbO, and its atomic weight therefore 223. The intermediate oxide is red-lead, or minium, and its constitution appears to vary from Pb_2O_3 to Pb_3O_4; but it is most commonly the latter, and its atomic weight therefore 685. The peroxide, or black oxide, or heavy lead ore, is PbO_2, atomic weight 239; and it differs from the two preceding oxides in being a conductor of electricity, just as the peroxide of manganese MnO_2 is. The sulphate of lead, $PbSO_4$, is also important in the present connection. It is a dirty white non-conducting substance, slightly soluble in strong sulphuric acid, but quite unsoluble in dilute acid and in water. It will be formed, of course, as soon as red lead or litharge are put into dilute sulphuric acid; and unless there is an excess it may happen that all the acid gets used up in this way, leaving only water, in which case the liquid will cease to conduct. A Faure cell must therefore contain a considerable space for the acid liquid in addition to the space occupied by the plates and their coatings. But even then the strength of the dilute acid will become gradually weaker if a new Faure cell is allowed to stand for some time before a current is sent through it; and its resistance will accordingly be pretty high when you begin to charge. While the current is passing, however, the $PbSO_4$ formed while standing will be gradually decomposed, the lead being either reduced or oxidised, and the acid being reformed; so that the resistance of the cell will gradually diminish for this reason. It will also diminish for two other reasons, one of which is that the liquid is warmed by the current, and the average number of dissociated atoms thereby increased; while the other is that the spongy lead formed on the − plate, and the peroxide formed on the + plate, are both conductors; and hence the acting surfaces of the plates are practically slowly advancing to meet each other all the time the current is charging the cell, and the layer of non-conducting oxides and sulphate is gradually diminishing in thickness. Hence the urgent necessity for the flannel or felt between the plates. For, if ever, in the process of charging, any portion of the peroxide were to reach across to a portion of the spongy lead, a bridge of metallic conduction would be completed, and the cell would be short-circuited. It would be as reasonable to try and charge up a bit of copper wire as such a cell.

---

* From the *Building News*. All rights reserved.

*From the *Engineer*.

We perceived in the last article that a current of one ampère was able, in 108 hours, to oxidise a pound of litharge to peroxide on the positive plate of every cell through which it is passed, and to reduce a pound to metallic lead on the negative plate in the same time. The oxidation of a pound of minium (Pb_3O_4) to the peroxide can be effected by a rather less quantity of electricity, namely, by 48,000 / 685 = 70 ampère-hours; there being four bonds joined up when Pb_3O_4 is oxidised to $3(PbO_2)$. But to reduce minium to metallic lead requires a greater quantity—eight bonds having to be loosed — namely, 96,000 / 685 = 140 ampère-hours. Hence, provided there is no waste and no gas given off, twice as much minium will be oxidised in each cell by a given current as is in the same time reduced. But with litharge the quantities oxidised and reduced are equal. When minium is used, therefore, either the coat of it on the + plate must be considerably thicker than the coat on the negative, or else the + plate itself must be expected to be eaten into somewhat before the reduction on the other plate is finished, and must be made of sufficient thickness to stand it.

Every pound of metallic lead thus oxidised to peroxide will require 48,000 / 207 = 230 ampère-hours of electricity.

If any gas is given off, every pound of hydrogen collected accounts for 12,000 ampère-hours; or, as a pound of hydrogen occupies about 180 cubic feet under ordinary circumstances, we may reckon the electricity necessary as 67 ampère-hours per cubic foot of hydrogen. If any free oxygen is detached, the electricity may be reckoned at the rate of 134 ampère-hours per cubic foot, or 1,500 Ampère-hours per pound.

Now let us take a single Faure cell charged with minium, and pass through it a measured current of C ampères for an observed time of T hours. Let the gas evolved be collected, and found to consist of h cubic feet of hydrogen and g cubic feet of oxygen. Let the weight of minium reduced to metallic lead on the negative plate be called x, and the weight oxidised to peroxide on the positive plate be called y, both being expressed in pounds avoirdupois. Further, let z pounds of the + plate itself be oxidised to peroxide; let a small quantity, say u pounds, of hydrogen remain associated with the negative plate, either mechanically as bubbles, or as a sort of alloy; and let v be the weight of oxygen likewise liberated but unable to escape, or else used up in some indirect way. Then the following two equations render a full account of all that has gone on, as far as electrical laws can express it:

$$C\,T = 70\,y + 230\,z + 1500\,v + 134\,g$$
$$C\,T = 110\,x + 12{,}000\,u + 67\,h$$

The quantity g is probably zero if a properly weak current has been used in charging. The quantities u and v will also probably be small;[*] and, therefore, perhaps, for practical purposes it may be sufficient to write

$$C\,T = 70\,y + 230\,z$$
$$C\,T = 140\,x + 67\,h$$

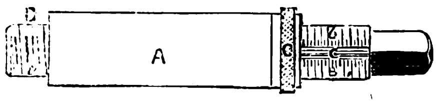
Now h, the volume of gas evolved, can be easily collected and measured. There remain then the three unknown quantities $x\ y\ z$. The above two equations are, of course, not sufficient to determine them; but they show us the kind of relation which must exist between them, on the hypothesis that u and v are negligible. Especially we learn how much the + plate will have been attacked at any time after the whole of its minium layer has been reduced.

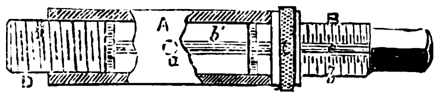
The most direct way of determining C T is to insert in the circuit some kind of voltameter, say a couple of large copper plates immersed in a solution of sulphate of copper; then by the time that one of the plates has gained, and the other lost, P pounds in weight, the quantity which has passed will be

$$C\ T = \frac{24{,}000}{63{\cdot}5}\,P = 377\ P \text{ ampère-hours.}$$

HANDY NUT MANDREL.

ANNEXED diagrams represent a handy tool for holding nuts while being squared up in a lathe. The holder consists of a thimble A, provided with a pin or spline, *a*. B is a mandrel made to fit snugly in the thimble, although not too tight to prevent its moving easily in same; *c* is a recess in which the pin *a* plays and prevents the thimble from turning on mandrels; *b*, *b*, are threads cut on either end. C is a nut for determining the distance that the nut (which is to be squared up) can be screwed on mandrel at the end D.





In operating the holder the milled nut, C, is moved back or forth until the nut, which is screwed on end D, and against thimble A, will sufficiently overhang the end of mandrel to allow of being squared up. By this arrangement any thickness of nut may be had without injuring the threads on mandrel. The threads on mandrels, as commonly made, are soon cut up and rendered useless.

The tool just described having proved itself time-saving and valuable, is, I think, entitled to a little space by which it can make itself known. As far as I know, it is not patented, and is, therefore, free to all.—C. C. Abbe, in *American Machinist*.

ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.—XII.[†]

(*Continued from page* 303.)

Printing.

IT will be noticed that the prints as they come from the frames are of a more or less unpleasant colour. The operation which is to be described, and which is called toning, is intended to correct this defect, and to give them the pleasing colour which we are accustomed to see. Toning may be said to be at once the easiest and the most difficult photographic process. Nothing is easier than to tone, nothing more difficult than to tone well. Anyone can change the colour of a print to a sort of slatey grey; there are not very many who can be sure of getting at all times a pleasing tone and the exact tint required. The difficulty lies in the direction so common in photographic operations. A certain result is gained, but the after-processes modify this result, so that great experience is necessary to know beforehand what will be the final appearance of the subject.

The toning solution mentioned in the last lesson (p. 303) is too concentrated to use as it is: it must, therefore, be diluted. The common practice is to use a large quantity of toning solution, and, if it is not exhausted, to keep it for after-use. This is very well for the professional who tones at regular intervals, but in the case of the amateur we think it is not advisable. The solution once used is very liable to "go bad," the gold being deposited at the bottom of the bottle. We therefore recommend that beginner estimate the amount of toning that will be necessary, allowing a little margin, and after he is done, throw it away. The waste will be very small—so small that it will not be found worth while to keep the liquid as residue. If the prints be trimmed before toning, one grain of gold is amply sufficient for each sheet of paper measur-17in. by 22in. Let, therefore, one ounce of the stock toning solution be taken for every sheet of paper, and let it be diluted with six or seven times its amount of water.

Now let the prints be taken one by one, and placed in any dish which is suitable for washing them in; a common small wooden tub is the best of all. Let the prints be kept from sticking to each other, and be moved about by hand. It will be seen that the water becomes milky from the nitrate of silver in the paper forming chloride and carbonate of silver with the salts in the washing water. The water must be changed several times till this milkiness disappears entirely, or almost so. The washing is best done by the light of a candle or lamp, as such will not affect the paper. The toning must be done in feeble white light, as it is difficult to judge the colours by yellow light. It is best performed in a flat white dish at least an inch larger each way than the prints. Let one print be taken from the washing water, and placed in the toning, first face downwards, then turned face up, then down, once or twice, so as to allow the solution to act evenly on it. Now let another print, and perhaps two or three more, be similiarly placed in the solution. It will be noticed that the prints, during washing, turn to a brick red. In the toning they will turn to a brown, and gradually to a sort of violet or purple. They must be kept in constant motion. The best plan is to keep continually lifting the undermost print, and placing it on the top. At first only a few prints should be attempted; after some practice, a dozen or two may be in the solution at once. When many prints are toned together, it is a good plan to have two dishes of toning, side by side, and keep lifting the prints out of one into the other, the whole of the prints being turned over in a mass when they are all in one dish.

The difficulty is the one indicated before—viz., at the time of toning to discount the change which will take place during the after-processes. The difficulty is greatly increased by the fact that every brand of paper acts in a somewhat different manner from any other. Very few ready sensitised papers will stand being pushed to the purple stage; that is to say, if the toning is continued to the purple, the final result will be disappointing, although the prints will look beautiful before fixing. It is usually advisable to remove the prints from the toning solution whilst they are still of a very warm brown in the shadows. It is a good test to watch the half-tones, and when these begin to become purple or violet, to remove the print. The prints when removed are placed in another dish of clean water. They must be moved about for a short time after first placing them here, so as to get rid of the greater part of the toning solution which is in the pores of the paper, and which would make the toning proceed after it was desired to stop it. When all the prints have passed through the toning bath they must be washed in several changes of water, being kept moving for about five minutes during each change. Now comes the fixing: the prints are removed from the washing water, and are placed in a flat dish. Sufficient fixing solution to quite cover the prints is poured in, and they are kept moving for about twenty minutes; more than one change of colour will be noticed during this time. The first will be an almost total loss of tone; afterwards the colour will return to something like its former self. A further change will take place when the prints are dried. After fixing, it is necessary to wash the prints most thoroughly for not less than twenty-four hours. Is is best done in running water, but if this cannot be had, then frequent changes will do. The smallest trace of hyposulphite in the prints will cause them to fade. The prints, after washing, are allowed to dry spontaneously, being placed on any clean surface; or they may be mounted wet on cardboard. In either case they should be afterwards rolled. A rolling press is an expensive article; but the amateur can generally find some neighbouring photographer who will roll his prints for a small consideration.

The great convenience of ready-sensitised paper is that it will keep for a very considerable time, either before printing, or between printing and toning. The means of preparing such paper is at present a trade secret, and when the amateur prepares his own paper, he will find that it will turn brown after about twenty-four hours. He must therefore do his sensitising and toning all in one day. If he has time to do this, he will probably be rewarded by superior results. We shall therefore describe the process of sensitising. "Salted" albumenised paper is purchased—that is to say, paper coated with albumen which is impregnated with soluble chlorides. A "silver-bath" is prepared by dissolving nitrate of silver in distilled water. The strength of the bath varies with the paper used. Every dealer in albumenised paper will state what strength of bath is best to use for the particular brand. One containing sixty grains of nitrate of silver to each ounce of solution will suit most papers. Enough of this must be prepared to cover the bottom of the flat dish to be used in sensitising to a depth of at least ⅛in. The dish should be half an inch larger than the paper in each direction. If much paper is to be used, it is best to sensitise in large pieces, and cut it into sizes before printing. Professional photographers usually sensitise a whole sheet at a time.

---

[*] They are multiplied by large coefficients though, and I am by no means sure how far it is practicable to neglect them. I believe the reduced lead is alloyed pretty strongly with hydrogen.

[†] Condensed from the *Photographic News*.

A room lighted by a lamp or gas is the best to carry on the sensitising process. Strings should be stretched in convenient positions for hanging the paper on to dry. American clips are useful for fixing the paper to the strings. Let the silver solution be poured into the bath, and let a piece of the paper be taken by opposite corners, and with the albumenised side downwards. Let the paper be so held that it will first touch the surface of the solution in a line between the two corners not held by the hands. We again take the simile of a printed sheet. Suppose the paper held by the right-hand upper and the left-hand lower corners. Now let the left-hand upper corner touch the surface of the solution, and let the paper be lowered till it touches in a line from the left-hand upper to the right-hand lower corners. Now let the two corners held in the hands be dropped, first one and then the other. If it be carried out properly, there will be no air-bells under the paper, but it is best to lift it from the solution after about a minute and look, to make sure. If there are any, they can be broken by gently moving about the paper whilst one-half is held out of the solution. The time of floating varies with different papers and different strengths of baths. It should be ascertained when the paper is purchased. With a sixty-grain bath from three to five minutes is usually ample. If the paper curl out of the bath at the edges, it may be caused to lie flat by blowing on it. After the specified time has elapsed, let the paper be removed from the bath by drawing its surface over one edge so as to drain off most of this silver solution. It is only necessary now to bring it up by one corner to dry. A small fragment of blotting-paper should be caused to touch the lower corner immediately that it is hung up. This will adhere by capillary attraction and collect a drop or two of solution which would otherwise fall on the floor.

If the room be warm, the paper will dry in ten minutes or a quarter of an hour.

USEFUL AND SCIENTIFIC NOTES.

Corn Cures — Dissolve 1 part of salicylic acid in 40 parts of collodion: apply several times a week. The corn dissolves with little trouble. For hard corns, apply at night a mixture of 1 part of carbolic acid, and 10 parts of distilled water, glycerine, and soap liniment. Envelop with gutta-percha tissue, and the corn may generally be removed the next morning. For inflamed and swollen joints, proceed in the same manner, but use, instead of the above mixture, liq. plumbi dil., 100 parts, and tinct. croci, 5 parts.

Fast Atlantic Steaming.—A bill, submitted by Mr. Robeson to the United States Congress, in regard to a fast mail steamship line, authorises the United States Postmaster-General to contract for and establish a weekly mail service between Fort Pond Bay on Long Island, and Milford Haven, Wales, by means of a line of first-class steamships, and provides that the vessels shall be iron or steel screw steamships, capable of making at least 18 miles per hour, and shall be wholly of American construction. They shall be allowed to carry passengers and their baggage in addition to the mails, and do an ordinary express business, but shall not engage in any freight traffic. The Government shall have the right, in case of war, to take for the use of the United States any or all of the vessels employed on the line, on paying a reasonable compensation to the owners, not to exceed in any case the original cost of the vessels. The compensation proposed for the mail service is graduated as follows:—12,500 dols. for each outward bound trip made within six days; 10,000 dols. for each trip made within seven days; 7,500 dols. for each trip made within 7½ days; 5,000 dols. for each trip occupying more than 7½ days. The project referred to will be recognised as the Corbin-Lorillard line of six-day steamers.

The number of hours of bright sunshine recorded by Campbell's sunshine instrument at the Greenwich Observatory during 1881 was 1,301, which is more than 100 hours above the average of the four preceding years.

SCIENTIFIC NEWS.

◆◆◆

As Comet Wells will be again visible in this country at the beginning of next month, the following ephemeris for Greenwich midnight may be found useful. The brightness is now decreasing, and on July 15 it will be equal to what it was on April 19:—

	R.A.			N. Dec.	
	h.	m.	s.	°	′
July 1,	9	35	58	11	57
July 5,	10	4	21	10	50
July 9,	10	28	2	9	47
July 13,	10	48	1	8	49

At Greenwich the comet sets on July 1st, 1h. 44m. after the sun.

Dr. Bergsma, who lately resigned the post of director of the Batavia Observatory, died on his way home while passing through the Red Sea.

The Council of the Society of Arts have awarded the Albert Medal to Prof. Louis Pasteur, for his researches in connection with fermentation, the preservation of wines, and the propagation of zymotic diseases in silkworms and domestic animals.

The annual general meeting of the Society of Arts will be held on the 28th inst.

Mr. R. S. Newall has issued a pamphlet (Spons) entitled "Facts and Observations relating to the Invention of the Submarine Cable," &c. It is written by way of reply to a paper by M. Bede, addressed to M. Dumas, in his position as President of one of the juries in the Paris Electrical Exhibition. Mr. Newall claims to have been the first to suggest laying telegraph-wires under water, and also to have laid the first submarine cable.

The Rev. E. J. Warmington, of Dengie Rectory, Maldon, says, apropos of the article on utilising the motions of the sea (p. 279), that the method of utilising the tides and wind combined was anticipated by him, and described in two letters to the *Times* (not inserted), and in one to Sir W. Thomson, whose remarks at the last meeting of the British Association gave rise to them. Mr. Warmington considers that a proper system of floats could be readily made to gather up the forces at present wasted on our coasts. Tidal power, with a rise of 6ft., can, he says, never give more than its theoretic maximum of 1-2117th of a horse-power per square yard, whereas if wave-motion were utilised by means of floats and levers it would give at least 1-15th. Floats could be fitted at many places where reservoirs would be impossible, and as they could be used at many points around the coast, the power could be transmitted by the shortest route. From the papers received by us, it is not clear how the motion of the waves is to be transmitted in such a manner as to drive a dynamo-machine.

Mr. C. Chevallier, electrician at Aden to the Eastern Telegraph Company, has modified some of the arrangements of Sir W. Thomson's siphon recorder. He dispenses with the large electro-magnets excited by a Daniell battery, and uses, instead, a powerful permanent magnet made, we believe, of steel containing from 2 to 3 per cent. of tungsten. With one of these improved magnets good signals have been obtained on the recorder through the Aden and Zanzibar cable.

Mr. G. W. Webster has discovered a method of correcting over-exposed gelatine plates. He adds to the developing solution a little citrate of soda, about four grains, presumably of a saturated solution, for every drop of ammonia. The effect is to check devolpment while allowing intensification to proceed. The best proportions are unknown: those given have yielded good results in Mr. Webster's hands.

The largest gas-lamp in the world is said to be one used at the Darlington Art Industrial Exhibition, made by Mr. Heron, of Manchester. It gives a light equal to 2,000 candles. It is 8ft. high by 6ft. broad, and has 50 duplex burners, each consuming 10ft. of gas per hour.

Some experiments on the conducting power of the earth for tremors, have been reported to the Seismological Society of Japan by Prof. H. M. Paul. He uses a vessel containing mercury slightly thickened with tin, which is screwed on to a post sunk about four or five feet into the ground. An express train passing at a distance of three-quarters of a mile set the mercury vibrating for three minutes, and a one-horse vehicle passing along a gravelled road 500ft. distant sensibly agitated the mercury whenever the wheels passed over a stone.

The report on the incandescent lamps exhibited at the Paris Electrical Exhibition has been published, and from that we find that the maximum efficiency cannot be assumed to exceed 300 candle-lights per horse-power of current. Edison's lamp takes the first place in these experiments; but since they were made considerable improvements have been effected in some of the other systems.

A splendid conversazione took place at the Royal College of Physicians, in Pall Mall, on the 14th inst. The Prince of Wales was present, and examined with great interest some fine stained specimens of the bacilli of tubercle, which were exhibited by Miss Watson Cheyne and Mr. E. M. Nelson. The greater part of the Prince's visit was, in fact, devoted to these specimens, which were shown to him by Mr. E. M. Nelson, and which excited also much interest among leading physicians as being now supposed to be the primary cause of consumptive diseases. Professor Tyndall also exhibited, by means of the electric light, his new experiment upon the interference and reflection of sound; also some curious phenomena of colour, due to exhaustion of the retina when the eyes are continuously directed upon discs of brilliant colour, and by consequence a white ground appears to be of the complementary colour. Many objects of artistic and scientific interest were exhibited.

Mr. Michael Reynolds' long-promised book on the important subject of "Continuous Railway Brakes," will be published this week by Messrs. Crosby Lockwood and Co., of 7, Stationer's Hall-court, Ludgate-hill, London.

Some interesting physical methods were described at the séance of the French Academy on 5th June. One is for ascertaining the specific heat of mineral substances, which it is difficult to get in large mass. It is devised by MM. Thoulet and Lagarde, and is on the following principle:—Suppose two thermo-electric junctions in two small tubes containing a liquid of known specific gravity. The substance under examination being heated to a known temperature and put in one of the tubes, the deflection of the galvanometer measures the rise of temperature. This result is compared with that obtained from a typical substance—*e.g.*, pure copper. Water or oil of turpentine was the liquid used. A comparison of the numerical results for several minerals whose specific heat was measured by Regnault, with the numbers got by that physicist, proves the exactness of the method. Again, a hygrometer, acting by condensation, was described by M. Crova. It consists of a nickelised tube, brightly polished interiorly, and closed at one end with ground-glass, and at the other with a lens. The observer looks through it towards a source of light, applying the lens to the eye. The air to be examined is drawn slowly through the tube, entering and leaving by tubulures at the ends. Round the tube is a cooling arrangement, a cylinder holding sulphide of carbon, through which air is passed. When the dew-point is reached, striking changes occur in the interior aspect of the tube, the dew appearing as dark brown spots. By raising and lowering the temperature several times, these are made to go and come, and a thermometer-bulb being inserted in the sulphide, the dew-point can be estimated very accurately. M Violle described a new calorimeter.

It has been recently announced by Herr Hermann, that germinating seeds (*e.g.*, peas), in water or moist surrounding, show a regular and strong electric current, the radicle being negative to the cotyledons. The strength is often over one-tenth of a Daniell. He is investigating the phenomenon.

From a comparison recently made by M. Pfarski it appears that the new Volga Bridge, near Syssran, 1,485 metres, is the longest in Europe; but it is exceeded by several in America —viz., the Victoria Bridge over the St. Lawrence; the Delaware Bridge, Philadelphia; and a bridge over the East River, each 1,500m.; Ohio Bridge, near Louisville, 1,615m.; St. Charles Bridge, over the Missouri, 1,993m.; and Parkersburg Bridge (the longest), 2,147m. After the new Volga Bridge, rank, in order, the Hollands-Diep Bridge, near Inverdyk, 1,479m.; bridge over the Pongabuda, near Gooty (India), 1,130m.; Dniester Bridge, near Kiew, 1,081m.; Rhine Bridge, near Mainz, 1,028m., &c.

While a considerable degree of comfort is now realised in railway travelling, there is still room for improvement, and we may invite attention to a new system of interior suspension in carriages, by M. Delessert, lately reported on with approval in the French Société d'Encouragement. It has been employed a few months in twelve first and second-class carriages of the Chemin de Fer de l'Ouest. Not only does the body of the carriage rest on springs, but the seats, backs, and (cut-out) foot-boards form one whole, which is supported on steel springs connected with a standard near the sides of the compartment. Thus a double suspension is obtained. The prevention of vibration, usually experienced through the floor, is of great advantage to invalids and nervous persons. The cost of alteration is about £38 for a first-class compartment; which would be somewhat high, it is remarked, were it not that there is compensation in increased durability, through reduction of shocks and vibrations. (Illustrations of the system will be found in the Society's *Bulletin.*)

In view of the large use now made of hempen straps for driving-gear, means of transport, slaters' chairs, &c., Herr Weinlig has recently made experiments with a variety of those straps (from a manufactory in Halberstadt), with reference to rupture. While cotton straps stretched about 6 per cent., the double hempen ones stretched 11 per cent., and the four-fold 9·5 per cent. It appeared—(1) That Russian hemp is superior to Italian, about 10 per cent.; (2) that cotton straps bear scarcely more than half the breaking load of hempen straps per square millimetre of cross section. (3) Straps broke quite gradually one thread after another. There was first a slight crackling, then the threads broke with distinct sound. (This property is valuable, as it insures great safety, if the straps are often tested). (4) The considerable uniformity of breaking loads in each case proves that these straps can be woven of great regularity and perfection. (5) In use of the straps for slaters' chairs and lifts, 8 to 10-fold safety could be attained; so that, on an average, 0·4 kg. per square millimetre cross section (not counting vacant interstices) may be taken as the permissible load.

For demonstration of the third pendulum law, Prof. Mach, of Prague, uses an arrangement whereby the plane of oscillation can be variously inclined to the vertical (the time of oscillation increasing with this inclination). The pendulum-bob is supported by two divergent rigid bars within a rectangular frame, which can be tipped and fixed. If the tipping goes as far as 90°, the time of oscillation becomes theoretically infinite (∞). The pendulum does not return to a position of equilibrium, but goes on in one direction till its kinetic energy is destroyed by friction.

The immigration to New York in April reached the high figure of 70,376, showing an increase of 9,100 over the same month last year. The total arrivals from January 1st were 142 716. As compared with April last year, the Norwegians show the greatest increase (2,332 against 317). The Danish immigration is increased nearly 100 per cent. The immigration of Russian Jews was increased more than 200 per cent., but there is a greater proportionate falling off in the Polish Jews.

In a paper recently read to the French Society of Civil Engineers, M. Cœne expresses surprise that the Seine is not better utilised for traffic between America and Europe. Rouen, with its new quays, has had an increase in tonnage of merchandise from 400,000 to 1,500,000 in five years, and is the fourth port in France. But it should be made possible (M. Cœne holds) for the large ships of modern build (some of them 5,000 tons) to come to Rouen; and the first thing to be done is to form, in the bay of the Seine, an embankment of large size, giving a better direction to the principal channel of the estuary. The estimated cost, 25 million francs, would be diminished by 15 millions for recovered land. An immense sheltered roadstead, 4,500 metres long by 2,200 broad, would be formed before the port of Havre capable of accommodating the largest fleets.

A curious fact in connection with instantaneous photography is noted by a correspondent of *La Nature*. In the photograph of a vehicle drawn by a trotting horse, all the parts are given with irreproachable distinctness, except the wheels, which, in their upper part, are less distinct than in the lower. The reason is (as can be easily shown), that the spokes of the wheel have a much greater velocity when at the upper part than when their extremities are near the ground.

By reason of improvements in the telephone, M. Van Rysselberghe, director of the meteorological service in Belgium, lately achieved the remarkable result of telephoning and telegraphing on the same line at the same time. A Morse telegraphic message was sent from Brussels to the engineer-director of telegraphs in Paris, and an oral message was sent by the same wire, which was heard while the Morse receiving apparatus was in action.

One feature of the interesting scheme for high-speed railway travelling, developed by Mr. Le Van in a paper to the Franklin Institute (and in which he aims at ninety miles an hour), is construction of the permanent way, so that stations shall be located at summits, and the force of gravity of the train assist the locomotive both in starting and stopping, it being important to lose as little time at the stations as possible, either in stopping or starting; to keep up a high speed to a point as near the station as possible, and in starting to get the train under full speed in the least possible space of time.

LETTERS TO THE EDITOR.

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original." —*Montaigne's Essays.*

◆◆◆

ζ HERCULIS.—Σ 1888 AND Σ 1884.—Σ 1555.

[20179.]—The following are some of the latest measures of ζ Herculis (letter 20122, p. 305):—

Hl.	120·75°	1·498″	(4 nights)	1879·46.
β	122·0	1·52	(3 ,,)	1879·45.
Seabroke.	120·7°	1·62	(2 ,,)	1879·65.
β	114·1°	1·34	(5 ,,)	1880·49.

The angle and distance at the present time are about 103° and 1·55″. Next year, the distance will be 1·65″ +, and the *comes* will remain at about this distance until 1888, when the stars will gradually commence to close up. Mr. Simms ought to see it with even a smaller aperture than 4in. Dawes saw it well with 3·8in. when the central distance was about 1¼″. The late Mr. T. W. Burr found "the pair well separated" with his 3⅜in. Ross; and I notice that Mr. Gardiner says on p. 278 of the volume of the English Mechanic referred to by Mr. Simms, that it was seen by him in June, 1880, with a 3½in. telescope reduced to 3¼in. The reddish colour of the companion is striking. I saw it last year, but with difficulty, with the 3¼in. Sheepshanks equatorial belonging to the R.A.S., the companion appearing as a reddish dot not perfectly separated from the large star. The object-glass of this telescope is, however, not a very perfect one, and the power used was not high enough to divorce the components.

Σ 1883. This star is probably a binary, and is now closing up. The latest published measures are, Hl. 257·17°: 0·730″: (3 nights) 1879·46. The principal star of Σ 1884 is brighter than that of Σ 1883; but the difference between the two components is greater. Σ says of his 1883, "*at prior minor.*" Σ 1884 is a naked eye star, and the components have been relatively fixed since 1829.

With regard to one star, Σ 1555, in Mr. Perry's letter (20070, p. 260), I would remark that Smyth's measure of C is "Smythian." I have noted in the "Appendix" to the "Handbook of Double Stars" two measures of C by De. and Eng., and in a recent communication to these columns I suggested a correction to Eng.'s distance, which brings it into excellent accord with those of De. and Mr. Perry. H. Sadler.

P.S.—Would Mr. Perry, kindly measure the third companion of ξ Böotis? There is only one measure in existence, viz., Mä's, and that is probably 100° in error, or else it belongs to Σ 1893. If this faint star is not physically connected with ξ it is probably now in about 350° + 24″ +. The discoverer, Sir J. Herschel, says it is almost the "minimum visibile" with his 18¼in reflector.

H. S.

WELLS' COMET.

[20180.]—Soon after writing letter 20036, page 237, containing the elements of an orbit for Wells' comet found by projection, I began strongly to suspect that the comet had been disturbed in its path about April 23rd, so that all observations prior to that date used to find an orbit would throw the results in error. I was confirmed in this opinion by the comet getting before the places I had assigned for it. In finding the orbit, I had used an observation of April 8th, before the supposed disturbance took place; and to make the orbit agree with that position, it had to be altered a little, making the perihelion distance too great, causing the predicted places, while on the same apparent path, to be behind those occupied by the comet. I have since found an orbit from observations since the supposed disturbance took place, which agrees well with all the positions, but which cannot be made to agree with the observed places before April 23rd, the place for the comet on the orbit and the observed place differing more than a degree and a half in apparent position for April 8th, the difference getting less as the observations approach the 23rd. This orbit agrees very closely with that given by Dr. Openheim, in your "Scientific News" column (page 258), except that I make the perihelion passage a few hours earlier, and distance a trifle less.

It may seem very bold to make this announcement, and I have hesitated to do so, while I have investigated and tested the matter in every way I can think of, and I have not been able to come to any other conclusion, the graphical method I adopt being very favourable to the discovery of any inequality in the motion of these bodies, while, from the mathematical method, though causing great difficulty, it might remain long undiscovered. Such, I think, has been the case with the present comet.

It seems to me there is nothing very improbable in the supposition that the comet may have passed through a dense portion of some meteor stream, and so have been deflected a little from its previous course.

I should like to direct your readers where to look for the comet when it is again seen above our horizon. My last observation was on June 3rd, and four weeks is a long way ahead, around so close a perihelion passage, to predict with accuracy. Asking, then, for the indulgence of your readers in this matter, I would say, search for the comet about 10° to the left of the planet Venus, at 9h. 30m. on July 1st, R.A. 9h. 40m., Dec. N. 14°, this point setting a few minutes after the planet. On subsequent nights the comet will be a little more distant from Venus, and set a little later. It seems that the comet will pass near the Earth's orbit about July 10th, near the place occupied by our planet on April 12th.

J. Lane.

29, Wyvis-street, Bromley, E., June 17th.

WORK DONE BY AN 8·5in. BROWNING-WITH REFLECTOR, 42 COMÆ BER., 25 CANUM VEN., Σ 1772, Σ 1819, β 224, ζ BOÖTIS, ε BOÖTIS, ξ BOÖTIS, 1 (B) CORONÆ BOR., η CORONÆ BOR., μ² BOÖTIS, δ SERPENTIS, O.Σ. 298, β 619 SERPENTIS 55, β 355, λ OPHIUCHI, Σ 2062, ζ HERCULIS—THE ORBITAL MOTION OF SIRIUS—OBSERVING WEATHER IN NORTHUMBERLAND.

[20181.]—I think Mr. C. Gaudibert (No. 898, p. 305, letter 20120) must be congratulated on possessing an exceptionally fine instrument if he can clearly divide 42 Comæ Ber. and 25 Canum Ven. It is a With-Browning reflector of 8·5in. aperture. Now, according to Dawes, the least separable distance of an object-glass of that aperture is 0·536″. Of 42 Comæ Ber., Dawes writes (quoted by Gledhill):—"It is one of the closest of Σ's discoveries. It requires the finest and largest telescopes." O.Σ. found it single in 1870, and the same observer gives the distance of the components at 0·30″ in 1874. Dunér measured it in 1875, and gives the distance 0·32″. The Washington observers in 1876 give the distance varying between 0·38″ and 0·42″, and Jedrzejewicz, in 1880, found it "oblong," but β, in 1879, gives the distance 0·68″. I have measured it on three nights this year, and find the vacancy 0·5″, 0·3″, 0·4″ respectively, giving a mean of 0·4″. I do not think the distance, as it is at present, is understated. Smyth could never fairly divide it, and Chambers's note on it is: "This binary is as remarkable for the closeness of its components (even when at their maximum distance), as for the shortness of its period, which is certainly no more than about 25 years. Observations of it are at all times very difficult." Now, assuming that Dawes' rule as to the least separable distance of an 8·5in. object-glass holds good for a mirror of that aperture, this star ought to be beyond the reach of Mr. Gaudibert's instrument; and if he sees a "black division between the discs (which he doubtless does), I think, in any case, his mirror must be a very fine one (which we should expect as Mr. With's handiwork), and it also raises the question whether a really fine mirror does not possess superior defining power to an object-glass, equally good, of the same aperture?

In regard to 25 Canum Ven, he merely elongates this difficult and unequal pair; but if he really sees the companion (which I do not doubt), I consider it a very wonderful feat, both for his aperture and eye, for this star is far more difficult than 42 Comæ Ber., and a much severer test. From 1856 to 1875 Secchi, Dembowski, Dunér, Wilson, and Seabroke, the Washington observers, and Gledhill found it "elongated" or "single." Schiaparelli measured it in 1876, P = 161·03°, D = 0·42″. β also measured it in 1880, P = 155·0°, D = 0·60″. I did not see the companion in 1881. Indeed, during the apparition of the star there was no night good enough to give me a chance of doing so; but I have made six measures of it this year, with the result stated in my last letter.

From 1833 to 1841 the angle was from 70° to 72°, and "O. Σ's." interesting note (quoted by Gledhill), says:—"The feeble angular motion from 1833 to 1841 indicates that the satellite was in aphelio in that period. The apparent ellipse is evidently very narrow. We shall probably see the companion emerge from the rays of the principal star under an angle of position between 180° and 90°. If so, the period of revolution does not greatly exceed a century." Doberck has assigned a period of 124 years. The inequality of the components (5, 7·6) as well as their closeness, demand that telescope, eye, and atmospheric conditions shall all be of a high order. I should certainly have thought it was beyond the reach of Mr. Gaudibert's aperature; but I am glad to see he is able to deal with it.

If you can spare the space, it will doubtless add much to the interest of my measures if I give comparison ones at intervals of a few years—at least in the case of rapid binaries—together with brief explanatory remarks. For these I shall be indebted almost entirely to Mr. Gledhill's "Handbook of Double Stars."

In continuation of my measurements, we have:

Σ 1772. R.A. 13·37. Mags. 5·8, 8·2.
P = 236·0° D = 2·65″ Ep. 1882·40

Gledhill truly calls this "a beautiful pair." He says it is a binary, and gives the colours of the components, A, yellow; B, very blue; remarking that the colour of B probably changes. I find it a purplish blue.

Σ 1819. R.A. 14·9. Mags. 7·9, 8.
P = 199·0° D = 1·3″ Ep. 1881·39
P = 198·6° D = 1·2″ Ep. 1882·38

A slow-moving binary discovered by Σ.

β 224. R.A. 14·7. Mags. 8·9, 9·3.
β, P = 71·0° D = 0·67″ Ep. 1875·7
Perry, P = 60·0° D = 0·41″ Ep. 1882·38.

One of Burnham's discoveries. There appears to be a diminution of both angle and distance, if my measures are correct. It is by no means difficult.

ζ *Boötis*. R.A. 14·35. Mags. 3·5, 3·9

P = 297·0° D = 0·72″ Ep. 1880·50
P = 294·3° D = 0·65″ Ep. 1881·39
P = 298·0° D = 0·57″ Ep. 1882·38

ε *Boötis*. R.A. 14·39. Mags. 3, 6·3

P = 329·0° D = 2·82″ Ep. 1882·37
P = 328·1° D = 2·58″ Ep. 1882·41
P = 327·5° D = 2·27″ Ep. 1882·42

H_2 says of this very beautiful binary—if it be such—that it is "one of the most difficult stars to measure correctly, Rigel excepted." His father, H_1, remarked that it "has the appearance of a planet and its satellite, both shining with innate, but differently coloured light."

ξ *Boötis*. R.A. 14·45. Mags. 4·7, 6·6

P = 269·0° D = 4·24″ Ep. 1880·52
P = 273·0° D = 4·7″ Ep. 1881·40
P = 271·0° D = 4·1″ Ep. 1882·39

1 (B) *Coronæ Bor*. R.A. 15·14. Mags. 5·6, 6·1

P = 302·5° D = 1·0″ Ep. 1881·39
P = 304·5° D = 1·1″ Ep. 1882·38.

η *Coronæ Bor*. R.A. 15·18, Mags. 6·7, 7·3

Dembowski	P = 44°0	D = 1″04	Ep. 1870·38
Gledhill	P = 44·6	D = 1·1	,, ·44
Dembowski	P = 66·0	D = 1·86	,, 5·41
Gledhill	P ≐ 71·6	D = 0·7	,, 6·34
Doberck	P = 92·6	D = 0·61	,, 8·40
Burnham	P = 114·3	D = 0·46	,, 80 62
Perry	P = 119·1	D = 0·46	,, 1·40
Perry	P = 133·4	D = 0·34	,, 2·38

This is a rapid and remarkable binary. Its period appears to be about forty-three years. From the above measures it will be seen that it is now closing up, and its change of angle is very rapid.

μ^2 *Boötis*. R.A. 15·20, Mags. 6·7, 7·3.

H_2 says: "This star is a severe test for a telescope," and delares that "none but the finest are competent to deal with it." Dawes says, "It requires a superb night." Chambers tells us that "the recent values for the period of this star differ widely." They range from 314 to 182 years.

The published measures seem to show that the distance between the components has varied (since its discovery in 1781) from the greatest, 1·69″, given by H_2 and South in 1823, to the least 0·31″, given by Mädler in 1851.

δ Serpentis. R.A. 15·29, Mags. 3, 4.
P = 191·5°. D = 3·8″ Ep. 1880·59.

Gledhill says that one of the components is probably variable in its light.

Burnham	P = 279°·3	D = 0″34	Ep. 1876·3
Perry	P = 267·5	D = 0·31	,, 82·40

Also one of Burnham's discoveries. It was clearly and neatly divided.

λ *Ophiuchi*. R.A. 16·24. Mags. 4, 6·1.

Washington observers,	P = 36°·1	D = 1″·45	Ep. 1876·44
Perry,	P = 38·0	D = 1·41	,, 81·39

H_1 says of this star:—"The object is uncommonly beautiful; but it requires a most excellent telescope to see it well. . . . The appearance of the two stars is much like that of a planet with a large satellite or small companion." It is a binary, but its period is variously computed at 88, 95, and 233 years. Chambers says the latter is most correct.

Σ 2062. R.A. 16·28. Mags. 8·3, 11.

P = 112°·0 D = 2″·6 Ep. 1881·38

In the "Observatory," Vol. III., p. 381, Mr. Gledhill makes an appeal to amateur astronomers possessed of large telescopes to examine certain stars, a list of which he gives. This is one of them. He says:—"Dembowski could not see the companion in 1865; Burnham saw it in April, 1874, but it was invisible on a very fine night in June of that year. He saw it well in May, 1875; distance, 2·8″."

ζ *Herculis*, R.A. 16 3; Mags., 3, 6·5.

Dembowski,	P = 190°·8	D = 1″09	Ep. 1870·49
Dembowski,	P = 149·0	D = 1·41	,, 1875·52
Doberck	P = 124·9	D = 1·28	,, 1878·61
Perry	P = 111·5	D = 1·2	,, 1880·67
Perry	P = 108·8	D = 1·0	,, 1882·41

A very remarkable binary, discovered by Sir William Herschel, who remarked:—"My observations of this star furnish us with a phenomenon which is new in astronomy; it is the occultation of one star by another." This was in 1803. It describes an orbit whose plane is nearly coincident with the visual ray. From 1828 to 1831 it appears to have been single; but in 1834 the companion was plainly seen again by Σ. Gledhill says:—"The sudden reappearance of the *comes* at first led him (Σ.) to suspect that variability was the cause of the difficulty he had so long experienced, and he was much surprised to find the companion in almost the same straight line as that in which he saw it eight years before. Great was his delight, on copying the observation into the book containing mean results, when he found that the *comes* was in the same line nearly, but in the opposite direction. There had been an occultation, and all the difficulty which had so often vexed him for eight years was completely explained." Σ. says this star "offers the astounding velocity of an apparent and very elliptical orbit revolving in little more than 14 years." Other computers, however, make the period from 31 to 36 years.

Your readers will not have failed to notice the exceedingly interesting item in your report of the Greenwich Visitation (No. 898, p. 802), in regard to the motion of Sirius, by which it appears that the spectroscopic observations on this star "reveal a progressive diminution from about 22 miles a second, in 1877 and 1878, to about seven miles a second, or less, this year; and, as other stars do not show anything similar, it appears likely that the change is due to the orbital motion of Sirius."

I am sorry to say the observing weather here has been very little, if any, better than it was last year, and my opportunities of taking measurements are rare.

Jevon J. Muschamp Perry.
St. Paul's Vicarage Observatory, Alnwick.

HOW TO MAKE A FLAT FOR A NEWTONIAN REFLECTOR.

[20182.]—I WILL describe a method that will suit the amateur better than the usual trade method, which is hard work, and, as 20 or more are made at once, is, of course, economical, but is beyond the requirements of the amateur. I can speak of its results being highly satisfactory to myself. Plate-glass (polished) offers a good start for flat-making. Any sort will do; I prefer, however, the St. Gobain or Union plate. Supposing that a flat 1in. in the minor axis is required, a circle 4⅛in. in diameter and not less than ¼in. thick must be obtained. This should be cut well away from the edge of the sheet. This is important, as the edges of plate-glass are much rounded off, and that would prove detrimental in this mode of working. If the operator has a pair of "shanks," or makes a pair, and he will require them further on in the process, he could get a square of glass and chip it round himself.

The "shanks" are very simple and useful tools, made of wrought-iron rods 7-16in. square. I give a sketch, Fig. 1. Length from rivet A to thumb-loop B, 7in., the loops 1⅛ by 1½ inside measure. There is no great nicety required about them; the rivet should be loose and easy. The mode of using the shanks is to hold them like a pair of scissors, then nibble off very small chips until the glass is nibbled into the required shape.

FIG. 1.

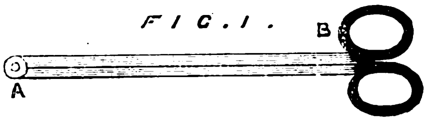

FIG. 2.

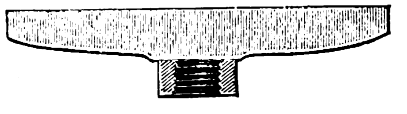


Three tools of brass or iron are required for grinding the surface; the diameter the same as the glass disc to be worked; these tools should be ¾in. thick in the middle, furnished with a screw-boss. Fig. 2 will give an idea.

The surfaces of these tools should be turned true across in a slide-rest lathe, then scraped and ground to fit together accurately, in any order; I will call them respectively, Nos. 1, 2, and 3. 1 and 2 must fit, 1 and 3 must fit, and 2 and 3 must fit—thus, each is a perfect plane. The mode described for specula tools will fulfil all the requirements of this set of tools.

It should be borne in mind that the absolute flatness of the tools in the first place is of the first importance. Any attempt to produce a perfect plane by using one surface only must fail. When the grinding-tools are got to perfect fitting, No. 1 serves the purpose of holding the disc of glass throughout the grinding and polishing processes. A mixture of 1 part resin and 4 parts beeswax is suspended inside an earthen pot in a piece of cambric—an ordinary jam-pot will do. This should be melted and strained through, by being placed in an oven if possible. A cover of card, or tin—no matter what, in fact, to keep out grit—should be placed over it while the double process of melting and straining is going on.

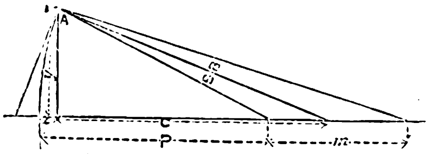
The tool, No. 1, now heated sufficiently to melt the cement into flowing, should be placed, when covered with cement, in a level position over a gas-stove or spirit-lamp. The glass circle, warmed, must be placed on the tool, and gently and evenly pressed down as close as possible. When the tool and glass are perfectly cold, tool No. 2 is secured on the "bench screw" or post, described in the letters on specula working.

No. 2 emery, or the flour emery of commerce, should now be used with water, and the glass ground "up" or made to fit the surface of No. 2 tool. This is best done with straight strokes in grinding of a length equal to half the diameter of the tool; that is, you expose the middle of the tool at each rub. Care must be taken to rotate the glass by a uniform motion, one revolution in 50 strokes is enough. When all the polish is ground off the surface being dealt with, the flat can be smoothed in the same manner as specula, with this difference; tool No. 3 must be used for the last emery's, the No. 6 described in my letters on specula working. As there would be a lot of travelling over old ground, I must ask our readers to refer to the letters mentioned many times yet, to save valuable space. **Prismatique.**

(*To be continued.*)

PARABOLISATION OF SPECULA.

[20183.]—I TRUST the following investigation will suit Mr. Wassell in his experiments on the parabolisation of specula (letter 20142). Referring to the accompanying diagram—



$$\frac{2x}{y} = \frac{y}{c} \therefore c = \frac{y^2}{2x}$$

$$\tan.\ A = \frac{P - x}{y}$$

$$\tan.\ (A + B)\ \frac{y}{2x}$$

$$\tan.\ B = \frac{y^2 - 2x\,(P - x)}{2\,xy + y\,(P - x)}$$

$$\therefore \tan.\ (A + 2B) = \frac{3xy^2 + y^2p - 4x^2p + 4x^3}{4xyp - y^4}$$

$$\therefore P + m - x = \frac{3xy^2 + y^2p - 4x^2p + 4x^3}{4xp - y^4}$$

$$\therefore m = \frac{2y^2p + 4xy^2 - 2y^2x - 4xp^2 + 4x^4}{4xp - y^2}$$

Now, $y^2 = 4fx$, where f = the focal length, or $\frac{1}{4}$ the parameter—

$$\therefore m = \frac{32f^3P + 8f^2y^2 - 16f^2P^3 + y^4}{16f^2P - 16f^3}$$

This equation holds for any values of m, p, and y.

If, therefore, we make $p = 2f$, then P will be the radius of curvature, and we get—

$$m = \frac{2p^2y^3 + y^4}{2P^3}$$

Perhaps some of our friends will kindly verify the above result.

W. H. G., Braintree.

ON THE ABERRATION OF A PARABOLIC SPECULUM.

[20184.]—Now that the aberration of reflectors is being discussed in these pages, I am glad to be able to contribute the following particulars, which have been supplied by your esteemed correspondent, Mr. J. A. Brashear. He, having brought the subject before the notice of Dr. Hastings, received from him a very explicit letter, confirming my algebraical analysis. As Mr. Brashear has kindly given me permission to publish this letter, I now do so; and I think it will be admitted that it contains the best and clearest explanation of this abstruse matter that has yet been given. I quote the following passages from Mr. Brashear's letter to me—they will be read with interest:—

"Dr. Hastings writes me that you are correct, which I had concluded some time ago from practical experience, though I never give any of my specula quite so much aberration as in your formula, for the evident reason that it is impossible to get the focus of the exact centre. One must take a zone large enough to yield light enough to test it, and that is, generally speaking, about as large as the flat. Secondly, one cannot depend on the extreme edge, as it, with the best workmanship, usually 'rolls back' slightly; so the formula of Dr. Draper, used in this way, is not far from correct; but it is plainly evident that in mirrors of small angular aperture, your formula is correct if the curve of the mirror is taken from centre to extreme edge.

"Two 10in. mirrors of Calver's make, tested by me, had a spherical aberration at centre of curvature, only half your formula. I studied them many hours, and speak from actual tests; they were beautiful in regularity of curve."

Dr. Hastings says:—

"Your perplexity concerning the aberration of a parabolic mirror at the centre of curvature is a natural, but amusing one. It affords a capital illustration of the difficulties which 'theoretical' and 'practical' opticians have in understanding each other. I give you a graphical explanation, which, I hope, may help you.

"Let V P (Fig. 1) represent a spherical mirror, with centre at C and V F = ½ radius = ½ R. Let ray S P, parallel to axis, fall on element P, then it will be reflected so that S P C = C P F′, and F F′ = V P² / 2R* (this is true to first approximation, which is as far as our assertions hold good). Now, if we wish that P F′ should correspond to P F; in other words, that there should be no aberration for parallel rays, we must rotate the element P by an angle equal to one-half of F P F′. This will make the element P correspond practically (if the rotation be accompanied by an almost infinitesimal displacement outwards rigidly) with the element of a parabola, having its vertex at V and centre of curvature (= centre of osculating circle at vertex) at C. By the rotation of the element P the direction of its normal has been changed from P C to Pn_1 such that angle C Pn = ½ angle F P F′. If, now, we make C a source of light, we are in a position to calculate the aberration of the parabolic mirror at the "centre of curvature." It must be observed that the quantative statements which follow are only true to the "first approximation"; or, in other words, practically true when V P is small compared to V C.

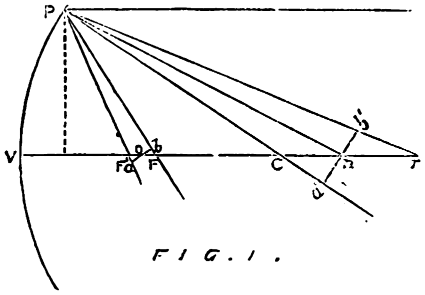


FIG. 1.

"Evidently any ray diverging from C and incident very near V will be reflected back again to C; but as the point of incidence is removed from V, the point of intersection of the reflected ray with the axis will fall farther and farther to the right of C. Consider the ray C P incident on the element P of the *parabola* P V; it will be reflected in the direction of P r, so that angle r P n = angle n P C; and the distance C r will be the aberration of the parabola with semiaperture V P at the centre of curvature. It is evident that $a'\,b' = 2\,a\,b$, since angle b' P a' = angle b P a and P n = 2 P o; but F′ F = $a\,b$ / cos. $b\,o$ F = $a\,b$ / sin. P o V = $a\,b$ / sin. S P o, and in the same way C r = $a'\,b'$ / sin. S P n = $r\,a\,b$ / sin. S Pn. From the law of reflection, however, we see that angles S P o = 2 angle S P n, and, since the angles are small by supposition, sin. S P o = 2 sin. S P n and Cr = 4 F F′ = V P² / 8 R = V P² / 16f.* Possibly you are not as accustomed to think in the language of Trigonometry as in that of Geometry, in which case the following demonstrations may be more acceptable, remembering always that the equations are only true when angle P F V is so small that it may be regarded as equal to P O V, &c.

"O F : ob = F P : P A ∴ oF = ob × F P / P A. F F′ = ab × F P / P A; nr : nb' = Pr : P A ∴ nr = nb' × Pr / P A = nb' × 2 F P / P A. Cr = 2 $a'\,b'$ × F P / A P = 4 ab F P / P A = 4 F′ F.

"Thus we see that the mathematical optician is right; *but* it should not be overlooked, that by no purely experimental method can one find the point C. What Dr. Draper and you find in experiment is not the centre of the circle osculating at V, but what might be called the *average* centre of curvature, which lies nearly midway between C and n (its exact position depends upon the manner in which average is defined, or, in terms of experiment upon the *method* by which it is sought). If it be assumed as lying exactly midway between C and n, the aberration corresponds practically with Dr. Draper's formula, and with your experience; since the precise focal distance for rays very near the centre is of no consequence. True, it may be urged that Dr. Draper ought to have protected himself against such criticism by properly-chosen limitations; but it seems to me that one could condemn with equal or greater justice a procedure which offers as a practical guide laws referred to a point which is absolutely incapable of a physical definition."

I think the above explanation will make it quite clear that the theoretical quadruple ratio is correct, which is, of course, all I contended for. Dr. Draper's double ratio may be a more convenient "working" formula—that point must be settled by practical men; but it seems to me that the objection which applies to the greater ratio, applies with equal force to Draper's ratio. The correctness of the former depends upon the accuracy with which the point C is ascertained; that of the latter upon a point lying midway between two extremes, of which C is one. Now, if neither of these extremes can be accurately fixed, by what method can we assure ourselves that we have hit on a point midway between them. Unless the place of the radiant point can be unerringly decided upon, this method of parabolisation is totally useless, for a very slight change in position may give either double or quadruple aberration. But if the mirror is made accurately spherical, before parabolisation is attempted, the position of the centre must be better known, than any other succeeding point can be known, and it must be the standard by which alterations must be made. The place of the lamp aperture is quite as important a matter as that of the sliding shutter, for unless we work from a fixed radiant point, no accurate judgment can be formed of either shadows or aberration.

Dr. Hastings has done good service in bringing forward the importance of the position of the radiant point; his letter is the most authoritative that has yet appeared on the matter, and Mr. Brashear deserves the thanks of all the readers interested, for allowing it to be published. I earnestly commend this subject to the consideration of Mr. Wassell, and other adepts in the use of the Foucault test. While a variation in the position of the lamp equal to one-half of the quantity sought either diminishes by half or doubles that quantity, I am inclined to think this method is not so easy to apply as the simplicity of the ratios would lead one to think.

There is this practical consideration in favour of Dr. Draper's rule: that as the margin is apt to "roll back," we can generally depend upon the mirror having more aberration than what is reckoned upon. When we know the tendency of any mechanical process, it is better to allow a slight margin in favour of under-correction rather than run the risk of overdoing it. However correct a rule may be theoretically, we cannot be certain of working up to it mechanically: where we have to judge one error by another, definite comparisons are not easy.

Orderic Vital.

NEW COMBINATION OF ALTAZIMUTH AND EQUATORIAL MOUNTING.

[20185.]—MR. GODFREY'S criticism (p. 328) of Mr. Grubb's combination mounting would have been more satisfactory had he indicated the "mistake which an optician should avoid," and also explained the principle of Smeaton's block. I am sure that many, besides myself, would be greatly pleased by a sketch of the latter arrangement. So far as my examination of Mr. Grubb's telescope went, it seemed quite steady, and I cannot imagine an optician of his eminence falling into such an error as Mr. Godfrey seems to think. Perhaps, however, I am the cause of a misunderstanding. It is due, however, to Mr. Grubb to state that he is in no way responsible for my description and sketches of his instruments, and that they were only the outcome of an afterthought.

More Light.

ASTRONOMICAL EYEPIECES.

[20186.]—"PAUGUL" has an excellent opportunity of establishing his position as a teacher of practical optics, by explaining in these pages how the crossing of the rays may be *experimentally demonstrated*. He has already been kind enough to offer me a private demonstration "by the help of lenses, how the rays go," but this I cannot accept. I hope, therefore, he will allow me to transfer my interest in the description for the benefit of our readers. **Aldebaran.**

ON THE ACTION OF EYEPIECES.

[20187.]—I RECOGNISE in "Aldebaran" a very able practical correspondent, and though he seemed to have got into a little difficulty about his imaginary cone, I do not see much of the "paradoxer" in him. Disregarding the mere literal meaning of this word, I imagine a "paradoxer" to be one who is so stupid that he neither can nor will see that anyone but himself is right. "Aldebaran" is certainly *not* one of this objectionable but fortunately insignificant class. The eye acts as a very perfect convex lens, and the curved form of the retina is admirably adapted for receiving the image. Were it not for this, our field of view would be very limited and distinct vision attained only about the visual axis. But owing to the adaptation of the retina, rays—or rather pencils of rays—crossing the axis are more or less perfectly focussed.

---

* There must be a slight mistake here: the focal aberration F F′ is V P² / 4 R or V P² / 8f. Hence the central aberration 4 F F′ is V P² / R or V P⁴ / 2f.

There is nothing in the phenomena mentioned by your correspondent inconsistent with the theory of parallelism of incident visual rays; on the contrary, it is in precise agreement. I do not see that there is need for much explanation, and as no good can arise by prolonging the discussion, with a few general remarks I will conclude my notice of this subject. Does not "Aldebaran" know that images formed by natural vision are inverted? Hence, an inverted telescopic image will be erect on the retina. The image seen by the bystander is a reflected one; it is caused by the cornea acting as a convex mirror. If he could simultaneously see the retinal image, he would find that was erect also.

"Aldebaran" said very truly (p. 263)—"A re-inverted or erect image may be rendered visible by holding a screen to receive the rays after they have crossed." Precisely the same effect occurs when the eye is used; the image is modified, not altered, in character, only the rays must have a certain disposition to enable it to do this.

Orderic Vital.

GRINDING AND POLISHING GLASS SPECULA.

[20188.]—"Orderic Vital" is quite right in supposing that a round luminous point is usually used for testing in the trade. The very ingenious iris of our much-esteemed contributor, Mr. Wassell, is very convenient, and my judgment leads me to suppose the shape of the point is not so important in zone-testing as it is in testing from centre of curvature with an eyepiece. The extreme smallness of the hole, I should say, is what is required in the shadow test, as there is no magnification of the objective itself in the usual sense.

Prismatique.

OHM'S LAWS OF ELECTRICITY.

[20189.]—Your correspondent in letter 20171 is, no doubt, bothered with the meaning of the term I in the formula $I = E / R + r$, generally known as "Ohm's Law." The true meaning of this formula is that $R + r$ stands for the whole resistance of circuit, E for the electromotive force, and I for the magnetic effect in the galvanometer, which used formerly to be called quantity. It does not mean intensity. What the old electricians called intensity is now named electromotive force, but this term I is at present often called intensity, which is true only for the magnetic, but not the electrical action.

Ohm's law would be better understood if it were stated that the magnetic action of a current of electricity, or the chemical action in a proper voltameter, is in direct proportion to the electromotive force, and in inverse proportion to the whole resistance of the circuit.

If the experiments supposed (page 331) were tried, a galvanometer would read in accordance with the calculations; but the readings would not show the amount of power used unless you also consider the chemical action in the batteries. For in the case where $R = r$, then $6\,E / 6\,R + r = {}^{6}/_{7}$; but the work in the battery by chemical action is ${}^{6}/_{7}$ for each cell, and for six cells will be $6 \times {}^{6}/_{7} = 5\,{}^{1}/_{7}$ total work in battery for ${}^{6}/_{7}$ work in the outside resistance; and when $1\,E / {}^{1}/_{6}\,R + r = {}^{6}/_{7}$, the chemical action in the battery is still ${}^{6}/_{7}$ for one cell, although the surface is six times the size; so that in this case we obtain the same work as before at six times less cost of zinc and acid. I trust this will explain the matter to your correspondent's satisfaction. He can, no doubt, work out the cost in the other cases in the same manner.

J. Sutcliffe.

[20190.]—All the calculations given by "Stud. Inst. C.E." (letter 20171) are correct. If the external resistance r is equal to the resistance R of one cell, the best arrangement will be either by twos or threes; but if the external resistance is one fourth of the resistance of one cell—then the best arrangement of the six cells is in series. It may easily be shown from Ohm's Law that the best arrangement will always be that which makes the internal resistance of *the battery* equal to the external resistance. In the examples given, this is *most nearly* the case, when the internal resistance is 6 and the external resistance 4 in the first case, and in the second when the internal resistance is either $2 \times \frac{1}{3}$ or $3 \times \frac{1}{2}$, the external resistance now being one.

X.N.X.

[20191.]—It is not easy to see what difficulty the writer of letter 20171 has in reading the formula given. In the second case, where the cells are coupled two abreast, the resistance of each is thereby halved, and we, therefore, have $I = 3\,E / 3 \times \frac{1}{2} + 4 = 3\,E / 5{\cdot}5 = 6\,E / 11$. In the case where the cells are arranged in two three-fold elements, the resistance of each element is only one-third of the original value, and we have $I = 2\,E / 2 \times \frac{1}{3} + 4 = 2\,E / \frac{2}{3} + 4 = 6\,E / 14$. There is an error in the formula as given, $\frac{1}{2}$ being written instead of $\frac{1}{3}$; but, of course, I do not know whether the error is in the book or the letter, or has occurred in the composing-room.

In the last case, where the cells are joined in multiple arc, the resistance is only one-sixth; therefore, $I = E / {}^{1}/_{6} + 4 = 6\,E / 25$. The querist should have mentioned the book he referred to, and given the page he wanted explained, and then he might have saved himself the trouble of writing so much, saved you the expense of engraving the very commonplace diagrams, and economised space.

Wm. John Grey.

Elswick Science School, Newcastle-on-Tyne.

PRIMARY AND SECONDARY BATTERIES.

[20192.]—Years ago, when I observed the waste of power arising from the blowing off of steam through the varying work upon which it was employed, I used to think that means might be devised for storing up the wasting power, by means of an electro-magnet engine automatically attachable to the engine's safety-valve, so as to act reversely upon a galvanic battery, and thus to redeposit the zincoid element which had been previously oxidised. I considered also that this principle might be applied to economise the uphill locomotive power required for vehicles by storing up the wasted downhill gravitating power for use when required.

I had these ideas long before secondary batteries were ever heard of, and am of the same opinion still as to these ideas.

But it is not every kind of battery which would answer the required conditions for success, for it is only one class of battery which would suit; and, practically, only one, and that is Daniell's. The batteries at present in vogue all give off gas, and by so doing, one of the elements—a combustible substance—is lost, thus preventing a recomposition, and the zincoid from being redeposited; and not only so, for a certain amount of energy is lost in the latent heat required to form hydrogen as gas, from its fluid state, as an element of water.

But in a Daniell's battery, after working, we have all the original elements still present, enabling us to recompose, to the extent it had been spent, by restoring the same amount of power as it had given out in working; and this we may do by reversing the motion of the e.m. engine (previously actuated by the battery), and applying the power of another motor—say, a gas-engine.

There is, however, one circumstance which would require to be provided for, and that is, that whereas in using the battery for work, our store of crystals was at the top of the fluid, so as to effect saturation by means of gravitation, when we are putting work into the battery, the reformed crystals (or granulations) would naturally fall to the bottom, and, unless roused up by some contrivance, saturation would be imperfect and the chemical conditions imperfectly attained. This, however, in no way affects the correctness of the principle of working a battery backwards, and could easily be provided for.

In order to make clear the chemical and electrical relations of Daniell's battery at work, and in being recharged, and to show the case as parallel with what takes place in the secondary batteries as now used, I will put the matter thus:—

First, the batteries side by side at work.

Battery's Cr. by
——> x-power ——>
Pb + 0 Pb − 0
——> x-power ——>
Zn + 0 Cu − 0

Recharging thus—

Battery's Dr. to
<—— x-power <——
Pb − 0 Pb + 0
<—— x-power <——
Zn − 0 Cu + 0

Any intermediate chemical action which may possibly be taking place, may be disregarded, seeing that the decompositions are exactly balanced by like recompositions; and the effect will be practically, therefore, as above shown, which is meant as an equation both ways.

To put the matter, now, in a practical way; suppose I employ a Daniel's battery to propel a vehicle by means of an electro-magnetic engine, and arrive at a descent, and desire to moderate the speed, there are three resources—1st, moderating the current; 2nd, cutting off; 3rd, reversing, and allowing work to be put into the battery with a current more or less modified to suit; the power being supplied by the vehicle through its descent; therefore, when arriving at home again, the cost of materials will be practically the same as if I had travelled all the way on a dead level. I next connect the electro-magnetic engine to the gas-engine, rotating it the reverse way, or instead, reversing the connections, and restore zinc to the zinc plates, and redissolve the deposited copper: this is of course effected by a reverse polarising of the plates; and thus my battery is as good as new again, and the expense, due only to the working of the gas-engine at home; and my apparatus is ready for another trip.

I am aware that there is some loss of power in the using of secondary batteries; but as this does not diminish the materials of the battery, the little extra expense would be for coal or gas.

The principles I have here put forward with a view to the construction of a Daniell secondary battery seem to me so obvious that "I should not be surprised to hear" that somebody had known it before, and that I am "teaching my, &c." But if so, why are people seeking to do the thing in another form, when they have (as it were) a Daniell at hand. Be this as it may, I shall be glad to find in these pages that trials have been made, and the results success.

Barry-road, S.E. **J. H. Huxley.**

P.S.—To save amalgamation, perfectly pure zinc should be used in the first instance, and as the redeposits are also pure, amalgamation need give us no concern, as there would be no local action in that case.

LECLANCHE BATTERIES WITH AND WITHOUT MANGANESE.

[20193.]—In reply to "Arch Key," I can mention a case where I was called in to see about eight batteries of three and four cells each, which had failed in about a month. These contained manganese and carbon, identical with the old Leclanché. Now, had these been made up without manganese, you would certainly have laid it on the absence of that mysterious manganese. Is it by virtue of its presence that it acts? I have had 100 cells of the Company's make to maintain, and quite 10 failed entirely every month. Remedy:—Take to pieces and well wash. Two cases here by would-be electric bell fitters'. They cannot get new cells to work. Another case: a gentleman divided a pennyworth of sal-ammoniac between three cells filled up with water—failed next day. Had the latter few cases contained no manganese—jump at the conclusion. I could cite a great many cases more. I only wish the addition of a few lumps of manganese would make some cells as strong as others are; some are 50 and some 90 per cent. stronger than others, although manganese cells. Manganese after 10 years in a sal-ammoniac cell is just as clean as the first day, not the slightest reduced; there can, consequently, be no action. Then why do these cells fail?

George Tolman.

ELECTRIC MACHINES, SYMPIESOMETER, AND CROWN-GLASS ACHROMATISM.

[20194.]—With a view to help amateurs, I wish to say that I have constructed a thoroughly efficient frictional machine, at a very trifling cost, by making the wheel of stout sheet (32oz.) instead of plate; it is 14in. diam.

The advantages of the sheet are:—Cheapness, facility with which it is cut round and made passable on the edge. I did mine with an American glass-cutter and a piece of whetstone; then the hole does not take so long to make, it also warms up quickly, being only ⅛in. thick; and, finally, if it does break, it does not cost much more than 9d. and the labour to put another on.

The drawback is its crookedness. To remedy this, I used a modified rubber, which consists in mounting the rubber on the end of as long a rod as the stand will take; then, with a screw at the other end, the rod is both fastened and pivoted, to allow the rubber to wag with the crooked plate, which plate must be selected to be as flat as possible.

My plate is mounted on an iron spindle, supported on wooden standards, and I find that the only place where there must be first-rate insulation is the stand of the collector or prime conductor, which must be an ebonite or glass rod, or a glass tube closed hermetically at the ends.

I have for some years noticed a phenomenon in sympiesometers which I should like a little explanation of, with the object of making the instrument more perfect.

The phenomenon is a gradual rising of the fluid in the tube. My tube is about 30in. long, and very carefully graduated, in accordance with the laws relating to the compression of gases, so that it gives accurate exhibition of every change of pressure on a scale of about ·9 to 1 of the mercurial, but after some months I find all its indications two or three-tenths higher than they ought to be. I then let in a bubble of air, which lowers the column to a correct height, only to find it too fast again by-and-by. I think my present instrument gains about ·1 in three months. I have seen the occurrence in a water and in an oil column. If any of "ours" can tell the reason of the above, I will, as a return, send a method of dividing the scale so that the readings are very true indeed, as compared with the mercurial column.

Allow me just here to state that although a "Robinson Crusoe" is at present writing to "ours," he is not "Rob. Crus.," and I wish to sign myself thus because I always have done so, and I am now writing on the old subject. Letters will be found in back volumes on optical matters, more especially on economical micros.

I there set forth pretty clearly what could be done with crown or plate lenses; I now should like to say a word on what cannot be done—viz., a combination of lenses cannot be made to produce achromatism in the way suggested by Mr. Penny, p. 273.

1. Then Mr. Penny says, that in order to compare the ordinary dialyte and his proposed dialyte "with regard to its achromatism, all we have to do is to write down side by side the conditions necessary for it in the two cases," then follow a long and a short equation, which I shall not need to notice.

2. In explanation of the equations, Mr. P. says "they are the equations used for making rays of different colours *emerge parallel*, and this is what is commonly meant by achromatism."

Now, to my mind, parallelism and coincidence are very different things, and it certainly is the latter which is required for achromatism; for, let an o.g., by its refractive action, disperse the colours to an extent $= x$, by the time they get half-way to the focus, it is plain that at the focus they will be dispersed to an extent $= 2x$. If, however, at the half-way point x the rays be received by a concave of half the focal length of the o.g., the dispersed rays will not come to a focus at all, but will emerge and go on in parallelism, retaining its dispersion $= x$. But clearly enough this arrangement is useless as an o.g., for it is a complete Galilean telescope; it is also plain that if the refraction of the concave be reduced, so will the dispersion be, and when our focal point is reached, the disperson will, on account of its parallelism, be nearly equal to what it is at the point of insertion of the concave.

My practice and experience bear me out. A microscope is but a reversed telescope, and in the micro. I have had an o.g. of two lenses so arranged as to give perfectly *aplanatic vision* and perfectly *parallel chromatism*, and by using parallel and central illumination of the object, and that object to be infinitely thin, I have had *exceedingly* little colour—some people saw none; but just let the light be displaced, or the object have appreciable thickness, then came the colour, and I never saw a colourless image produced by lenses until they were helped out by a *flint* concave. Nor will Mr. P. succeed in doing so either. **Rob. Crus.**

WILDBAD AND ITS CURES IN THE BLACK FOREST.

[20195.]—The frequent inquiries I have seen in your valuable journal respecting rheumatism, gout, and similar complaints, and especially lameness from accidents, induces me to send you the following account of this celebrated spa.

I am now staying at the Belle Vue Hotel, one of the most charming and well-conducted retreats I have ever seen, and so gratifying by a month's visit a desire I have long felt to visit this deservedly popular resort. Surely, the pine-scented air, the murmuring—I might say sometimes the rushing—river, the Enz, the mountain elevation (1,400ft.), the delicious waters, and *recherché* music must contribute mightily to work some of Nature's most wonderful restorations.

The history of this place, as its name declares, teems with a wild and ancient interest. Count Dillen, who forty years ago greatly enriched this place, actuated by a cure effected here on the countess, informs me that he then brought their own beds! What, then, must have been the reception of princes five hundred years ago? The archives go back to the 12th century. Innumerable fires and inundations have destroyed the village. There are traces still left of the Romans. Diana's altar is a few leagues hence. These luxurious hot springs were doubtless frequented by them, for which they had a passionate love.

Eberhard (called the great) had a medal struck in the 12th century to celebrate and perpetuate the values of the Wildbad springs. Formerly, the arrival of a stranger was signalised with all the pomp of welcome the little *cur-ort* could muster. A procession conducted him, presents were exchanged, and he was surrounded with honourable attentions. In 1513 Dr. Widman published the first treatise on Wildbad. But in 1525 when the place was full of princes, cavaliers, and abbés, 23 houses and the church were burnt down, owing to a singular custom—all the *hostels* were decorated with the arms, plumes, and banners of the noble guests, which served as fuel for a *conflagration*, a custom forbidden in future. Passing over the names of the noble worthies who have visited this place, I shall now relate the effect of the baths upon Duke Christopher in 1543. To demand the hand of the daughter of the Margrave of Brandenburg, the young duke braved the rigour of a terrible winter. The intense frost seized all his limbs. His father opposed his desire for Wildbad, as it was considered unfit for stout persons of a sanguine full habit like his son. (In this account is recorded a valuable experience, still in full effect in 1882.) He declared that contrary to the physician's advice to repair thither, many examples there were that even old healed wounds were attacked by the waters, and in the forcible *language* of the day compared his son's obesity to that of a fat hog which entirely forbad the use of these baths. But May 2nd, 1545, the duke wrote to his father—he had taken a hundred baths, and loved to refresh himself in the water. On his ascent to the throne he constructed new buildings, and the reputation of the Wildbad waters rapidly spread. Chemistry first displayed the composition of the waters in 1801, then they were *successively* analysed in 1824, 1830, and 1836. Great ravages were inflicted upon the valley in 1816 by the furious inundation of the Enz; a catastrophe now guarded against by the deepening and graving of the river bed, protected by massive stone walls. In 1837 a greatly increased stream of visitors followed the glowing description of the bath by Dr. Granville, and in the same year Dr. Fricker, who had 23 years' experience at Wildbad, introduced the use of whey (le petit lait) in conjunction with the waters.

Some of the most remarkable effects have been recognised among military invalids. In 1840, the inauguration of the Belle Vue Hotel replaced the old Bath Hotel. Wildbad owes an immense debt of gratitude to the King of Wurtemberg, and the inhabitants illuminated the place on his visit. In 1843, his queen and princess arrived, the latter afflicted with paralysis of the feet. The waters again demonstrated the truth of their ancient reputation. Their well-beloved queen testified her gratitude by munificent gifts devoted to the poor visitors, in order to signalise the wonderful recovery of the princess, her daughter. A long list of crowned heads, princes, and nobility elaborates the Wildbad records. Her Royal Highness the Princess of Wales stayed two months at the Belle Vue Hotel, attended by Sir James Paget. As for the sources of these hot springs, inasmuch as they principally rise in deep clefts of the granite, these crevasses were formerly dangerous from their width and depth. At different points the waters are collected and conducted to the baths and drinking-fountains. An immense advantage that Wildbad enjoys over its first cousin, Gastein, is the constant temperature of the water, its natural heat requiring no artificial heating. The supply appears inexhaustible. The water is constantly being renewed, and all the baths, including the spacious open baths, are perfectly purified three times a day. But to me the most astounding of all is the virtue or healing quality of these thermal springs, so apparently unaccountable. About four or five grains of various matters are dissolved in a pint of the water, but it is enriched with gases. Granting the cures—how are they effected? The water seems utterly tasteless, yet its action is often profound. Are the elements in a nascent form? Indeed, as we know oxygen has two forms—in one called ozone, which, as soon as developed, has an electric odour—can we imagine that the chemical elements are held, as it were, lightly combined by great pressure and heat applied for ages, bubbling up from great depths and, perhaps, cooling as they rise? In the bath, myriads of gas-bubbles rise from the sand, some very large; and this compound gas is extremely rich in nitrogen—nearly 96 per cent., the rest consisting of carbonic acid (champagne gas) and oxygen.

Again, the recent discovery of the *storage of electricity* suggests the possibility of these and similar waters possessing the power of storing the earth's electricity, and in some degree giving it forth to the bather. I myself received a storage of electricity from the Faure Company, contained in some leaden rolls placed in a box. This electricity had been derived from the earth by means of rotating magnets forcibly driven by steam or gas engine. All electric lighting is ultimately derived from the earth, and again this world derives it from the sun. But the Wildbad waters have been thoroughly tested for electricity by means of the galvanometer. Herman and Krebs found a deviation of 75 degrees for Wildbad. If, then, stored electricity is set free by the conducting power of the body of the bather, here we have, perhaps, some mysterious explanation of that *action* of the water which many persons perceive. Minute currents at myriads of nerve fibrils spread over the skin during the liberation of nascent gases probably *enter* the system and promote systemic changes of considerable power. Further, just as we experience at the sea side the subtle influences of minute saline particles charged infinitesimally with traces of nascent oxygen, ozone, bromine, and iodine, besides other matters, where there can be no question of quantity, so the traces of potent agencies cannot be ignored here. Fehling (about 1859) analysed the water mixed from ten different springs, and found traces of arsenic, nitric acid, boracic acid, phosphates, ammonia, lithia, baryta, strontian and manganese, and even tin. Indeed, at the sea side the air is often said to be too strong, and many persons are peculiarly affected by these minute atmospheric doses. Another thing is noticed, that the purer waters as contrasted with what are called *mineral waters* are more easily absorbed or assimilated than the latter. Contrasting, then, these two kinds, my surprise at the sanitary powers of the Wildbad hot springs is only subdued by such considerations as these:—The application and inhalation of nascent gases or other elements, the natural heat, whether latent or telluric; the free electricity and the *abundance* of chemical elements presented by the waters most delicately combined, instituting radical constitutional changes, supplying elements which are required by the patient, and eliminating those which have banefully accumulated in the system *in special cases.* True, it may be objected that the electricity is very feeble in quantity. It is a well-known fact, however, in electrical science, that feeble electric currents enter more easily as the conducting surface is larger. The human body exposes a surface of more than fourteen square feet, everywhere studded with minute pores. Sir E. Wilson calculates the minute tubing of the perspiratory glands of the human skin to be 25 miles in length. Supposing then these waters store electricity in a weak form, the amazing amount of *conduction* may enable it to penetrate and unite with the electric nerve currents constantly traversing the nervous system. The belief of electric action in the water I find rooted completely in the minds of every intelligent person here that I have conversed with. Dr. Granville was here one day. I do not find a fortnight nearly sufficient to gather the interesting facts daily presenting themselves to my notice. Granville was enraptured with a single bath. Eight have convinced me that there is something very different in the natural heat of these deep springs to an ordinary hot bath. I should be loth to realise the effects of simple water at the same temperature. The water, though not quite so blue as Buxton, has (contrary to Granville) a deep colour, without odour or taste, but it nevertheless makes one's eyes smart considerably. Tranquillity and exhilaration are certainly combined effects, but hardly is produced Dr. Granville's "*ecstatic state of a devotee blended with the repose of an opium eater.*" The baths, however, have great charms, perfect freshness and cleanliness, being thoroughly changed alternate hours, besides being constantly supplied with running water at the rate of several cubic feet per minute.

Our own Faraday showed long ago that the separation of the elements of a single drop of water disengaged as much electricity as, *in quantity*, would produce a thunderstorm; that no chemical changes were without electric action. There is no end to the constant development of this omnipresent agent in every change in matter. The human body is constantly traversed by electric currents coursing along the nerves. They promote vital actions, and often have a highly curative action. Electrician for two years to the Cambridge Hospital, I used to administer them by measurement with a galvanometer above 30 years ago—a system lately re-invented. The extreme purity and mystery of the Wildbad waters make one glad to revive the extraordinary powers of electric action. It seems probable, indeed, from their rapid effects on sensitive persons, that the tingling and pricking, the excitement and peripheral action (by which the waters seem to drive offending matters outwards by stimulating nature to relieve herself), all point to some subtle action, which may be electric, and therefore also magnetic. The old theory of undulation — vibration of the ether — during the play of heat, light, or electricity, is most probably destined to be swallowed up in the gorgeous theory of universal electro-magnetic action, so profoundly developed by Clerk Maxwell. I am not at all sure that the direct electro magnetic action of the sun upon the earth does not regulate the earth's electricity and magnetism, and thus even charges the earth's oceans and springs with its potent forces.

G. W. Royston Pigott, M.D., F.R.S.

(*To be continued.*)

SMALL DYNAMO MACHINES.

[20196.]—According to promise made a few weeks back, I send you drawing and description of small dynamo weighing, without gearing, 6lb. 14oz. I cannot say that there is anything new or remarkable about it (at least the field-magnet is a little out of the common); but as there have been three or four columns devoted in back numbers by the theorists, on the impossibility of *small* machines working, owing to the absence of *heavy masses* of *cast-iron* (I suppose they were like "Dr. Lardner on Steam Navigation,"—wrote what they thought, and no more, without reading "Montaigne's Essays"), I thought the inclosed particulars might be useful to intending makers of such apparatus.

From private letters I receive, I know several who had given up the idea of making a *small* one on account of the former misstatements. I hope this will restart the subject once more. Speaking of *smallness*, one I rigged up a few months ago was only 3lb. 8oz., and it worked first-class; sorry I cannot send a description, as I intend to secure it; am sure one would work under 2lb. weight. No doubt very small ones have been made, but have not seen any description of them.

The inclosed sketch, Fig. 1 is exactly one quarter full size. The armature is 3 by 1, have wound them with 24, 22, 20, and 18 wire. Field-magnets can be wound with any size wire. If of the same resistance as armature for working in the circuit for "shunting," should be 12 or 15 times greater than armature.

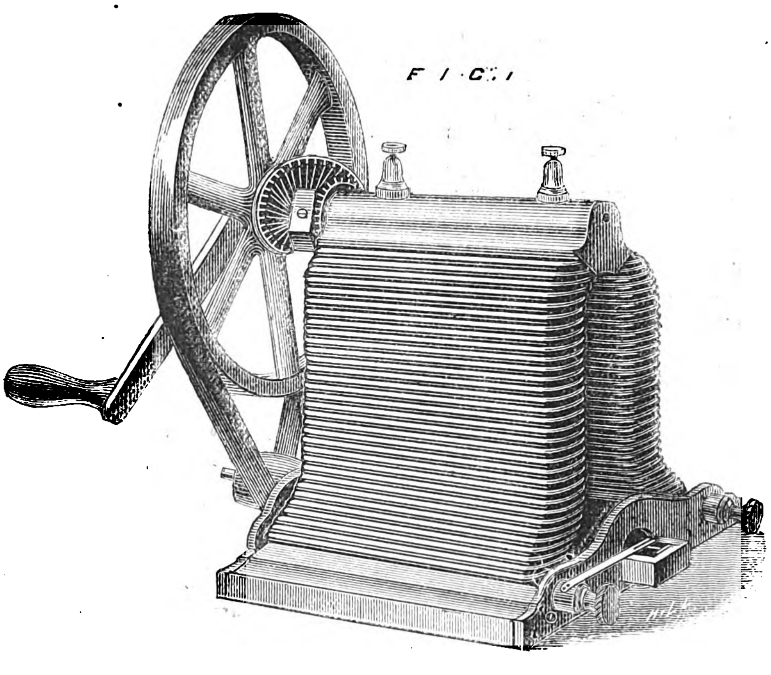

FIG. 1

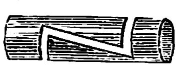
Commutator is made of four pieces of brass tubing ⅞in. long, ¼in. diameter, cut across thus—

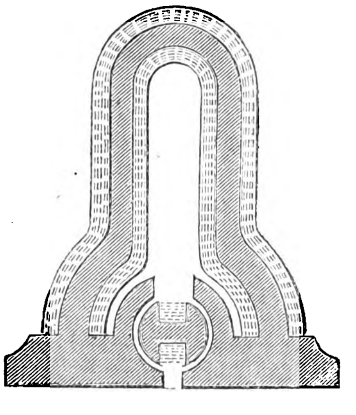
or like this—



Brushes, two pieces of sheet brass, split to give springiness. The "Jack in the Box" gearing is old; has been used for this purpose years ago: being the best form, have adopted it for hand-machines.

The field magnet (section shown in Fig. 2) is of common cast-iron direct from the foundry, and requires no further preparation than winding on the wire, except, perhaps, boring out, facing the ends, and a little filing.

FIG. 2.



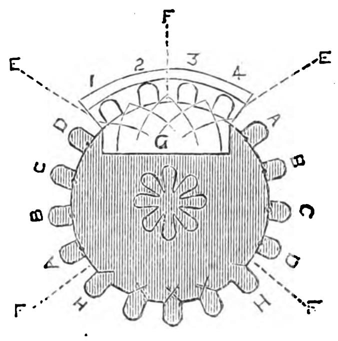
When wound, connect up to a Bunsen cell, and place a soft iron keeper across the poles; leave it so for five minutes, disconnect, and this heavy mass of cast-iron will sustain from four to eight ounces, quite sufficient to cause it, when in action, to bite. A piece of ¼in. square iron may always be left on as a keeper when in action and otherwise, as it gives *steadiness* to the machine, prevents sudden disappearance of magnetism when the springs cut the armature out of circuit. This is an immense advantage in large machines. The current can be regulated by placing on larger keepers.

I would strongly advise any one to make a larger machine while they are about it—say a 4 by 2 or 6 by 3 armature, as they will be amply repaid; any form of armature will do with this F.M.; the latter being all in one piece, requires no fitting, must consequently be stronger than one in several pieces, with the *grain* in all directions. I think it will be unnecessary to take up any more space in describing minor details, as this has been done before, but shall be quite willing to give further advice on any part I have not made clear.

Wolverhampton. **George Tolman.**

FITTING NEW TEETH TO WATCH AND CLOCK WHEELS.

[20197.]—As a continuation of my former letter upon the above subject, I have the pleasure to present my readers with an accurate and simple mode of dividing off new teeth, where several have been broken out of either clock or watch wheels, and a blank piece of metal has been soldered or dovetailed in. It is of my own devising, so it will have the merit of novelty, if nothing else. I, however, have proved its practical utility, and in the hope it may likewise be of service to others, I now, for the first time, make it public. As I have intimated, the principle is applicable to either watch or clock wheels, the mode of dividing being the same, but the tools used being a little different in size or kind. For watch wheels, or small clock wheels, as in the figure, the depthing-tool is best; for large clock-wheels, either a clock depthing-tool or a pair of compasses. On reference to the figure it will be seen that a piece of metal, G, has been fitted, out of which it is desired to cut four teeth. This piece of metal is, presumably, finished off to the actual thickness of the wheel, and faced down. Set the wheel up in two of the poppets of the depthing-tool, and adjust one of the others to the base of the teeth, so that when the wheel is revolved the point will describe a circle round the wheel F. It is necessary only, though, to mark from four teeth on each side of the blank where four teeth are being divided, and three if for three, and so on. Then set the point to the extreme tips of the teeth, and score off the blanks from E to E. Now, on the line F, in the centre of each of the four teeth on either side, make a small drill-mark—it must be exactly central. This mark is to receive one of the points of the tool. Then set the other point so that when one is placed at A the other intersects the angle of the tooth H. Now, if this point is brought round to the blank it will strike off one side of the tooth, 1. Now place the point in the tooth A on the other side of the wheel, and score the blank. This will mark the other side of the new tooth 1. No. 2 tooth is produced in the same way by putting the point in the drill-marks B B and scoring off on the blank, 3 and 4 being likewise scored off. A mere scratch is sufficient to determine the position, and if the dividing is accurately done the teeth cannot fail to be set out right. The line E determines the exact length of the teeth, so the blank can be filed away to that, before the spaces between the teeth are cut out. The line F will determine the depth of the spaces. Although the wheel, figured here, has only a few teeth, and is not a "bar" wheel, the same principle will hold good in dividing off, whatever the number of teeth, or the make of wheel. Where the teeth are exceedingly fine, as in watch wheels, the scoring off must be correspondingly so. In *small* wheels, it will be found necessary to score off from, say, the 8th or 10th tooth to the sides of the blank, for the reason that the poppets of the depthing tool could hardly be set sufficiently close to each other. When once a correct idea of this principle of marking off for teeth has been got by the workman, a wheel may be scored off in about three minutes, so that it may be justly called a simple plan, and, as such, I commend it to your notice. **Alfojoe.**



THE TURKISH OR HOT-AIR AND VAPOUR BATH, AND THE SCIENTIFIC PRINCIPLES ON WHICH IT SHOULD BE CONSTRUCTED.

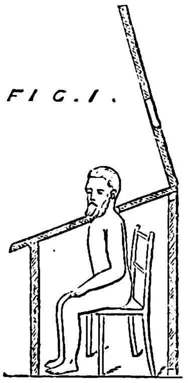
[20198.]—Some years ago I stopped in my travels at an hotel in ——, tired and dusty, and in want of a good wash, when a cheery English voice said, "Have a Turkish bath, sir?" "All right," said I, and I was shown into a comfortable room and requested to undress; at one side of this room was a tier of rows of boxes in a frame, numbered and lettered as in London clubs. My attendant handed me a key, with number and letter on it, which corresponded with that of one of these boxes. "If you have any valuables or money with you, sir, you had better place it in the box and hang the key round your neck when you undress and put on your bathing-suit." No sooner said than done; five minutes found me divested of my clothes, my watch, keys, and purse deposited in the said box, and myself dressed in a flannel suit which covered me from my neck to my heels. I remarked that this room was comfortably warm, and had a Turkish carpet on the floor. A thermometer hanging on the wall near the door showed a temperature of 70° Fahr.

My attendant opened a side door and admitted me into what appeared to be a small dressing-room. The temperature in this was rather higher, about 80° Fahr. On one side of it was an ordinary sitz bath, and also a portable shower-bath. On the other side of the room there was what appeared to be a monster wardrobe with door reaching nearly to the floor. My attendant handed me a thin blanket sheet of flannel, which is known to all East Indians as a coarse Rampu Chudder; so I divested myself of my flannel suit. Rolling this round me, I stepped inside the wardrobe, and very soon the temperature began to rise. I seated myself comfortably in an easy-chair, and in a quarter of an hour I was bathed in sweat from every pore. My attendant opened a slide, and passed into me a basin of strong soap suds and a sponge with which he advised me to rub myself all over as quickly as possible. Ten minutes more, still sweating from every pore and soap-sudded all over, I was brushing myself with a bath-brush and had peeled considerably; the temperature had been attended to by him, and had now fallen to 100° Fahr., which was also the temperature of the small-room. "Sitz and shower-bath both ready for you, sir," said my attendant. Throwing open the door of my bath, I stepped out and seated myself in the sitz bath for a minute or so, when I stepped into the shower-bath, and was well soused with water about 110° Fahr., and felt myself thoroughly clean. "Now we must save you from taking cold, sir," said he. "Look out!" No sooner said than he pulled a string, and down came on me torrents of cold water. Before I could recover myself from the shock, he said, "Come out, sir—you have had enough." I stepped out, and he covered me with a large blanket-sheet of twilled cotton, and set to work to rub me dry. In a couple of minutes I had again donned my flannel suit, and felt comfortable. On looking at the thermometer, I found the temperature had fallen to 80° Fahr. He handed me a pair of slippers and a dressing-gown, which I put on over the flannel suit, and at his invitation I stepped into the next room, and lay down on a couch and drank a cup of delicious coffee. A few minutes sufficed to get me into my own clothes, and "Gereb Admi" was himself again.

I cannot describe how light and comfortable I felt after this. It was as good as a night's rest, and I felt inclined to start off homeward again. A few days took me to my own house, where I was welcomed by wife and bairns by very nearly, though not quite, a round dozen, and on detailing my experience, we began to think what was good for the *Bap* (father) would be equally so for the *Ma* and *Batcha log* ("children folk" literally), pronounced Butcha loque.

So *Bap* set his wits to work and tried to make a Turkish bath for use in his own house. He began by making inquiries, and found that in one of the hotels in the town he was living in, it was said visitors could have hot air or vapour-baths. A visit to this hotel showed him the plan adopted. He was shown at the head of the landing a box 3ft. 6in. square standing on its end; one side was shorter than the other, which we call the front side; it was 3ft. 6in. high; the back side was 5ft. high, the upper end consequently was sloping; the back side opened like a door; the upper end of lid was hinged at the upper side, and could also be opened; it had a hole in it, through which the bather's head protruded. The box was just large enough to admit a cane or rush-bottomed chair, on which the bather sat. Through a small hole, which had a door to close it, was passed in a common gas-stove; it was said to answer perfectly, but I was not sufficiently credulous to submit myself to a bath in this ingenious, simple, but very primitive arrangement, which is illustrated in Fig. 1. I did not like the idea of leaving my head outside while my body was being plotted. It had one great defect—there was no ventilation; the heating arrangement was not under the control of the bather, and there was no means of reducing the high temperature gradually, and I thought that, while bathing, the occupant would be possibly subjected to partial draughts from defects in the woodwork, or from badly-fitting doors.

FIG. 1.



Section of hotel vapour-bath closet, with bather in it: 3ft. 6in. by 3ft. 6in. = plan; 3ft. 6in., front side, high; 5ft., back side, high. Back opens like a door below framing. Top shown both shut and open.

I began to think the matter over, and came to the conclusion that a vapour-bath for home use must be built on the following principles:—

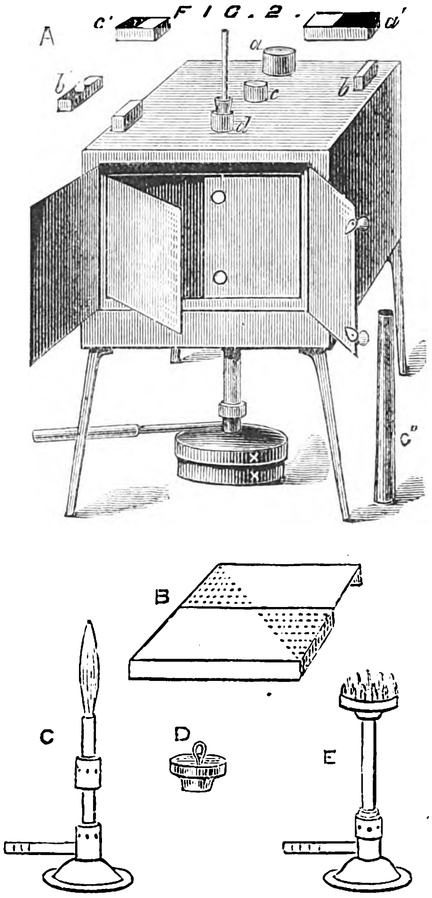
1st. It must be sufficiently large to admit the whole body, head included, and to admit of the bather scrubbing himself well with hot soap-and-water, as I did when I had my first Turkish bath, just described.

2nd. The heating apparatus must be under the control of the bather, who must have light, so as to be able to consult a thermometer hung in the bath beside him. He must have some arrangement of valves or slides communicating with the cool atmosphere outside, so that he can gradually reduce the temperature when he desires to do so.

3rd. The heated air supplied to the bath must be pure air specially heated for that purpose, and the burnt air by which this heat is produced must be utilised to carry off the impure air of the bathroom, contaminated by the products of respiration and the exhalation from the body—perspiration, &c.—produced by the heat to which the body has been exposed.

It struck me at once that in my student days I had seen such an apparatus in the laboratory of the late Dr. Thomas Clark, and that I had seen a description of it in Griffin's "Chemical Recreations," a book which had some twenty years before delighted my young heart. On searching for it it was not to be found, so I proceeded to Griffin's establishment and at once recognised the apparatus in question. I found that they had just published (in 1866) a most interesting work which was not a mere trade catalogue, but a highly scientific description of chemical apparatus of all sorts, and on pages 131, 132 I found a drawing of the apparatus, and a full detailed account of the principles of its construction. It was the very thing I wanted to guide me in arranging a domestic hot-air bath for my own use. As many of your readers may not be able to consult this work, I show the apparatus in question under Fig. 2, attaching to each Griffin's own reference numbers, and herewith I copy his description, which will make the principle of it plain to all.

FIG. 2.



A, Griffin's hot-air bath, 1281; *a*, chimney for escape of hot air; *a'*, cap to put on the chimney; *bb*, openings to admit fresh air; *b'* cap to cover *b*; *c*, escape tube for hot pure air; *c'* chimney foot from copper chamber; *c''*, long chimney for increasing draught; *d*, escape tube for hot pure air, sometimes utilised to take temperature with a thermometer as shown; B, false bottom to copper chamber where the air is heated; C, Bunsen burner, single flame; D, rose burner to insert in above to distribute the flame; E, the rose burner complete.

"No. 1281. GRIFFIN'S HOT-AIR BATH, for drying substances in a rapid current of hot air, kept within a few degrees of any desired temperature up to 500° Fahr. See the drawings, Fig. 2 A.

"This apparatus consists of a copper chamber, measuring 12in. from left to right, 9in. from top to bottom, and 8in. from front to back. This chamber is inclosed in a case made of stout sheet iron, which measures 14in. from right to left, 12in. from top to bottom, and 11in. from front to back. There is consequently a clear space of at least an inch all round between the copper chamber and the iron case. Hot air rising from a rose gas-burner (shown separately at C, Fig. 2) is made to pass continuously through the space, while a rapid current of heated atmospheric air is made to pass through the chamber containing the objects that are to be dried. The arrangement for carrying out this plan is as follows:—

PRODUCTION AND REGULATION OF HEAT.—The bottom of the iron case has a round hole in the middle, rather wider than the head of the rose gas-burner (shown separately at 974, see Fig. 2). This burner being lighted and applied there, air rushes up through the flame into the space between the copper chamber and the iron case, and passes out by a chimney on the top marked *a*. If it is desired to diminish the draught, the cap *a'* is put upon the neck *a*. This cap has an oblong form; when pulled to the right it opens the chimney *a* entirely, when pushed to the left it closes it, more or less, as may be desired. Attention to this chimney must be combined with due attention to the burner; the latter can be fully or only partially supplied with gas, and it may be pushed up close to the copper chamber, or be lowered two or three inches from it, the clay plates shown in the figure × being used to regulate the height of the burner. A ledge or partition of copper runs along the front lower edge of the copper chamber, and closes the space between that chamber and the iron case; a similar ledge runs along the back upper edge of the copper chamber. The former is intended to prevent the rising of the flame from the gas-burner into the copper chamber when the front doors are opened; the latter seems to prevent the flame passing directly from the gas-burner up the back of the chamber and out of the chimney *a* The effect of these obstructions is to force the hot-air to rise up on each side of the chamber, and to pass over the top to make its way to the chimney *a*. On applying a chimney such as *c''* to the neck *a*, and removing the flame, the whole apparatus is rapidly cooled.

CIRCULATION OF HOT-AIR THROUGH THE COPPER CHAMBER.—The copper chamber has a false bottom, which is divided into two compartments, as shown by Fig. 1282. It is a sort of shelf or stool that lies about an inch above the solid bottom of the chamber. Each half of the space included between the true and false bottom is open at one end and closed at the other, and the surface is perforated in the manner shown by the figure. Air passes into the inclosed spaces by two flat copper tubes, the upper ends of which are marked *b b* in Fig. 1281, and the lower ends of which communicate with the open ends of the spaces marked by arrows in Fig. 1282. These air-tubes are fixed in the space between the copper chamber and the iron case, and being exposed to the hot-air that rises from the gas-burner, while the flame of the burner acts directly upon the solid bottom of the chamber, the air supplied by these tubes becomes rapidly and strongly heated, and is delivered in that condition through the holes in Fig. 1282 into the hot chamber from which it escapes by the two openings *c d*, after passing over the objects that are placed in the chamber.

REGULATION OF THE CURRENT OF AIR.—When a strong current of air is required, the tubes *b b* are both left open, and the chimney *c''* is placed upon the neck *c*. When less air is required the chimney *c''* is taken off, or is replaced by an oblong cap *c'*, of which the chimney *c* can either be entirely obstructed or opened to any desired degree. The draught of air *into* the chamber can also be regulated by two caps of the form of *b'*, which are adapted to the openings *b b*, and can open or shut the passage to any necessary degree by merely sliding along them. The neck *d* can be closed by a cap, or it can be used for the insertion of a thermometer to indicate the temperature of the hot chamber. The four pipes, *b*, *b*, *c*, *d*, shown in Fig. 1281 are all in communication with the copper chamber, and have through holes in the top of the iron case. The chimney *a* alone communicates with the space between the two chambers.

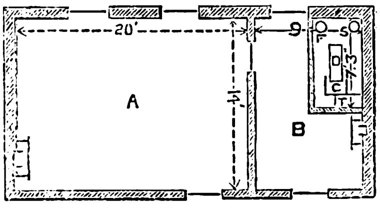
This construction of the apparatus enables the operator, by attention to the gas-burner and the chimney *a a'*, to regulate the amount of heat applied, and by attention to the ventilators, *b b'* and *c c' c''*, to regulate the circulation of air through the drying chamber.

For operations which do not demand a drying heat beyond 300° Fahr., the small rose gas-burner No. 973 is sufficiently powerful; but when a higher temperature is required, and especially when a large quantity of air is to be forced through the chamber, the rose burner No. 974 is requisite.

The iron case and copper chamber are separately opened by double doors in front, as represented in Fig. 1281. The copper chamber contains two movable stools to sustain capsules, crucibles, &c.

I have copied the whole of this out, so that there may be no difficulty in the principles of its construction being thoroughly understood. Some days elapsed before I could make up my mind what to do.

FIG. 3.

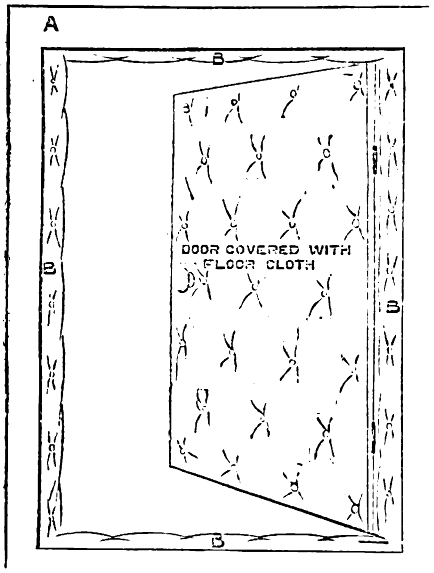


A, large bedroom, 20ft. by 14ft.; B, dressing-room, 14ft. by 9ft.; D, chamber for vapour-bath, 7ft. 3in. by 4ft. 6in.; F, vapour-bath furnace as described; S, shower-bath; C, chair; T, table for basin, &c.; all rooms 10ft. high.

The house we resided in was a roomy one; but as I had a large family every room was occupied except a dressing-room adjoining the paternal and maternal bedroom, and appropriated to my use. I therefore decided to devote this to the bath.

In Fig. 3 you have a plan, A being the bedroom and B the dressing-room. After thinking the matter over, I decided that I must make the little dressing-room as nearly air-tight as possible; fortunately both doors opened outwards, so a very simple arrangement made them draught proof. I covered both doors with a piece of felt floor-cloth, so as to close keyhole and cracks, if any; and I lined the framing sides top and bottom with a piece of pantile lath 2in. by ¾in., covered with the same floorcloth which, when the door covered with the drugget was closed against, prevented the slightest passage of air. This arrangement is shown on Fig. 4. The next step was to cover the floor with oilcloth, so that no air could pass in from below; in place of a carpet the oilcloth was covered with two or three pieces of cocoanut matting, which could be taken up readily, and removed for drying if they became wet.

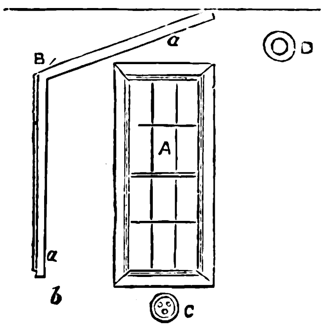
Fig. 4.



A, door-frame; B, inner sides of frame lined with drugget, and padded.

The next thing to be attended to was the window. I should have liked to have a double window, or to have had a single window with double panes of glass, so as to induct between them a space filled with air, which would have prevented that loss of heat by radiation, which constantly goes on in our dwelling houses, but that would have been expensive, so I treated the window-frame as I had the doors, with an inner frame of lath covered with felt floor-cloth. I then made a strong wooden frame, which I hinged to the upper part of the inner framing of the window, and by a cord and pully pulled it up against the ceiling, where it was out of the way when not required. It was also at the sides and edges lined or covered with felt, so that when placed over the window it jammed against the felt lining and prevented any passage of air. This frame was not glazed, but was covered with stout blind-cloth, which I rendered semi-transparent by varnishing with Canada balsam dissolved in turpentine. To provide for fresh air from without I made a hole under the window-ledge through the brick wall, into which I passed a piece of conical iron tube, which I bought for a shilling at a scrap iron and metal store; it had a flange on it inside, where it was about 8in. in diameter, being about 4in. at the other end. This arrangement is shown on Fig. 6 A, which is a rough sectional sketch of the window-frame and wall underneath it, showing the conical tube and its fittings in situ. Before putting it in place, I turned up the face of the flange true on the lathe, and fitted to it a flat piece of boiler-plate, fixed by three small nuts and bolts. Between the faces of the iron was a canvas washer, well covered on both sides with white-lead; the centre of this plate was bored with three holes, and tipped to take four short pieces of iron pipe. This arrangement is shown roughly on an enlarged scale on Fig. 6 B, in section showing only three for the pipes; one of these pipes had a tap, so as to admit fresh air direct into the dressing-room, if required. The other three pipes were closed by boxwood junctions, screwed on and connected to the tubes by white-lead; these had the form of a nipple, as shown on Fig. 6 C, to take an indiarubber tube to connect them with the heating arrangements, to be presently described; it could be closed, when the rubber tube was removed, by a plug. I had now the means of admitting fresh air directly into the room, or by attaching pipes to any of the iron pipes to convey fresh air to any apparatus I might wish.

Fig. 5.



A, window; B, section; C, perforated iron plate for giving fresh air to furnace; D, flue to carry off foul air; *a*, inner window shown shut and open. This window is a frame of calico made transparent, the sides of frame being covered with felt; *b*, frame described under *a*; *c*, fillet covered with felt round the frame of window proper.

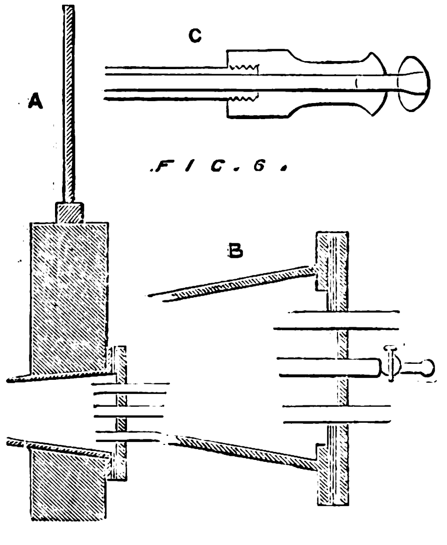


FIG. 6.

Now, all I had to do was to design a cheap and easily-constructed double chamber, like that of Mr. Griffin. This I did in an inexpensive manner. My chambers were constructed from two small iron drums used for holding oil-paint. These drums can be purchased from vendors of oil-paint, when empty, at prices varying from 4d. to 3s., according to size. I give here a list of the ordinary sizes:—

A	To hold	7lb.	white lead.	6in. high.	5in. diam.
B	,,	14	,,	8 ,,	6 ,,
C	,,	56	,,	10 ,,	7 ,,
D	,,	112	,,	14 ,,	9 ,,
E	,,	?	,,	17 ,,	12 ,,

I give the sizes to enable anyone to construct such a bath furnace as will suit his own requirements. I used C and D.

I began by preparing D to receive C. These drums are cylindrical vessels of iron, with a lid which shuts in the top, as shown in Fig. 7.

(*To be continued.*)

THE CONCENTRIC MICROSCOPE.

[20199.]—Speaking from my own knowledge of the origin of the main principle embodied in this microscope—the centralisation of the movements upon the object as a common centre—I say the principle was not originated by Dr. Edmunds, neither by reason of his remarks on Wale's microscope at the R.M.S. in Nov., 1880, nor through his having made some communication to the junior secretary of the R.M.S. in Dec., 1878, those being the dates which Dr. Edmunds has been pleased so far to assign as the grounds of his claim.

The idea has formed the subject of many a conversation among those interested in the improvement of the microscope long before 1878, when Dr. Edmunds joined the R.M.S. As a matter of fact, I discussed the matter repeatedly in 1868, with Messrs. Hartnack and Prazmowski, the well-known opticians of Paris, with particular reference to the facilities that would be gained for oblique illumination; but those opticians did not see their way clear to a commercial success with the idea. The plan I had in view was to suspend the microscope by two trunnions, one on each side of the stage, on pillars, so that the axis of inclination would pass through a diameter of the object on the stage. The idea was suggested to me by examining the Thury-Nachet Traverse Substage (recently figured in the *Journal* of the R.M.S., Vol. III., 1880, p. 1060). I do not, however, claim the principle, for it must be obvious to any candid-minded person that the principle is embodied in every microscopical apparatus in which the object is made to rotate on the optic axis. In several of the microscopes devised within the last ten years, notably, Tolles's, Zentmayer's, Bulloch's, and Beck's, when the microscope-body is inclined to the horizontal, the centre of the rotating base is in a perpendicular line, passing through the object on the stage; the rotation of the microscope on its base then presents the object to a fixed source of light in the then horizontal plane (say a lamp-flame used with bull's-eye condenser) at all obliquities from 0° to 90°. This is unquestionably an application of the principle which Dr. Edmunds claims to have discovered.

As I have said, the main principle of Mr. Wenham's microscope has been in the minds of many microscopists for a considerable number of years; the difficulty has been to hit upon a design that would impress an optician with a favourable prospect of success. Mr. Wenham has been so fortunate in his design that Messrs. Ross have spared neither labour nor expense in their efforts to carry it out successfully. I believe they have secured the assistance of one of the best mechanicians in Europe to supervise certain matters of detail with a view to the greater accuracy of construction; and I have no doubt the microscope will soon be in such a condition as regards workmanship that it will withstand the disparaging criticism of even Dr. Edmunds.

I do not, of course, undertake to assign the precise origin of any idea Dr. Edmunds may have had for the construction of a "concentric" microscope; but it appears to me probable that this gentleman, having heard from some one more experienced than himself that such a microscope would be a desideratum among microscopists, has puzzled himself into obliviousness of the fact that he picked up the idea in conversation, and has imagined himself to have originated it. To use an old saying, "he has dreamt what he desired, and believed his own dreams," which is by no means an uncommon process among claimants to fame.

I think it is regrettable that Dr. Edmunds should still seek to maintain that Mr. Wenham is indebted to him for the main principle embodied in the new stand, in spite of Mr. Wenham's distinct repudiation *on the matters of fact*—matters of fact on which we are bound to accept Mr. Wenham's statements. I should hope that Dr. Edmunds will now see that his persistent attempts to associate himself with Mr. Wenham's microscope are, to say the least of them, in very bad taste.

F.R.M.S.

[20200.]—I have not the slightest recollection of aiming at anything further in the *arc* than keeping the weight nearly over the centre of the base when the microscope was inclined.

The suggestion of Dr. Edmunds was the first intimation of making the focal point the centre of motion, to my knowledge.

The writer of letter 20072, p. 261, must be under some mistake.

Montclair, N.J., June 6. **Geo. Wale.**

[20201.]—Several letters have appeared in your columns, which have been written, apparently with a view, first to deprive Dr. Edmunds of the credit of being the inventor of the concentric microscope; secondly, to impute that, if he were really the inventor, he had merely copied or taken the idea from Wale's microscope, when it was exhibited at the R.M.S., on Nov. 10th, 1880. I hope, therefore, in justice to Dr. Edmunds, you will publish the following statement:—

I was present at the R.M.S. on Nov. 10th, 1880. I was on the platform, talking to Dr. Edmunds, and inspecting the apparatus that was being exhibited, after the business of the meeting was finished. I was one of the knot of gentlemen to whom he expounded the principle of his concentric microscope. Dr. Edmunds invited me to see the drawings he had made of his invention. Having seen those drawings a few days afterwards, I am in a position to testify that Dr. Edmunds is an original inventor of the concentric microscope.

June 17th. **Edward M. Nelson.**

STEAM-LAUNCH SPECIFICATION.

[20202.]—With regard to specification (letter 20115) of boat generally, there is not much to object to; but I should certainly prefer some other type of engine than Willans. There is nothing better than a suitable size pair of vertical engines, and the size required for such a boat will be two cylinders, 6¾in. diameter and 7in. stroke. Revolutions per minute not to exceed 350, i.h.p. = 45; speed of boat 9 knots. The boiler I should prefer would be a horizontal one; but I see no great objection to a well-designed vertical one. In any case, the heating-surfaces should not be less than —grate = 4·25 square feet, surface in furnace and tubes = 180 square feet; propeller No. 1, four-bladed, diameter 3ft.; pitch, 3ft. 10in.; greatest length on line of keel, 5in. This pair of engines are supplied with steam from a horizontal boiler having the above surfaces. Diameter of boiler, 3ft. 8in. by 5ft. long, boiler pressure, 70lb. per square inch. **W. Trathern.**

[20203.]—On page 310 "E. M." of June 9, 1882, "Robinson Crusoe," in letter 20146, in reply to "Steam-Lauch," advises him to have no keel. How does "R. C." propose to fasten on the stern-post and stem, also the first strake on either side? I was always under the impression that the keel was the most important part of a launch. I would advise "Steam-Launch" to adhere to his builder's specification.

Regarding Willans engine, "R. C." has evidently had no knowledge or experience of them, or he would not talk of not being able to get at what he calls the *vital* parts. I will undertake to take a Willans three-cylinder engine to pieces as soon as "R. C." will an ordinary double-acting engine; and what is the use of taking a thing to bits that does not require it, as I see per *Field* of June 17th, page 820, that one of Willans' engines has run six seasons without any repairs.

"R. C." had better take back to his island a "single reversed cylindered engine, with a good heavy balance-wheel." It will just suit his keelless canoe, which, according to last accounts, was high and dry. **Live and Let Live.**

[20204.]—"Edinburgh" (20146) should see that the 5in. compound Willans engine is specified. The difference in cost is not great, but the advantage in economy is considerable. Within the last year or two, the inventor has begun making the engines, at Thames Ditton, from patterns which are a great improvement upon those used by the other firms, which make them under license. There are many other points in the specification which seem to me very defective—too many to take up valuable space with. If "Edinburgh" will advertise his address, I shall be happy to write to him. **Wave.**

"PROPELLING."

[20205.]—It may be interesting to your readers to know that the inclined screw-propeller was patented in 1852 (No. 1002), by a Mr. Wilson, who preferred an angle of 45°.

Also that the "coupling-rod" propeller, referred to by one of your correspondents, with a number of floats on each rod, was patented by Mr. Burnside in 1856 (No. 869.) **Thomas Moy.**

June 17th.

MR. SCOTT RUSSELL AND THE VIENNA DOME.

[20206.]—Your notice of the death of Mr. Scott Russell, with whom I sometimes came in contact, professionally, and who, I think, was an abler man than many people recognised, reminds me of a very curious fact (as I suppose it is) respecting his great iron cone—rather than "dome"—of the Vienna Exhibition; which is 360ft. wide, and, therefore, covers 6½ times as much ground as the domes of the Pantheon, St. Peter's, or Florence Cathedral, and 3 times as much as the Albert Hall (220 × 185).

The gentleman who was his resident assistant then in building it, told me that they were at first uneasy about the expansion and contraction being likely to keep the pillars on which it stands continually leaning outwards and inwards to a serious extent; for according to the tabular expansion of iron, it would vary half an inch in a radius of 180ft. between many days and nights, and an inch between summer and winter; but that Scott Russell came to the conclusion that it would not; and that they did find no motion at all in the pillars. And further, that it had been found by experience that the rollers which were carefully provided for all the earlier tubular bridges to expand and contract upon never act at all, and that other such bridges do as well without any.

I confess all this sounded to me surprising, and still is so, and probably it will be to most people. But it is never of any use to disbelieve experience for theories, if it is certain. The result is so important to all who have to deal with iron beams and rods in holding buildings together, that it is very desirable that we should know how the fact really is, and then (but not before) to investigate some satisfactory theory about it. Railway engineers must know by this time whether it is necessary to allow any play in the fish-joints of rails, or between the ends of the rails if laid down in cold weather; though, to be sure, the length of a rail is quite insignificant compared with the width of the Vienna dome or the Menai bridge. This seems a convenient occasion to start the question, and get it settled for good. **Edm. Beckett.**

ORGAN IN ST. VINCENT FERRER CHURCH, N.Y.

[20207.]—The following are the details of scheme of the above organ, built by Mr. H. L. Roosevelt, the well-known American builder:—

Three Manuals, Compass C C to A^3, 58 Notes.

Great Organ.

	Ft.	Pipes.
1. Open Diapason	16	58
2. Double Gemshorn	16	46
3. Open Diapason	8	58
4. Violon Diapason	8	53
5. Melodia	8	58
6. Principal	4	58
7. Flute	4	58
8. Wald Flute	2	58
9. Mixture	(4 ranks.)	
10. Cornet	(4 and 5 ranks.)	
11. Trumpet	8	58
12. Clarion	4	58

Swell Organ.

	Ft.	Pipes.
1. Bourdon	16	58
2. Open Diapason	8	58
3. Rohr Flute	8	58
4. Keraulophon	8	58
5. Principal	4	58
6. Flute Traverse	4	58
7. Mixture	(4 ranks.)	
8. Cornopean	8	58
9. Oboe	8	58
10. Vox Humana	8	58

Choir Organ.

	Ft.	Pipes.
1. Doppel Flute	8	58
2. Gambia	8	58
3. Dolce	8	58
4. Concert Flute	8	58
5. Viol d'Amour	4	58
6. Rohr Flute	4	58
7. Piccolo	2	58
8. Clarinet	8	58

Pedal Organ.

	Ft.	Pipes.
1. Open Diapason	32	27
2. Open Diapason	16	27
3. Double Gamba	16	27
4. Bourdon	16	27
5. Violoncello	8	27
6. Bombard	16	27
7. Tuba	8	27

Guernsey, June 10th. **C. H. Domaille.**

THE PORTSKEWET PIER ACCIDENT AND THE TWO-MINUTE BRAKE.

[20208.]—Upon the 25th of April a collision occured at Portskewet Pier Station on the Great Western Railway, between the 6.40 p.m. passenger train from Cardiff and three empty coaches standing near to the buffer-stops at the end of the pier. Colonel Rich held an inquiry, and his report has just been published.

The passenger train consisted of a tank-engine, fitted with a steam-brake, a van, five carriages, and a rear van, fitted with the Sanders and Bolitho automatic vacuum brake, as modified by the Great Western Railway Company.

Colonel Rich reports that "the collision was caused by the vacuum brake failing to act when it was required." . . . in consequence of there being a very small amount of vacuum in the pipe and cylinders; possibly none, as the train approached the pier, after the driver had applied it three times during the short journey from the junction. He thinks the efficiency of this brake has been materially interfered with by the hole in the piston-rod, which allows it to leak off in a short time; he experimented on the carriages of the train, and found that the brake leaked off the front van in about 30 seconds, and off one of the coaches near the tail of the train in about *two minutes*. Colonel Rich also mentions that on the same day, after his inquiry, there was very considerable leakage in the vacuum brake upon an express train; "the pump rose the gauge very slowly to about 22in. to 23in. while the train was running; but the whole of the brake power appeared to be exhausted before the train was half stopped when running into Taunton station, so that at that momentous time there was actually no continuous brake available until the vacuum was recreated by the application of the ejector, after which the train was stopped at the platform. I doubt whether this was considered by the engine-driver as a failure of the brake, and would be reported as such; to my mind it was a very important failure."

I trust that the very important facts to which Col. Rich refers will be seriously considered by the directors of the Great Western and Midland Railways before some disaster occurs.

In my letters to the English Mechanic, and also in the third and following editions of my pamphlet, I have pointed out the very great risk and danger which results from the use of what is generally known on the Midland and Great Western Railways as "The Two-Minute Brake," because it is purposely constructed to leak off of itself in two minutes. Col. Rich calls attention to the fact that "the whole of the brake-power appeared to be exhausted before the train was half stopped, when running into Taunton." This is no unusual occurrence, as I have myself frequently seen trains come into stations with the vacuum brake "leaked off," and the final stopping of the train effected by means of the steam brake upon the engine and tender; of course the vacuum brake was useless until the driver recreated another vacuum which, when applied, would again "leak off" in two minutes.

It will be noticed that your correspondent, "A Driver," letter 46828, p. 334, this week calls attention to the Board of Trade Returns and the failures of brakes.

The Railway Returns (Continuous Brakes) Act, 1878, enacts that "Any person who makes, or is privy to the making of a return under this Act which is to his knowledge false in any particular, shall be liable, on summary conviction before a court of summary jurisdiction, to a fine not exceeding fifty pounds."

This penalty has not been inflicted, and is therefore regarded by a few companies as a "dead letter," the result being that their returns become more and more incorrect each half-year, until now they are practically useless for comparison.

The Portskewet Pier accident, and the report of Col. Rich is a warning which the two companies which now use "Two-Minute Brakes" will do well to seriously consider without delay, and before any other accidents take place. This brake frequently leaks off, and allows trains to run past signals and stations, but as the companies in question do not profess to consider "leaking off" a failure, these cases are never reported to the Board of Trade, and therefore do not appear in the returns; they also consider that a steam brake on an engine is not continuous, and therefore do not report any of the numerous steam-brake failures. **Clement E. Stretton.**

Saxe Coburg-street, Leicester, June 17th.

CUTTING SCREW-THREADS WITH A SLIDE-REST ONLY.

[20209.]—The following is a very simple way of cutting screw-threads with a slide-rest only. Turn a couple of wooden pulleys, and fit one of them on to the bar on which the screw is to be cut, and the other on to the screw of the slide-rest, and connect them by means of an elastic band. By altering the sizes of the pulleys different threads may be cut. It is a good plan to have a set of pulleys answering to the change-wheels of a screw-cutting lathe. As it is required to use the same pulley very often, a plug is fitted tightly in the old hole and a new one bored to fit the diameter of the bar is to be turned.

Hartwell. **E. Thomas.**

MEDICAL REPLIES.

[20210.]—Bright's Disease (47154.)—I cannot imagine that any physician would really have ordered stout and gin for a patient suffering from Bright's disease, and in the teeth of a very wise recommendation from the local medical adviser, who was undoubtedly right and in accord with the best modern practice. Follow the advice of your family doctor.

Iron Medicine (47188.)—The best medical preparation of iron for internal use is that known as "dialysed iron," which may be got at any druggist's The finest and most certain preparation of dialysed iron is that known as Wyeth's, to be obtained from Burroughs and Co., of Snow-hill. The ordinary acid solutions of iron destroy the teeth, and should never be taken, now that a beautiful preparation like the Wyeth's dialysed iron is accessible.

Indurated Liver (47200.) — No one can say, without examining the patient, what is the cause of the induration of the liver, or estimate the probability of recovery. "Induration" is merely another word for *hardening*. If cancerous, the disease is a fatal one.

Jas. Edmunds, M.D.

NEW ELECTRO-MAGNETIC CLOCK.

[20211.]—My criticism of Mr. Huxley's pendulum, figured on page 263, was based on the assumption that it was to be hung on a spring, as usual, in which case it is very evident it would "wobble." It requires very little gumption to see that.

Now, it appears, it was intended to be applied to the clock-motor described on the same page, and if the rods are made a fixture in the armature, it will, no doubt, prevent the wobbling; but the tendency to do so will remain and give rise to very objectionable twisting strains.

There are other forms of compensation-pendulums—the zinc tube for example, quite as simple as Mr. Huxley's, to which these objections do not apply. But, may I ask, what end is supposed to be served by applying a compensated pendulum to a clock whose motive force is as variable as an earth battery current? The small temperature error would be quite lost amongst others.

Mr. Huxley's remarks about the wheels of clocks and the human leg are altogether beside the question, and require no notice. J. E. Floyd.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[45338.]—**Preservative for Iron Ships.**—I am particularly anxious to let Mr. Clifford have the pamphlet I address to you herewith. Although such a favour as forwarding it must be foreign to your custom, will you, in consideration of the great distance at which I am from home, put a line in your "Replies" to say that it is awaiting his address?—W. B. Denny, Magistrate and J.P., Singapore, May 6th.

[We depart for once from our rule, and Mr. Clifford may have the pamphlet by forwarding his address and two stamps.—Ed.]

[46346.]—**M.S.L. Engine 399 (U.Q.)**—This engine commenced running in February, and was put on the Manchester and Liverpool line. When I mentioned her (p. 618, No. 884), she was settling down, but so long in doing it that the men changed the pet name they had given her "Robert the Devil" to "Jumbo," for, like the elephant, they could not keep her out. Several alterations have been made, and I understand she is likely now to behave better. I am told she has taken 20 coaches from Manchester to Liverpool in 50 minutes, including five minutes' stop at Warrington. The driving-wheels are 7ft. 6in. diameter, and the cylinders (outside) 18in. by 26in. The driving-axle only has inside bearings, and the outer framing has a massive appearance, which is increased by the pistons and cross-heads being entirely hidden from view; but the big end of the connecting-rod can be seen below the framing at the half-stroke. The counterweights are on the same arrangement as the bogie-engines on that line; instead of being on the rim of the wheel, they are fixed close to the boss, and are very large. The engine and tender weigh about 70 tons, and were constructed at the company's works at Gorton.—R. N. H.

[46578.] — **Roof Ventilator (U.Q.)** — The neatest way of forming ventilator for roof 30ft. long will be to continue the ridge piece about 2ft. past the point of junction with hips at each end; fix short rafters on each side of said continuation down on to the hips, and fill in the upright face with louvre-boards; finish off on face with cut barge boards, and fix a flashing at bottom.—Ditton.

[46603.] — **Induction Coil Failure.** — I feel sure the secondary is at fault as regards insulation, as it has only two thicknesses of paraffined tissue between layers, and I have not thickened this at the ends, where I see now the struggle to get out would be fiercest. I have pulled my first one to pieces, and shall try again, and if I succeed will report result for benefit of others. I have two small brass balls on the secondary terminals of my present coil, and using three bichromates (series), though no sparks will appear till they are 1-16in. apart; yet, while this small violet spark goes on, a good ¼in. flash every now and then jumps from the side of one ball to that of the other. —B. H.

[46694.]—**Brick-Kiln with Down-Draught.**—I am obliged to "Brick-Burner" for his information on p. 312, and should be glad if he can tell me how the flue from the fires to the centre flue is arranged. Is there only a straight flue from the fire to the centre, and how is the draught controlled? Suppose one part of the kiln is finished burning before another, how is the heat diverted? If "Brick-Burner" could give a sketch of the bottom of the kiln I shall be obliged. The kiln would be for Bridgewater—he may know what the clay is there.—Brick Kiln.

[46771.]—**Zincography.**—Will "P. N." or any other of "ours" kindly give full directions for the photographic process as given in the above? Proportions of mixture, gallic acid or infusion of nutgalls, commercial or glacial acetic acid. If the bitumen is rendered insoluble by the action of light in turpentine, how is the whole plate cleaned up by turpentine? Would it not remove the whole at the first application.—W. B. S.

[46771.]—**Zincography.** — "P. N.," in describing the photographic method with bitumen, writes:—"To dissolve out first the bitumen, which has not been acted on with spirit of turpentine;" and futher on he writes—"the whole plate is then cleaned up with essence of turpentine." How does the turpentine not remove all the bitumen on the first application, if it can on the second? Or is there a difference between spirit of turpentine and essence of turpentine? Or when is the bitumen got rid of? Will "P. N." kindly explain this little difficulty in an otherwise simple method, and oblige?—Try Again.

[46775.]—**Staining Walls and Plain Decorations (U.Q.)**—According to "Spon's Workshop Receipts," any shade of pink may be obtained in distemper with vermilion. Indigo and yellow ochre will give green; so indigo, with small quantity of yellow ochre, would give greenish blue; the pigments should be ground quite fine. Distempers with lime in them are apt to turn black.—Ditton.

[46779.]—**Bleaching Small Articles.**—I presume that this inquirer resides in a town, and is not within reach of a grass-plat whereon to put out cuffs, collars, &c. Such articles, as well as pockethandkerchiefs, do require, every few weeks, to get a good "stewing" in a warm oven, often having to be left there, in a good large "stew-mug," for several days at a time, until they look white. As a preparation for washing, always steep white (I mean not colour-printed ones) articles in cold water for a few hours, and then the soiled parts can be very much cleansed by a good pressing together between the hands,—no violent rubbing,—then use good white soap on them, and let them remain over night, folded flat on a dish, not in water, but yet wet enough to completely melt the soap through the texture of the articles. Do not be too stingy of soap; you can use the lather with other articles of a less fine sort. A little practice will bring you to the use of enough without waste. Next day pour on to said clothes a kettleful of very clean boiling water—boiling, mind you; for if only one degree below the boiling-point it will not be hot enough to whiten them. Cover your washing-mug (or basin) at once, so that the steam is kept in; after 20 to 30 minutes has passed, wash your things, and give them a rinse in plenty of tepid water. If now they are not to your satisfaction, spread them, well pulled out, while wet upon a large dish, which place at, or outside, an open, sunny window, sprinkle them with clean cold water several times a day, and they will bleach lovely. Keep thus going for two or three days; then wash again in a clean "scald," as above described, and when you have them finished it will be your own fault if your laces and handkerchiefs are not a wonder to all beholders. N.B.—Never starch your lace articles, but crisp them in cold water, in which two or three lumps of loaf-sugar are dissolved; also be sure to stretch out the work while wet, then dry flat on a towel upon the bed.—An Experienced Old Hand.

[46797.]—**Academy Boards.** — I have found academy boards very convenient for sketching in oils, but unless you manipulate your colours skilfully they are apt to sink in in the course of time. For good, permanent work I should certainly recommend canvas. For the enlightenment of "Nun. Dor." in connection with query, I would say that academy boards are millboards, prepared to receive oil-colours, and may be had of any of the artists' colourmen.—Edward Flowerday.

[46814.]—**Caledonian Engines.**—To "Carstairs."—Many thanks for details. I have never yet seen a Caledonian engine, having only heard of them, and principally through your interesting papers in the "E.M." I suppose the old six-coupled goods would not be like the modern ones in the arrangement of wheels! If there are any other classes of exceptional construction, either on the Caledonian or neighbouring lines, I am sure the information would be welcome.—R. N. H.

[46847.]—**Equation.**—The second solution of "A Medical Student" is only a repetition of what has been done before—viz., casting out a factor from a biquadratic. He has, however, this time discovered that that can be done without introducing unnecessarily other unknown quantities; but how he should think that the "appearance" of a quadratic, the square of which he is unable to complete, is quite sufficient, I must leave your readers to judge. "R. E. D." has been a little hasty in giving what he calls a decisive proof of the fallacy of my solution. The fallacy he pointed out is known to most of us from our school-days, when, by it, we used to perform the wonderful feat of proving 1 = 0, &c. But in applying this fallacy to my solution he has proved too much. He has proved the truth, and not the fallacy, of my result; for if $(a - b) = \pm (c - d)$, then the terms are, as pointed out by "M.I.C.E.," each = 0. And, moreover, this does not arise, as "M.I.C.E." thinks, through a curious coincidence, but through the arithmetical progression of the terms, as I will now endeavour to show. In my solution (*b*) $2zx - xy = 18$. Then $18 - zx = zx - xy$. $\therefore xy, zx, 18$, are in arithmetical progression, where $zx - xy$, or $zy/3$ = common difference. Then

$$\begin{array}{ccc} zx - xy, & zx, & zx + xy \\ \frac{zy}{3}, & zx, & 36 - zy \\ 9 - \frac{xy}{2}, & 9 + \frac{xy}{2}, & 9 + \frac{3xy}{2} \end{array}$$

are identical in value, but not in terms. Now the following equations, which appeared in my first solution—

$$zx - xy = \frac{zy}{3} \text{ .... } (c)$$

$$zx + xy = 36 - zy \text{ .... } (d)$$

are manifestly *not* identical. If we multiply these together, we still have an independent result, viz.:—

$$z^2x^2 - x^2y^2 = 12zy - \frac{z^2y^2}{3} \text{ .... } (3)$$

and substituting for zx^3, from the progression, the value $\left(9 + \frac{xy}{2}\right)$ is quite legitimate. Then—

$$\left(9 + \frac{xy}{2}\right)^2 - x^2y^2 = 12zy - \frac{z^2y^2}{3}$$

reducing and completing the square, we have, as before—

$$\frac{x^2y^2}{4} - 3xy + 9 = \frac{z^2y^2}{9} - 4zy + 36$$

$$\frac{xy}{2} - 3 = \pm \frac{zy}{3} - 6$$

$$\frac{xy}{2} - \frac{zy}{3} = -3$$

$$\frac{xy}{2} + \frac{z}{3} = 9$$

$$\therefore xy = 6 \quad zy = 13 \quad zx = 12.$$

From the progression we also get readily, without any substitution—

$$\frac{12 - \frac{2zy}{3}}{(xy - 6) + \left(\frac{zy}{3} - 6\right)} = \frac{xy - 6}{6 - \frac{zy}{3}}$$

$$\therefore 2\left(6 - \frac{zy}{2}\right)^2 = (xy - 6)^2 + \left(\frac{zy}{3} - 6\right)(xy - 6)$$

By completing the square and reducing, we get—

$$9 - \frac{zy}{2} = \pm (zy - 6) + \frac{zy}{6} - 3$$

$$\therefore 12 - \frac{2zy}{3} = xy - 6$$

$$\text{or } \frac{zy}{3} = xy$$

$$\therefore zy = 18, \text{ and } xy = 6$$

$$\therefore \frac{zx \cdot xy}{zy} = \frac{12 \times 6}{18}$$

$$x^2 = 4 \quad x = \pm 2 \quad y = \pm 3 \quad z = \pm 6$$

—J. Lane Davies.

[46834.] —**Churchwardens (U.Q.)**—Though addressed to Mr. Wetherfield, as it has not yet been answered, I give the following:—The only alteration I know of in the law of voting at the election of churchwardens is that now the occupiers of small tenements on which the rates are paid by the owner are qualified to vote in respect of their occupation. All householders may vote in vestry, also on a poll; at the latter the voting is regulated by the rateable value, in respect of which the occupier votes. By 58, Geo. III., c. 60, sec. 3, it is provided "that every inhabitant present, who by the last rate made for the relief of the poor shall have been assessed in respect of any annual rent, profit, or value, not amounting to £50, shall give one vote and no more; if assessed for any such annual rent, &c., amounting to £50 or upwards, he is entitled to give one vote for every £25 in respect of which he shall have been assessed; but so that no inhabitant shall give more than six votes." Of course in vestry, when the voting is determined by show of hands, each individual can give but one vote, irrespective of the amount of his assessment.—DITTON.

[46863.]—**Painting on Silk.**—I understand that the proper method of preparing silk for painting is to size it—using preferably isinglass size. The silvering and gilding will be done as usual with gold size and metal in leaf, unless Bessemer's paints are considered good enough. The paints are of course the usual artist's oil-colours.—T. P.

[46881.]—**Boring Working Barrel.**—In the back volumes there are all sorts of devices for boring out cylinders, &c. Perhaps that on p. 628, No. 753, will suit you. Possibly, however, you will find a simple cutter, mounted in a disc the size of the barrel, will work easiest, if slow.—E. G. M.

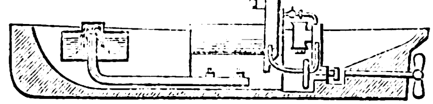
[46885.]—**"Austral" and "Sahara."**—The engines of the "Austral" are compound surface-condensers; one high-pressure cylinder, 62in. diameter, and two low-pressure, 86in. in diameter, with a stroke of 5ft. The crankshaft is "built" and the propeller-shaft is of fluid compressed steel. The four boilers are of mild steel, cylindrical, 16ft. in diameter, and 17ft. long, with six furnaces in each, being fed from both ends. The working pressure is 95lb. The length of the vessel is 474ft., breadth 48ft. 3in., depth 37ft. I have not seen any published dimensions of the "Sahara."—ESSAR.

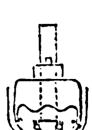
[46886.]—**Model Marine Engines.**—The engines would do for any boat into which they can be placed; but they most certainly will not drive any boat at 10 miles an hour even with the tide. Test the boiler according to directions given last week, p. 331. But suppose your model finished, and the engines will drive it at the rate of 10 miles an hour, what are you going to do with it? Models of the kind, which are in reality "models" of nothing at all, serve only to show the skill of the workman, and are utterly useless when finished.—ESSAR.

[46911.]—**Lathe.**—If choice lies between a 4in. with backgear, and a 5in. without, the former will be most useful, as by it you will be able to turn metal.—X. P.

[46926.]—**Regilding Candlesticks.**—How can anyone answer this question, without knowing the material of which the candlesticks are made? By the fact that leaf is mentioned, they may be wood; but the querist seems to be further in doubt whether he wants gold or bronze.—DUBEX.

[47000.]—**Model Steamboat.**—The dimensions given by "Amateur" for the engine and propeller would do very well for his boat, but it is hardly long enough for a boiler 6in. long; and instead of a round boiler I should recommend one made to fit the shape of boat, and about 5in. long; and if the top of firebox is corrugated, you would get as much heating surface as a plain boiler 6in. long would give. The propeller should have only two blades, with a fine pitch. The lamp should be made as shown in sketch, the object being to keep the supply of spirits away from the boiler, and well above the bottom of tubes and burners, which should be filled with wick as shown in sketch, to act as a siphon, and so keep the burners regularly supplied with spirits. You should have two of these tubes, with two burners on each, about ⅜in. diam. The exhaust steam should be turned up chimney. The whole of the metal-work should be as light as possible consistent with safety, as the boat is rather small for a steamer. If you can refer to back numbers, you will find plenty of information on the construction of boilers for model steamboats.—E. L. P.





[47004.]—**Bread.**—In the issue of 9th June, your correspondent has quite overlooked the drift of "A Disgusted Foreigner's" query. No one can doubt that the bread on the Continent is infinitely superior to that made in this country; we have only to consult our travelling friends on that head. What he wishes to know is, as I take it, what do the Austrians (who have the name of being the best bakers in the world) and other foreigners use in the making of their bread that Britishers do not? Of course, we do not call "Yankees" foreigners: they have more or less the habits of Britishers, and further, what judges could there be where there are few professional bakers, where in most places they bake for themselves, not being able to purchase the commodity from bakers, and scarcely any of them used to good bread—certainly not such palatable bread as the Europeans make. The question is not so much what makes the English bread bad, as what makes the Continental bread so good, and this is a thing a good many of us would like to know.—SEMPER FIDELIS.

[47016.]—**Repairing Ebonite Dish.**—Ebonite dishes when broken are very awkward things to repair. The only safe method of mending is to make a small metal frame to fit over the broken corner, and then to cement this frame tightly to the corner; the dish may then last a long time, but all attempts to rejoin the broken corner will fail, unless there is a strong support underneath to keep the corner rigid.—W. J. LANCASTER.

[47029.]—**Difficulty with Coil.**—To MR. LANCASTER.—In the first place, from your query I fear that the insulation of primary is bad, and that as the primary is, it is insufficient to induce the strength of current that the secondary ought to produce; and, secondly, the joinings of secondary are faults, each one taking away from length of spark. I would rather use only half the quantity without a join than all that you have with a number of joinings. You should also have had better insulation between primary and secondary; the thin layer of paraffin is insufficient. I would advise you to unwind part of the secondary, then test with battery until you get the ½in. spark again; then put plenty of paraffin around coil, and bake it for a night, clean off the outside, and having carefully gone over every joint, resoldering where necessary, rewind the wire, gradually thickening it to the centre of coil, leaving the ends bare, something of this shape ⬭; then test after every two layers, and if spark increases in length go on winding; but the moment the spark seems to be going back, stop winding; put in paraffin and bake again. I think you will then have a good coil.—W. J. LANCASTER.

[47043.]—**Camera.**—You will have to give more information about your lens before anyone can assist you. Say in another query how many lenses there are in it, and the diameter of the lenses. I am afraid you have a centre lens only, belonging to a "Jamin"; if you have, it is of no earthly use without the other part.—W. J. LANCASTER.

[47053.]—**A Question for Spectrum Analysis.**—This is not a question for spectrum analysis at all. It has only to do with the reflection of light by the roughened surface of the glass; this scattered reflection does of course prevent direct sunshine entering the conservatory; but the light that does enter differs only in quantity from what would enter if the glazing were of clear glass. Why don't you have half a dozen of the panes removed, and clear glass put in just where the sun would shine through? Even then I am afraid the plants would not thrive, and that the question would still be an open one as to the cause.—W. J. LANCASTER.

[47054.]—**Incandescent Lamps.**—Don't attempt to light one of the lamps with Leclanché cells; it will only end in failure. You may get a light for a few seconds, and then it will be all over. Rig up a few Bunsens, and the effect will be good.—W. J. LANCASTER.

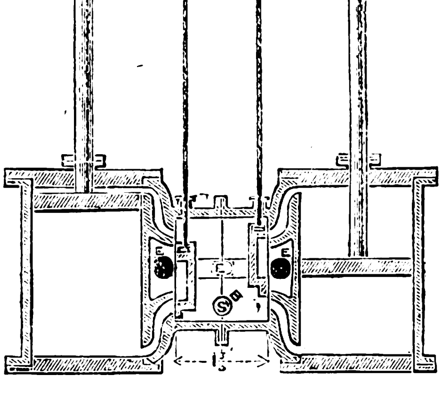
[47055.]—**Cardboard.**—The use of cardboard for shutters is a failure. Better get a piece of blackened block-tin; one sheet of tin will make a number of shutters. You might get a 14 by 10 ferrotype plate, and cut it up into 9½ plate shutters, or 4½ plate. This will cost you about 5d., and is already blackened. By the bye, you can make a nice dark slide out of ferrotype plate. Make a block a little larger than plate, then bend over it the ferrotype plate, and make a flange in front sufficient to allow the shutter to slide down; then remove the block, bend over the top piece, and let this go lower down than the other parts to allow shutter to slide over. Now cut out a thin wooden frame just large enough for plate to drop in, and to fit tightly into dark slide, join up the corners clean, and solder; put two little turn buttons on to carrier to keep plate in place, and the slide will be made, and will work very well.—W. J. LANCASTER.

[47056.]—**Bacteria.**—I am very thankful to Mr. Thoms for his kind reply to my query; but he has, unfortunately, mistaken the purpose of the barm in question, which being "intended for distilling—alcoholic fermentation," and my object with it, to obtain as thorough and low an attenuation as possible, the remedy so kindly suggested is hardly applicable, as I work on the thick-mash system, and nothing is strained, all "grains" passing through the fermenting-tuns and stills. With your kind indulgence I will explain further, hoping that Mr. Thoms will again reply. The barm is made from 50 per cent. each of rye, barley, and malt meal, mashed with water at 185° Fahr., or so, in order to give it the proper consistency and saccharine concentration, when mashed to 150° temp.; it is then covered for two hours, when covers are removed, and it remains open for ten hours more before being roused, which rousing is continued every two hours, till a proper acidity (as indicated by Ludersdorf's oxymeter with ammonia) is observed. This takes about 24 hours, the temperature of the barm mash being then about 124° Fahr., and the acidity from 1¾ to 2¼. It is then cooled as rapidly as possible to 65° Fahr., mother added, and after a good rousing, again covered. After nine hours the mass is generally found to be nearly half-attenuated, and to be of a temp. of 83° Fahr.; the mother is then taken off and rapidly cooled, while the mass remains another hour or two, and is then put into the fermenting-tun with the mash to be fermented. The quantity of barm is 7 per cent. to 8 per cent. weight (of meal) of the mash fermented, and attenuation ought to arrive at 1002 (Bate S. G.), temp. 60° Fahr. (this being a filtered sample from mass), in 48 hours: pitching temp., 66° Fahr. My remarks on barm not always rising to the surface will now be, perhaps, better understood. Such skimmings never show any other than pure torulæ germs. Sometimes a lactic rod will appear; but very rarely, although fermenting barm abounds with them. This system of making yeast is general all over the Continent. I do not think now that Mr. Thoms will recommend the use of sedimentary yeast, and am sorry that the misunderstanding as to the rising of the barm arose. Will Mr. Thoms please tell me the way to prepare the ash of carbonised raisins or grapes, and give me also his opinion on the use of ammonia for invigorating the growth of our torulæ?—CYGNET.

[47065.]—**Gaiffe's Medical Battery.**—The coil in Gaiffe's is a little induction coil without a condenser. You can make one easily with primary and secondary circuits. I make a little coil that you can almost put into your waistcoat pocket, that would give you more current than you would care to receive.—W. J. LANCASTER.

[47069.]—**Fruit-growing.**—The "Fruit Manual," by Dr. Hogg, published at 171, Fleet-street, and Scott's "Orchardist," are two most useful works on fruit-trees. The latter was published by H. M. Pollett, 10, Bridgewater-gardens, E.C.; but don't rely too much on manuals in planting. See what kinds suit your own neighbourhood best, or you may be led into error. Dr. Hogg is a well-known authority on fruit-trees, and Mr. Scott is, or was, a practical orchardist at Merriott, Somerset.—BETA.

[47093.]—**Double Steam-Chest.**—Hoping that I understand your case correctly, I should like to suggest the plan shown in the sketch, where the valves used in the old arrangement work in one steam-chest. This valve-chest could be made by bolting each of the original valve-chest flanges to one of the flanges of the middle part of the casing of such a width as to keep the faces 1⅜in. apart. You require then only one steam-pipe, which may be bolted to a branch on the middle part of the casing. The exhausts must be joined by a short double-elbow pipe, with a branch for the exhaust-pipe (B in the sketch). If the discs of your eccentrics are split, it is easy to change their positions from outside to inside; if not, as is often the case in models, I can see no other way but to make new eccentrics with such discs.—R. KANTHACK.



[47093.]—**Double Steam-Chest.**—I should say that "J.M.L." could easily arrange his valves, &c., as he requires. If he will say what the length and breadth of his exhaust port is, and the length of shaft available to put his eccentrics on, I shall be glad to give him a sketch for the same.—G. I. C. E.

[47094.] — **Combustion of Coal.** — If freely supplied with air, the products of combustion will be carbonic anhydride CO_2 and water H_2O. In 100cwt. of coal, we have per question 88·42cwt. of carbon, 5·6cwt. of hydrogen, and 5·97 cwt. of oxygen. Since in water H_2O the proportion by weight of H to O is 1 : 8, the atomic weight of oxygen being 16, the quantity by weight of O necessary to convert 5·61cwt. of hydrogen into water is 5·61 × 8 = 44·88. Similarly since in carbonic anhydride CO^2 the proportion by weight of C to O is 3 : 8, the atomic weight of C being 12, the quantity by weight of O necessary to convert 88·42cwt. of carbon into CO_2 is 8-3rds of 88·44 = 235·792. Therefore, the total weight of oxygen required to burn the H and C is 44·88 + 235·79 = 280·67cwt. But of this amount 5·97cwt. are supplied by the coal; therefore, weight of oxygen required from the air is 280·67 − 5·97 = 274·7cwt. Now, oxygen by weight in the air is 23·16 per cent.; therefore, weight of air necessary to supply 274·7cwt. of oxygen is 1 / 2316 of 2,747,000 = 1,186cwt. approximately. Therefore, weight of air necessary to burn 20cwt. of coal, and 1-5th of this is 293cwt.—Mide.

[47094.]—**Combustion of Coal.**—In 20cwt. of coal we have—

$$\text{C} \ldots \frac{20 \times 88{\cdot}42}{100} = 17{\cdot}684\text{cwt.}$$

$$\text{H} \ldots \frac{20 \times 5{\cdot}61}{100} = 1{\cdot}122\text{cwt.}$$

$$\text{O} \ldots \frac{20 \times 5{\cdot}97}{100} = 1{\cdot}194\text{cwt.}$$

$$\overline{\quad 20\text{cwt.} \quad}$$

The combining weights of C, H, and O being 12, 1, and 16, we require

$$\frac{32 \times 17{\cdot}684}{12} = 47{\cdot}157\text{cwt. of O to form } CO_2$$

$$\text{and } \frac{16 \times 1{\cdot}122}{2} = 8{\cdot}976\text{cwt. of O to form } H_2O$$

Thus, total weight of O required for complete combustion = 56·133. 1·194cwt. being in the coal, 54·939 have to be taken from the air, which contains 23·14 per cent. of O. The weight of air required is then $\frac{54{\cdot}939 \times 100}{23{\cdot}14} = 237{\cdot}4$cwt. of air, or 2,942 cubic feet of air. (In practice, much more air is supplied to furnaces.)—R. Kanthack.

[47094.]—**Combustion of Coal.**—The combining weight of carbon is 12, and that of oxygen 16; therefore 12 parts of C will require 2 × 16 = 32 parts of O. The atmosphere contains about 23 of O in every 100 parts by weight. We must now find by proportion what weight of air contains 32 parts of O. Thus:—32 × 100 / 23 = 139·131. To find the weight of air required for the combustion of a body containing

Carbon........................	88·42	parts
Hydrogen	5·61	,,
Oxygen	5·97	,,
Total	100·0	,,

We must first find the weight of O. required for 88·42 parts of C. This we do by proportion. If 12 requires 32, how much will 88·42 require? The hydrogen would burn to form water (H_2O). The combining weight of H is 1; therefore 2 parts of H will require 16 of O, in the same way as for the C. We must now find how much O is required for the 5·61 parts of H. We now know how much O is required for the combustion of the C and H, and must now subtract the 5·61 parts of O in the body from it, so as to obtain the amount of O. required for the combustion of the whole body. We must now find, as in the first part, how much air contains the quantity of oxygen calculated. To find the weight of air required to burn 20cwt.: we know how much is required to burn 100 parts; how much will be required to burn 20 parts, supposing the whole amounts to be in cwts? Proportion again.—Burette.

[47098.]—**Engine Queries.**—I will answer query 2 first. Let D A, D B, Fig. 1, be the position of the crank at the beginning and end of stroke. A B represents length of stroke of piston; A D = half-stroke of piston, and any portion of A B represents distance travelled by piston. Produce A B indefinitely, and take A C = length of connecting-rod between centres. About A B, as diameter, describe a circle A E B F. Let *h* = position of stroke at which it is desired to find angle of crank. Then lay off *n*C′ = A C, and with centre C′ and distance C′*h* describe arc of circle G*n*H join G D. Let arrow indicate direction of rotation, then G D A = angle of crank at given position of piston. With regard to query 1, the solution is entirely relative. If "Phenix" requires a solution of a particular case, I shall be happy to offer him one if he will furnish particulars; but if he requires a general one, I would refer him to Dr. Zeuner's method as found in Rankine's "Useful Rules and Tables." Query 3: Let A B C D, Fig. 2, represent tank with inclined base. Through centre of C D draw F E G; *h*′E = mean pressure, *h*D = greatest pressure, and *h*″C = least pressure; total pressure on base = area of C D × *h*′E.—Ligurian.

FIG. 1.

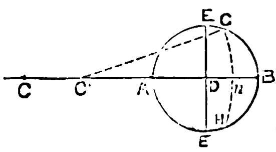


FIG. 2.

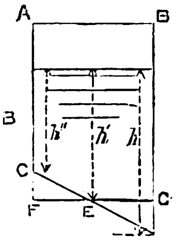

[47098.]—**Engine Queries.**—1. The angular advance can be found graphically, and by the formula sin. (angular distance) = lead + lap / throw of eccentric. In Fig. 1. C D represents the travel of the valve, and C E D F the eccentric circle. Bisect C D at O, and draw E F perpendicular to it. On O D from O mark off lead + lap on the same scale as C D. If O B represents this distance, draw A B perpendicular to C D, join A O, and A O E is the angular advance, its sine being equal to O B / A O = lead + lap / ½ travel. 2. In Fig. 2 let A B C D represent the cylinder, E F the piston in a given position, K P or R the connecting-rod, O P the crank, and O the centre of crank-shaft. Also call the stroke S the remaining part of the stroke at a given position S′. Then, if G H are the positions of K at beginning and end of stroke, K H = S′, H L R, and because O L = O P = 3 / 2. H O = R − S / 2; therefore, K O = K H + H O = S′ + R − S / 2. O P = S / 2 and K P = R. We can now easily find sin. θ (= sin. P O K) by the formula: $\text{Sin. } A/2 = \sqrt{\frac{(s-b)\,(s-c)}{bc}}$ where

$$A = POK,\ S = \frac{R + S/2 + S' + R - S/2}{2}$$

= R + S′ / 2, *b* = S / 2, *c* = S′ + R − S / 2. (3) In Fig. 3 let H be the head of water at B C in feet, H′ that at A D. Then the average head H + H′ / 2 × ·434 × the surface of incline base in square inches gives you the total pressure.—R. Kanthack.

FIG. 1.

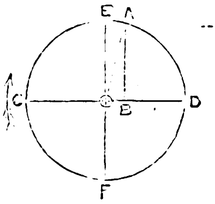

FIG. 3

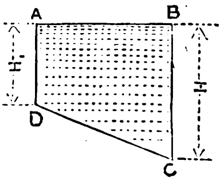

FIG. 2.

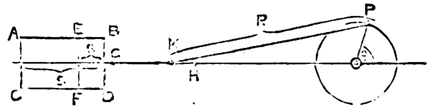
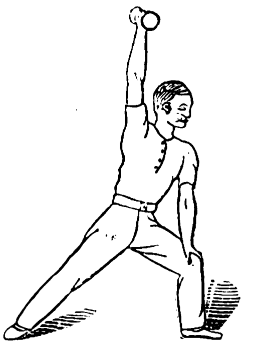


[47101.]—**Polypus.**—Not long ago, I read in a medical paper of a very simple and efficacious way of getting rid of nasal polypus. Dr. Cesarini injects with a fine squirt (as used for subcutaneous injection of morphia) 4 or 5 drops of chemically pure acetic acid in the polypus, which, four to five days after, withers away. A serious operation is very seldom required. This operation is painless. Should, after the lapse of many years, the polypus reappear, perform the same operation.—C. W.

[47103.]—**Explosions in Collieries.**—You would be unable to do any good by introducing nitrogen into the pit. The nitrogen would, if in sufficient quantities to dilute the explosive gases, merely add another terror to the miners, producing death from oxygen starvation. Better have the explosion and an instant death than be gradually starved to death through want of oxygen. The death of a miner from an explosion is in all probability a very rapid one, except, of course, when imprisoned by falling rock, and how much worse was the death of the 123 who perished in the black hole of Calcutta. It seems to me that the risk will remain as long as coal-mining exists. It may be that by more perfect ventilation and the use of fans a better circulation of air may be obtained; then the risk would be lessened, but this will take time. There are precautions, of course, taken now, and the inspectors, I believe, are very useful men. The training of mining engineers is now very different to what it was 20 years ago, and it will still improve.—W. J. Lancaster.

[47106.]—**Dry-Plate Photography.**—A simple lens may mean anything, just as a single lens is used to denote either really a single lens or an achromatic lens. However, use an achromatic lens, you can have them now cheap enough. Don't try to work with bad tools, get good ones, and do good work. Many a man has been ruined as a workman by having only bad tools to work with, and in photography, a bad lens will only be a source of annoyance and disgust. It may be that the amateur possessed the germs of success, to be annihilated by a bad lens. Emulsify means to make into an emulsion. Soaking a gelatine film in a saturated solution of alum will harden it.—W. J. Lancaster.

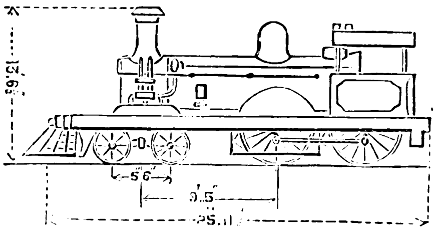
[47109.]—**Gymnastics.**—The following exercise would, I think, be beneficial:—Take up your position with the feet together and at right angles, the left foot pointing to the front; step to the front with the left foot, keeping the right foot firm, and the feet still at right angles. The step should be about a yard. Keep the rear leg quite straight and the front one bent; with the left-hand grasp the thigh, just above the knee, and with the right-hand seize one of the bells (which should be just in front of you), and raise it above the shoulder, bending the arm during the ascent, and raising it to the full extension, leaning, meanwhile, with the left arm on the left knee; put down the bell and raise it again six times as before, then step back and step forward with right foot, and repeat the exercise with the left arm. After this, go through the same exercise, only raising both the bells, first with left foot forward and then the right. I think it would be best to use both arms, only I should use a heavier bell with the left arm—say 16lb. and 10lb. with the right, although after practice these weights might be considerably increased. This would tend to equalise the two shoulders. The position is very important, and should be carefully studied. I shall be pleased to give further particulars, if not clear. I send figure of the position with the bell raised. If possible, "D. D. M. L." should consult Maclaren's "Physical Education."—Hemisus.



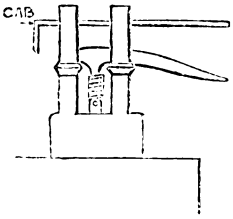
[47111.]—**To Mr. Lancaster.**—I do not know of any source from which you will gain more information about small dynamos and storage cells than in the pages of "ours." Certainly there is "electric light," electricians, "telegraphic mem's," &c., which contain accounts of large machines. Now to tell you the truth—and I would not mislead a single reader of "ours"—small dynamos are a "failure," and it will be some time before anything really good will be made. The storage cells are almost equally bad. I cannot get 60 per cent. out of them of the current used up in charging them. There is a lot of bosh written about them by men who ought to know better.—W. J. Lancaster.

[47121.]—**Indian Locos.** — In answer to "Russell," I send the following particulars of some locos. for Bombay, Baroda, and Central India Railway, which came out in March and February, 1882. They were built partly by the Vulcan Engine Company, Newton-le-Willows, and partly by Messrs. Stephenson and Co., Newcastle. The loco in question is an eight-wheeled one, having four coupled wheels and a bogie. The principal dimensions are:—Gauge of road, 5ft. 6in.; cylinders, 17in. by 24in.; driving-wheel diam., 6ft. 1in.; bogie, 3ft. 7in.; wheel-base of bogie, 5ft. 6in.; centre bogie to centre drivers, 9ft. 5in.; wheel-base of coupled, 8ft.; from leading buffer-beam to trailing buffer-beam, 25ft. 11½in.; wheel-base, total, 20ft. 2in.; h. s. of tubes, 1,019 sq. ft.; h. s. of firebox, 90 sq. ft.; grate area, 16½ sq. ft. Boiler:

length, 10ft.; diam. outside, 4ft. 7½in.; thickness of plates, ½in.; thickness of tube-plates, ¾in.; pitch of rivets, 1⅞in.; diameter of rivets, 13-16in. Firebox casing is flush with boiler. Length of firebox 4ft. 10½in.; breadth at bottom, 4ft. 7½in.; thickness of plates, ½in. Smokebox: length outside, 2ft. 8⅜in.; breadth, 5ft. 2⅜in.; diameter of doorway, 4ft. 1in.; thickness of plates ⅜in.; diameter of rivets, ⅞in.; pitch of rivets, 2½in.



Chimneys of BB Staffordshire iron with polished copper cap. Length, 4ft. 1in.; diameter inside at top, 1ft. 3⅜in.; diameter inside at botton, 1ft. 5⅞in.; plates, 3-16in. and 1-14in. Ash-pan door made to work from foot-plate independently. Thickness of plates, 5-6in.; depth of ash-pan, 1ft.; width of ditto, 4ft. ½in. Number of tubes, 189; length, 10ft. 5¾in.; diam. outside, 2in.; at smoke-box a length of 4in. is 2⅛in. diam.; thickness 13 W.G. at smokebox, 10 W.G. at firebox; safety valves, Ramsbottom, blow off at



140lb.; blast-pipe cast iron; diam. nozzle, 4¾in.; height, 3ft. 6in.; distance from centre to centre of cyl., 2ft. 8in.; distance from valve spindle centres. 5¼in. The valve motion is of Allen's straight-link type, axles of Yorkshire iron. Driving and trailing, diam. at centre, 7in. and 6in.; diameter at wheel, 8½in.; diam. at bearing, 7in.; buffers, Turlon's patent; buffer beam teak. Injectors are by Messrs. Sharp, Stewart, and Co., Atlas, Class F, No. 9, two to each engine. Smith's vacuum ejector and brake are fitted to work from left side.—E. W.

[47130.]—**Decorating Organ-Pipes.**—"J. E. B." does not say whether his pipes are wood or metal. I may inform him that I have made the bottom octave of a principal of zinc, scraped them bright, and, after burnishing, gave them a coat of pale varnish, and they look well and keep their polish excellently.—STATIONMASTER.

[47132.]—**Hæmorrhoids.**—If "Grateful" will follow the following prescription of Dr. Gullon, jun., I think he will very soon get relieved. Make some camomile tea, pour out a saucerful, add thereto 10 drops of "aqua plumbi," dip in a pad, and place this on the piles; as soon as it gets dry wet it again. In a few days the piles shrivel together. Inwardly you take homœopathic nux vomica as long as you feel the piles, and continue with the pads. Take the sixth dilution, three doses a-day—*i.e.*, morning, mid-day, and evening, half an hour before eating. The dose is one drop to a tablespoon.—C. W.

[47143.]—**Aluminium.**—This is rather a cool request. The querist has discovered a method of obtaining aluminium easily (which means a moderate fortune) except one step, and he placidly asks the readers of the ENGLISH MECHANIC to give him the information required to complete his process, without the slightest hint of payment. The analytical separation of Al and Zn is easy enough; but that is not what is needed: and the separation of metallic aluminium from its alloy with zinc is a much more troublesome problem.—WM. JOHN GREY, Elswick Science School.

[47146.]—**Tin Plates.**—The following is the mode generally employed to render the plates chemically clean. They are first immersed for four or five minutes in dilute sulphuric acid, then they are raised to a red heat in a reverberatory furnace, and when cool hammered flat. To remove scales of oxide they are then passed through rollers, after which they are kept for about two hours in a mixture of bran-and-water which has become sour from exposure, thence they are transferred to a vessel containing a mixture of dilute sulphuric and hydrochloric acids. Lastly, they are scoured with bran, and may then be kept for any length of time in pure limewater. In some works after being scoured they are further cleaned with hydrochloric acid holding zinc in solution. After being so prepared the plates are plunged, one at a time, into a vessel of melted tallow, and after being kept in this for an hour they are immersed in the bath of melted tin, over which is a stratum of grease 3in. or 4in. thick. Here they are kept for about an hour and are then allowed to drain. After this they are again plunged into a second bath of pure tin, and excess of tin removed by heating in a bath of tallow; the tin melts and collects at edge of the plate; when cool this margin is finally reduced by dipping the edge of the plate into tin kept at a high temperature; the superfluous metal is quickly fused and then detached by a sharp blow.—MIDE.

[47151.—**Washing-Machine.**—The way that I would do this would be to bore an auger-hole, the size of the square of the iron, right through the roller, drive the axle through, also drive a ring of, say, 4in. diameter by ⅛in. thick, and about 1in. deep, with one edge hammered sharp into each end of the wood; and finally drive four iron wedges between this hoop and the axle at each end, and you will have a firm fixture.—J. J. A., Liverpool.

[47152.]—**Field - Glass.**—If "Spot-lens" is quite sure that the spots are in the cement, let him take one o.g. apart first by warming it over a hot plate, and then boiling the separated lenses in turpentine or spirits of wine. When quite clean and dry, put the concave lens on the plate; when warm drop a little Canada balsam into the centre of lens, and carefully slide the convex lens into its place, taking care that the same surfaces touch as before separation. Allow the o.g. to bake until the superfluous balsam (when cold) is slightly brittle. Clean the edges with turps and replace in cell. It would be wise to mark the edges of o.g. with a lead pencil before separating, to keep true.—GOBO.

[47153.]—**Weston Dynamo-Machine.**—Not much Weston. Is it Siemens'? He patented winding the wire in slots on a cylinder. You cannot get 70 yards on each coil. Better do without the slots. Make 8, 12, or 16 coils of 14 wire; circuit machine; splendid arc: several incandescent lamps. Sorry I cannot give the current in Webers.—GEORGE TOLMAN.

[47155.]—**Boehm System.**—In reply to "Bassoon," the Boehm system aims at placing all holes in wind instruments as near their correct distance from mouthpiece as possible, and having them proportional to the size of bore, and in geometrical ratio as to distance from each other. But, as this subject is a special one, and not of much general interest, if the querist advertises his address, I will give him every information, or tell him where to get it.—VULCANITE.

[47157.]—**Heat.**—The rate of cooling is expressed by Dulong's and Petit's formula: $ca^r(a^\theta - 1)$ or $c(a^{r+\theta} - a^r)$, where r represents the temperature of the surrounding air, $r + \theta$ the temperature of the thermometer—*i.e.*, of the radiating body. If r and θ are expressed in Centigrade units, $a = 1{\cdot}0077$; if in Fahrenheit units, $a = 1{\cdot}0043$. This formula applies to all cases where the temperature of the hot body is less than 320° C., the difference of temperature of hot body and inclosure being less than 240° C. c is a constant with which $a^r(a^\theta - 1)$ has to be multiplied to find the absolute loss of heat per hour per sq. ft. of different surfaces, its value depending upon the nature of the surfaces. Values of c:—For polished silver, 2·7; polished copper, 3·31; polished brass, 4·55; rough cast iron, 67·21; lampblack, 85·79.—R. KANTHACK.

[47158.]—**Homogeneous Immersion Objectives.**—In all work where difficult resolutions under high powers are needed, the homogeneous objectives are immensely better than water-front lenses. Get catalogues from Zeiss, of Jena, or Powell and Lealand, of London.—JAMES EDMUNDS.

[47158.]—**Oil-Immersion Objectives.**—For all ordinary examination of diatoms, a good one-eighth or one-tenth water immersion o.g. will be found amply sufficient; and it is far less troublesome than one requiring oil or glycerine. But if you are bitten (like myself I confess) with Amphipleura pellucida, or desire to distinguish, if possible, between Frustulia saxonica and Navicula crassinervis, and to decide whether they are anything else than small examples of N. rhomboides, there is nothing for it but a high-class "homogeneous" objective.—ANTARES.

[47159.]—**Heating Greenhouse.**—I should recommend that, if the vent-pipe is not so large, it should be increased to 3 or 3½in. If this does not stop the down-draught, an Archimedean cowl should be put on of the same diameter as the pipe, or a little larger.—HEMISUS.

[47159.]—**Heating Greenhouse.**—I think the down-draught would be effectually cured by one of Boyle's caps, which act on the principle of the ejector. They are so made that if any wind is blowing it passes through the vanes or louvres in such a way as to pump up air from the chimney to which it is affixed.—NUN. DOR.

[47159.]—**Heating Greenhouse.**—It seems to me that the cause of this downward draught is, first, the coldness of the upper portion of the pipe gives a down-draught for some time after the gas is lit; and, secondly, the sudden gusts blow down the pipe in the usual manner. I should recommend "W. R. S." to cover his pipe with painted felt from above the point where the pipe gets very hot, to its top. This, when the pipe is once warm, will keep it so, and draw up the burnt gas-fumes; and I should then place an ordinary cowl on the top to foil the sudden gusts. I tried this method with a flue some years ago, and it was successful.—B. H.

[47160.]—**Recovery of Silver.**—"Porous Cell" had better ascertain, properly, how much silver there is in his lead before he asks about its recovery; the fact that the lead will do for use in a (Smee) battery does not prove much. Carbon can be used in a nitric-acid cell, instead of platinum; but it would be a foolish thing to conclude that, therefore, the carbon contains platinum.—WM. JOHN GREY, Elswick Science School.

[47161.]—**Sulphate of Alumina.**—The best method of obtaining the sulphate from bauxite is first to obtain from it the soluble trisodic aluminate. The ore mixed with soda-ash is heated to bright redness until no effervescence occurs on addition of an acid. On lixiviation the trisodic aluminate, $3Na_2O, Al_2O_3$ is dissolved and separated by filtration. Through this solution carbonic anhydride, CO_2, is passed, when sodic carbonate is produced, and alumina Al_2O_3 deposited, which is then dissolved in sulphuric acid, giving the sulphate.—MIDE.

[47161.]—**Sulphate of Alumina.**—The method of preparing this from the mineral bauxite, is as follows:—The bauxite is first broken up small in crushing machine; the powdered mineral is then mixed with carbonate of soda, which is obtained as a by-product, as shown further on, or else with a mixture of sulphate of soda and charcoal, and heated strongly in a furnace. The mass is afterwards lixiviated with water in tanks, when it yields a solution of aluminate of soda; carbonic acid gas is then passed into the solution, causing the alumina to be precipitated in the form of a hydrated gelatinous mass; carbonate of soda, being formed by the double decomposition, remaining in solution. The precipitated alumina is next washed and formed into the sulphate by adding it to dilute sulphuric acid, contained in lead-lined tanks, kept at about 90° Centigrade, until the acid will dissolve no more. This solution is then placed in copper boilers and boiled down to sufficient strength, and afterwards poured into moulds. The original solution from which the alumina was precipitated is also boiled down and the carbonate of soda allowed to crystallise out.—ARTHUR E. MORRIS.

[47161.]—**Sulphate of Alumina.**—There are several patented processes for making sulphate of alumina, the best of which is, I think, that described in Newlands's Specification, No. 5287, 1880. The following is a brief description:—Bauxite is first ground to a fine powder, and then dissolved in sulphuric acid, the operation being performed in a mixer, such as is used in the manufacture of superphosphate. The acid acts in a very energetic way on the mineral, and the mixture which is at first liquid, sets into a mass, which varies in hardness according to the strength of the acid employed. The crude cake thus produced is dissolved in water by means of steam, and the solution either allowed to settle, or filtered by means of a filter press, whilst hot. In the former case, the solution will have to be evaporated down to such an extent as to produce a magma, or mass of crystals; but in the latter case, the solution can be filtered sufficiently strong to produce a magma on cooling. The magma is pumped, or forced into a filter-press (lined with lead), and in a short time, cakes of sulphate of alumina are produced (yield No. 1) of very good quality. The mother liquor is evaporated, and another magma is produced, which on being pressed produces a second quality (yield No. 2), and in like manner a third quality can be obtained, or even a fourth, and the final residue, which is very small, and contains much iron, is evaporated to such an extent, as to set into a hard mass on cooling. This impure salt can be sold for sewerage purposes, or for the manufacture of brown paper. The quality of sulphate of alumina obtained in each operation of pressing, varies with the specific gravity of the magma. Following this will be found a statement of an experiment made with the process, but which gave by no means the best results obtained, and is only given on account of the process having been carried through to the end, all the yields being carefully weighed and analysed. The bauxite from which the sulphate of alumina was produced, contained rather more than 2½ per cent. of peroxide of iron. If the first and second yields are redissolved in a small quantity of water, and converted into a magma again, and the operation of pressing repeated, the amount of iron is reduced to about half the quantity originally present. By a slight drying in a stove, heated by steam pipes or a flue, the percentage of alumina in the cake can be increased and the product much improved in appearance. The bauxite, brand Irish Hill, best quality, contains 59·37 per cent. of alumina, and only 0·53 per cent. of peroxide of iron, according to the analysis of Mr. J. Pattinson, of samples dried at 212° Fahr. I can supply bauxite in any quantity and of four qualities.—G. G. BLACKWELL, Liverpool.

[47165.]—**Casehardening.**—I beg to inform "Cycle" that prussiate of potash will not penetrate, probably, the sixty-fourth part of an inch, and he will do well to make his bearings of "double shear steel" of best quality, which is what I would use for the hardened cones of a lathe also, and then, with care and a little soap in the water, he need not fear that they will crack.—J. J. A., Liverpool.

[47167.]—**Floor.**—I think that the floor proposed by "W. L. P. P." would spring far too much, with even ordinary weights, to be satisfactory, and would soon get unsafe. It might be done with H-rolled girders about 7ft. apart and 4½ deep, and 3in. deal floor laid straight across (not at an angle). The floor would be further strengthened if, instead of dowels, a ½in. iron rod were passed through the centre of the boards midway between the girders and tightened up at each end.—HEMISUS.

[47167.]—**Floors.**—From this query I gather "W. L. P. P." requires a floor for a shop, to cover a space 14ft. by 14ft., and not be more than 3in. thick. This is impossible with any arrangement of iron joists. The only method would be to make a similar floor to that referred to in Tredgold's Carpentry, as described by Rondelet in "L'Art de Batir," as being at Amsterdam in a room 60ft. square. In this, the wall-plates are very strong round all sides of the room, firmly secured at the angles by iron straps, and rebated to receive the floor, which is formed of three thicknesses of 1½ boards; the first thickness is laid diagonally, the ends resting in the rebates of wall-plates; the second is also laid diagonally in the reverse direction to the first; both are well-nailed together. The third thickness is laid parallel to the walls, and well-nailed to the floor below—all the boards are grooved and tongued together, and the whole forms a solid floor 4½in. in thickness without joists. In "W. L. P. P.'s" case the boards would probably be sufficient if 3½in. total thickness. But is it not possible to alter level of shop floor, so as to allow of joists in the ordinary way?—DITTON.

[47168.]—**Tinning Copper Sheets.**—The surface of the copper is rendered clean by rubbing it while heated with sal-ammoniac; when quite bright the copper is sprinkled with a little rosin to prevent oxidation, and melted tin is then poured on and spread over the surface with tow by the workman, who keeps the article constantly at a high temperature; the superfluous tin is wiped off with the tow.—MIDE.

[47169.]—**Throttle-Valve.**—I strongly disadvise you to use a stop-cock instead of a throttle-valve, the former giving rise to very much friction, however well made, and requiring twice the travel that a throttle-valve of equal diameter would to produce equal differences in the steam-supply.—R. KANTHACK.

[47169.]—**Throttle-Valve.**—You will not find this work well. In the first place, the aperture is too small unless the engine is very diminutive; then the friction will be very great upon a tap with brass working upon brass. This could be partly reduced, as I have tried formerly, by making the plug of iron; but, after all, it is much inferior to a properly-constructed throttle-valve.—J. J. A., Liverpool.

[47171.]—**Action in Voltaic Cell.**—Action in Bunsen cell: $Zn + H_2SO_4 + 2HNO_3 = ZnSO_4 + 2H_2O + 2NO_2$, or perhaps $3Zn + 3H_2SO_4 + 2HNO_3 = 3ZnSO_4 + 4H_2O + 2NO$; this NO, however, seizes one atom of O from the atmosphere to form NO_2. The second part of your query I cannot answer with certainty; I however, found for my own purposes the following equations:—$K_2Cr_2O_7 + H_2SO_4 = K_2SO_4 + 2CrO_3 + H_2O$, $2CrO_3 + 3Zn + 6H_2SO_4 = 3ZnSO_4 + Cr_23SO_4 + 6H_2O$.—R. KANTHACK.

[47171.]—**Action in Voltaic Cell.**—In either case the action of the zinc on the dilute sulphuric acid is—

$$Zn + H_2SO_4 = ZnSO_4 + 2H.$$

In Bunsen's battery this hydrogen decomposes nitric acid, reforming nitric acid, and liberating hydrogen on the surface of the carbon-plate, when it is oxidised by the nitric acid as follows:—

$$2HNO_3 + 2H = 2NO_2 + 2H_2O$$
$$\text{or, } 2HNO_3 + 4H = N_2O_3 + 4H_2O$$

In the bichromate cell, the hydrogen reduces the bichromate in presence of sulphuric acid, forming potassium sulphate, and chromium sulphate as follows:—

$$K_2Cr_2O_7 + 4H_2SO_4 + 6H = K_2SO_4 + Cr_2 3SO_4 + 7H_2O.$$

—X. N. X.

[47171.]—**Action in Voltaic Cell.**—I presume Mr. Salt understands the theory of the transference of elements or radicals under the influence of a current, and merely requires the chemical action involved. In the Bunsen or Grove the hydrogen passes through the porous pot, and it is a moot question as to whether it there attacks the acid, or whether it is passed on to the negative plate. Reasoning by analogy from the Daniell cell, it should go to the plate; but the Leclanché battery rather points to the reaction occurring at the porous pot—a view which is held by Professor Guthrie ("Electricity," p. 142). It is not exactly known as to whether the acid is reduced to NO thus:—$3H_2 + 2HNO_3 = 2NO + 4H_2O$, or to NO_2 thus: $H_2 + 2HNO_3 = 2NO_2 + 2H_2O$. Personally, I incline to the latter view, because the acid in the battery turns green from absorbing the NO_2. It is quite possible that both reactions go on, and that N_2O_3 may be formed also. In the bichromate battery the chemical change consists in the reduction of the potassic dichromate to chrome alum, and the following equation fairly expresses the action:—$K_2Cr_2O_7 + 4H_2SO_4 + 3H_2 = Cr_2K_2\ (SO_4)_4 + 7H_2O$, the change being rendered evident by the solution turning from orange yellow to that undescribable colour which is so characteristic of chromium acting as a base.—WM. JOHN GREY, Elswick Science School.

[47173.]—**M. R. Engines:**—

Eng.	Class.	Cylndrs.	Wheels.	Date. Orig.	Date. Reblt.
2	Passenger	17 × 24	6ft. 8in.	1873	1878
3	,,	17 × 24	6ft. 8in.	1871	—

192	,,	16½ × 22	6ft. 2in.	1867	—
330	Goods	17 × 24	5ft. 2in.	1853	1880
382A	,,	16 × 24	5ft. 2in.	?	1872?

Nos. 2, 7, and 41 are of the same class. They belong to a set of 23 engines built at Derby, with inside frames to the driving and trailing-wheels, and outside to the leading-wheels. Nos. 3 and 23, 110A, 192, and 29 have outside frames to all wheels. No. 193 (172—199) was built by Beyer, Peacock, and Co. The asterisk opposite the date of No. 29 means that in 1879 a boiler taken from some other engine (I believe one of the 800 class) replaced the old one. I do not know anything of engines 151—155, 160—164. Can any reader oblige with a few particulars and dates? Also of 77—89 class.—METEOR.

[47175.]—**Varnish.**—Dissolve shellac in methylated spirits. This makes a good negative varnish.—HIGHLANDER.

[47175.]—**Varnish.**—The following is by Valentine Blanchard, in the "Yearbook of Photography," for 1881. Take half a pint (or less, according to taste), of deep red shellac varnish, to be obtained of most oil and colourmen, and one pint and a half of methylated spirits; shake well together, and let it rest for a day or two before use. Mr. Blanchard says two pints cost less than 2s. 6d.—DITTON.

[47176.]—**Broken Tracing-Pen.**—Drill a hole through the bone, stick the tang of a small rat-tail file into it and heat over a gas, then screw it out.—J. J. A., Liverpool.

[47178.]—**Dynamo.**—The disc is of iron. Is in reality a ring edgeways; is magnetised as a ring. Have sent particulars of small dynamo.—GEORGE TOLMAN.

[47179.]—**Magnets.**—Strength of a current = E.M.F. / R + r, r being the external and R the internal resistance.—R. KANTHACK.

[47179.]—**Magnets.**—The strength of an electro-magnet is proportional to the quantity of electricity circulating round it—that is, until the core approaches saturation. The lifting power depends on the "strength" above named, the form of the magnet and its poles, and the quantity of wire, or number of turns.—NUN. DOR.

[47184.]—**Special Express Train on Midland Railway.**—The special express train which conveyed T.R.H. the Prince and Princess of Wales from St. Pancras to Leicester and back, on Whit-Monday, May 29th, upon the occasion of the opening of the Abbey Park at Leicester, consisted of engine and tender, No. 1483 (driver, H. Leadbeatter, of Kentish-town), leading van, directors' "bogie" saloon carriage, T.R.H. bogie saloon-carriage, first-class carriage, rear van. The load was, therefore, equal to seven ordinary vehicles, and it will be seen from the following details of the running that, although the trains started considerably late, they arrived at their destination before time. This result was attained by running up the inclines at a high speed, which was possible in consequence of the load being light compared with the ordinary express trains—

		Due time a.m.	Actual time a.m.
St. Pancras	dep.	10.50	11.5
Bedford	arr.	11.54	12.0
	dep.	11.57	12.3
Leicester	arr.	1.0	12.59
Leicester	dep.	4.55	5.6
Bedford	arr.	5.58	6.4
	dep.	6. 1	6.7
St. Pancras	arr.	7. 5	7.2

Upon the 22nd inst. T.R.H. the Prince and Princess of Wales will travel by special express from St. Pancrass to Saltaire, via Kettering, Manton, Nottingham, Eckington, and Water-lane Junction (Leeds), upon which occasion the new Pullman dining-car will be used. The train will be drawn from St. Pancras to Nottingham by the same engine (No. 1483, driver Leadbeatter); the engine which is to convey it thence to Saltaire has not up to the present time been finally decided upon.—CLEMENT E. STRETTON, June 17.

[47187.]—**Bacteria.**—"R. V.'s" questions read easy and look very simple; but they are a long way from being easily answered with an approximation to truth. The lowest temperature that will coagulate the different albuminoids in malt, cereals, &c., depends upon whether the albuminoids are in a soluble state in fluid, and, along with the non-soluble fibrine, free from the tissues where they originate. The answer in this aspect is: The vegetable albumen proper, which is simply a part of the semi-fluid protoplasm of the tissue-cell, is already coagulated, and in part carmelised by the kiln-drying process, between 160°F.—170°F.; the diastase comes next, between 180°F.—190°F.; the fibrine cells at 190°F.—212°F.; and the casein, without hops, and as in milk, at 230°F., under pressure. We only assume, from the absence of the lactic organisms in British beers, that the casein of malt is coagulated by the tannin of the hops and prolonged boiling, aided, no doubt, by the chlorides and sulphates in the hard water. Inasmuch as the albuminoids of malt, as found in unboiled worts, are only in part free from the endosperm tissue-cells, the coagulating temperatures given will not hold good except for such albuminoids as are free. That is the other aspect of the question. And to coagulate the albuminoids in the seemingly small particles of endosperm seen floating in well-strained worts, said particles consisting of hundreds of cells which have been in part only influenced by the mashing process, require not only a boiling temperature, but prolonged boiling to cook and disintegrate. Whether the coagulated albumen, by prolonged boiling, is or is not again rendered soluble I could not say, but think it highly improbable, or, if so, that it would encourage the growth of bacteria, I see no reason to believe. These schizomycetes are not permanent types of life. They are simply free components of higher cells, not necessarily vegetable. In a thoroughly sterilised malt infusion they will never arise, and any added with the yeast or falling from the atmosphere (where they are of a spherical and non-motile form, except when the atmosphere is surcharged with moisture, when they become ovoid and may form spores), have a powerless existence, if there is a sufficiency of digestive elements in the wort, such as the chlorides and sulphates of lime and soda. Every moment of our life we all are fighting with them; they seethe and swarm in our lower stomachs in countless myriads, and that we are masters and enjoy existence is due to the sodium in the bile, in which they cannot exist; they are dissolved, and we feed and grow upon them, instead of them on us.—W. A. THOMS, F.R.M.S.

[47189.]—**Bridge Opening.**—Taking your sketch and numbers, No. 1 pinion has to revolve 5·181 times to turn wheel No. 2 through one revolution. Pinion 3 gearing into wheel No. 4 has to revolve three times to turn No. 4 once, consequently 5·181 × 3, or 15·543, equals number of revolutions of capstan head to turn No. 4 once. No. 4 being 3ft. 9-16in. in diam., gives a circumference of 10·405ft. This divided into 40ft. (length of rack), gives 3·844. Multiply this number by the number of revolutions of capstan to one of No. 4, and the product, 59·747, is the number of revolutions required to turn the bridge from end to end of rack. STANLEY HAWKINGS, S.E.R.

[47190.]—**Fernery.**—As the querist does not state what shape he wishes his fernery to be, I will offer him a few hints for making one of a rectangular form. We will suppose that the case is to be one yard long and about 30in. broad, and the height may also be about 30in. Five pieces of glass will be needed; three of this number must be 36in. long and 30in. broad; one of them will be for the top, and the others for the sides of the case; the remaining two will constitute the ends, and each ought to be 30in. square. "Sheet" glass should be used, and let it be as clear and as flat as can possibly be procured. After having ascertained that it is the exact measure, clean it well. Now make some very strong glue, and also obtain some wide tape; then lay the piece of glass intended for the top of the case upon the table, or any other convenient place. Covering the tape with hot glue, lay half its width on the edge of the glass. Having done this all round, raise the glass up, supporting it on a box or any other suitable article. The height raised should be about 30in. Now the remaining half of the tape should be glued; and bringing one of the glass sides to the edge of the top, press down the tape so that they are attached to each other. Now repeat this operation with the other side and the two ends. Half a day should elapse before touching the case again; this will give the glue time to harden. The next step, after the interval, is to turn the case upside down, then tightly press into the internal angles some narrow tape. A short time will be required to allow this to dry, after which tinfoil, a little wider than the tape, should be glued all round. It will be all the safer and better if the process is continued inside. If this is done, about four coats of oak varnish should be given it for protection from moisture. The tin-foil outside should have two or three coats of black Japan varnish. The next question is the bottom of the case. This is very easily made. A frame of wood of the required size, and about 1in. in thickness, will be needed. This should be made with a groove for the case to rest in. To this frame a bottom must be secured, the whole forming a kind of box. Into this should be placed a pan either made of earthenware or zinc, to hold the soil and plants. In the centre should be placed a pipe, to allow any waste water to escape into a pan placed beneath to receive it. You have now a simple, respectable, and inexpensive fernery. The cost will be about 10s.; and if the case receives proper and careful attention it will last a very long time. There are many more elaborate cases, and of different sizes and shapes; but the one described is, perhaps, the easiest to construct, and it certainly has one good quality—cheapness. With a little ingenuity and skill, various ideas and additions might be appropriately made. One thing I should like to impress—"all that is done should be thoroughly done, and no work which is at all incomplete should be passed over."—W. Henly Richmond.

[47195.]—**O.G. Making and Correcting.**—I have no doubt "J. C. L." might considerably improve some of the common object-glaeses if he knows what to do and how to do it. This is entirely a practical matter, altogether out of my line, and he must wait till "Prismatique" takes up the subject. It is this final work which makes a fine object-glass so costly, for the figuring by polishing is long and tedious, just as in parabolising a mirror. I believe the general form of the curves is somewhat as follows:—Crown: 1st surface, elliptic; 2nd, hyperbolic. Flint: One or both surfaces somewhat hyperbolic. This may to some extent indicate the character of the working required, to one who is master of the action of a machine, but it must be remembered that the exact curve cannot be defined by any regular form. There is also another serious matter, viz., the quality of the glass. A pair of 3in. discs of Chance's "best" would probably cost about 10s. each; these could not be put into an o.g. sold for about a couple of sovereigns.—Orderic Vital.

[17196.]—**Electricity v. Gas.**—The querist might as well ask if we could not differentiate a tom-cat by means of polarised light; and decompose the two together in a spectroscope.—Wm. John Grey, Elswick Science School.

[47203.]—**N.E. Engines.**—I send a few dimensions of the Darlington class of passenger engines on the N.E. Railway. Cylinders, 17in. by 26in.; diameter of driving and trailing-wheels (coupled) 7ft.; boiler, length, 11ft.; diameter, 4ft.; 158 tubes, 2in. diameter; total heating-surface, 1,100 sq. ft.; firebox length, 4ft. 5in.; width, 3ft 6in.; height, 5ft. 8in.; diameter of leading-wheels, 4ft.; working-pressure, 140lb. per sq. in.

	Tons.	Cwt.
Weight on leading-wheels......	11	0
,, driving-wheels	10	4
,, trailing-wheels	10	4
Total	31	8

The tender runs on six wheels, 4ft. diameter, and carries 2,400 gallons of water, and six tons of coal. Weight of tender, 21 tons; total length of engine and tender, 44ft. 5in. The dimensions are those of No. 1068, the engine at the Darlington jubilee. It was designed by Mr. Bouch in 1874. I do not know Nos. 1160 and 1161, but if they are "Quakers," I presume they belong to the standard class, of which 1068 is one. The engines built since 1879 have this difference from the old ones—that a pattern of ovals in the driving-wheel splashers has been substituted for the older pattern; 1162 belongs to the newer class. Is "Cleaner" sure of the number 1160? No. 1160 at Darlington (1875), was a bogie passenger engine built by Stephenson and Co., 1860. I have not a drawing of the "Quakers" to hand.—Meteor.

[47204.]—**L. and N.W.R.**—If "Cleaner" means that small regulator handle on the left of the "starting regulator," and similar in shape, but smaller, it is for putting the "steam brake" on the driving wheels. When opened it admits steam through a pipe near the safety-valve into a small cylinder under the "foot-plate," which actuates the brake.—G.

[47201.] — **Instantaneous Photography** — In order to answer this, it is necessary to know the sort of plate used by "Tyro." So-called instantaneous pictures can be obtained with any of the "rapid" dry plates, with a suitable development. Use a developer strong in all its constituents, and perfectly fresh.—Ditton.

[47206.]—**Dry Plate-Developer.**—Citric acid is no use for this purpose. Make a stock solution as follows, and use a dropping bottle:—Pyrogallic acid, ½oz.; methylated spirit, 4oz.; glycerine, ½oz. I have some of the above solution more than a year old, and it is still fresh and active.—Highlander.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

Since our last "R. N. H." has replied to 46346; "Ditton" 46578, 46775, 46834.

The Growth of Coral.—After a cruise of a few months in the South Pacific, a French man-of-war was recently found to have specimens of living coral growing upon her hull. This interesting discovery has thrown some light on the question of the rapidity of growth of corals. The evidence tends to show that the vessel on passing a reef of the Gambier Islands, against which it rubbed, had picked up a young fungia, which adhered to the sheathing of the ship, and grew to the size and weight it had when observed, a diameter of 9in. and a weight of 2¼lb., in nine weeks.

The trains on all sections of the Great Western Railway, with the exception of the "Flying Dutchman" and the limited mails, now carry passengers at third-class or Parliamentary fares. This concession does not include the Bridport company's line. Minor alterations in some of the fares between stations west of Bristol will gradually be put in force.

M. Pierre Manches says he has found that when sulphurous acid is passed into water through which an electric current is conducted, the sulphur is deposited as a yellowish-white powder on the negative pole.

The use of the Siemens regenerative gas furnace enables a ton of crucible steel to be melted with an expenditure of only 1⅓ tons of coal, as against 2 tons of coke in the ordinary furnace.

The vane of the Osler's anemometer at the Greenwich Observatory made in the year 1881 fourteen revolutions in the positive direction N., E., S., W., N.

QUERIES.

[47208.]—**Chamber Organ.**—During my leisure hours I am amusing myself by constructing a small organ from the excellent information found in "our" columns: have made bellows 4ft. 6in. by 2ft., and Stopped Diapason pipes CC to G, 56 notes, and voiced them on a kind of hollow box fixed over bellows in a temporary frame; have loaded bellows to a pressure of 2in. So far everything works very fair, excepting when small pipes are on I notice they rise in pitch every time the feeder of the bellows is closed. What is the cause of this?—will they do so when fixed on proper soundboard? Box is 16in.×8in.×4in., so it must contain plenty of wind for six or eight pipes that I can stand on it at a time. Bellows are made exactly as described by Mr. Dresser in his articles; soundboard is 3ft. 6in.×19in. I have not quite finished this, as I have only the pipes named, and do not know how wide to make bearers and slides. Should like the following stops, and shall be obliged if someone will advise me:—Stopped Diapason, Bass, 12 notes; Stopped Diapason, Treble, 44 notes; Open Diapason, Tenor C to G Alto; Dulciana Principal, CC to G Alto, and Flute to Tenor C; the end of instrument to be formed by six of the largest Diapason (Stopped) being planted at each end, and front decorated by 20 of the largest of the Principal. What width must I make the sliders and bearers for each? If there is not room for all, I must sacrifice flute.—Station-Master.

[47 209.]—**Lever Watch.**—Some time ago the mainspring of my watch (an English lever) broke in the middle. I sent the drum with broken spring in it to a firm that advertises in "ours," and they fitted a new spring for, I believe, 1s.; so spring is doubtless all right. While the drum was away I took the watch to pieces and cleaned it, got it all put together (as I thought) first-rate. On getting the drum back and put in, I found the watch kept time with our regulator on being hung up, but when it was worn it gained four or five minutes a day, and the same when it is laid down on its back. I used best watch oil when putting it together, and find cap over balance is screwed down so that there is but little end shake. Was I correct in oiling jewel holes and the small pin that works the lever backwards and forwards? Or, can someone suggest a remedy? I find it gains more when nearly run down. Have set spring up one turn, but this makes no difference.—Station-Master.

[47210.]—**Pedometer.**—I have a pedometer which I am desirous of using occasionally when out rambling in the country. I have taken it to a local watchmaker; but, unfortunately, mine is the first which he has seen the inside of. I notice there is a fast and slow regulator, and my idea is that its use is to regulate the lever so that it will indicate on the dial, say, one, two, or three minutes to the mile, instead of indicating 1¼ or 1½ minute to the mile if unregulated, and thus save having to calculate the fractions. If I altered my pace faster or slower, what would be the action of the pedometer? If some of your readers can give me any information, it will be received with pleasure by—Don Carlos.

[47211.]—**Magneto-motive Force.**—Would Mr. Huxley, or some other reader who understands the theory of electricity, inform me of the best method of measuring the magneto-motive force (or the intensity of a magnetic field)? Also, the units generally used for such measurement, and how to obtain the E.M.F. of a battery or dynamo-machine? Any information on the subject will greatly oblige—H. S.

[47212.]—**The Fingernails.**—To Dr. Edmunds.—Will Dr. Edmunds kindly advise on the following?—One of the fingernails and one of the thumbnails grows very thick. There seems to be a growth underneath them of soft improperly-formed nail. The skin all round the nail, but chiefly the part nearest the first joint, does not adhere to the nail as on the other fingers, and the skin of the affected fingers is dry and scaly. There is little or no pain, but they are unsightly.—No Name.

[47213.]—**Camel's Hair Brushes.**—How are "camel's hair" paint-brushes made and pointed? I am told the hair is generally that of a squirrel's tail.—A. Trotter.

[47214.]—**A Clock to Strike Quarter-Hours.**—Would "Alfojoe" kindly let me know how to make an eight-day clock strike the quarter-hours? It is one of those gilt American ones. Also, how to regild same?—A Poor Irish Boy.

[47215.]—**Embossing Glass.**—Would someone kindly elucidate my difficulty in embossing? After putting the acid upon the glass, I find it sometimes gives a beautiful transparent effect; another time, a rough ground appearance. For instance, I once left the acid on seven minutes, the result being clear; another time three minutes, which gave a ground glass,—some places white, others semi-transparent. The seven minutes caused a white ash to peel off. I use the acid pure.—Phonetic.

[47216.]—**The Berliner Violin.**—Can anyone suggest a plan to improve the violin after Berliner's method without taking the instrument to pieces? I should be glad to make the alteration, and no doubt should get it to pieces easily enough, but the rebuilding would beat me.—Frank Smith.

[47217.]—**Gaiffe's Medical Induction Coil.**—Can I use this in connection with telephone and microphone? If so, how can I connect it?—Frank Smith.

[47218.]—**Circulating Decimals.**—Can anyone direct me to a book or paper (in English or French) dealing fully with the theory of circulating decimals? I have seen a reference to Clarke's "Rationale of Circulating Numbers," but I cannot find it mentioned either in the English catalogue of books, or in the Royal Society Catalogue of scientific papers.—A. J. Smith.

[47219.]—**Textbook of Physiography.**—What are the most complete textbooks of physiography, going over the ground required for both the Elementary and the advanced stages of the Science and Art Examinations?—A. J. Smith.

[47220.]—**To Mr. Lancaster.**—I am making a shocking coil, wooden reel, 6in. inside reel-ends, ¼in. core, three layers of No. 16, five of No. 24, six of No. 30, and four of No. 34, all cotton-covered, well insulated with shellac and paper, and have got on the No. 16. Would you advise me to proceed with what now appears to me so disproportionate a primary ?—J. H. A.

[47221.]—**Dyeing.**—I attempted to dye a large piece of cotton in a tin bath with rosaniline, having mordanted with fustic. The colour is bright enough, but throughout the whole piece black patches came, of which I cannot get rid. Is it owing to using a tin bath ? Will some kind reader oblige by advising me how to remedy the evil, or is it possible to get rid of the rosaniline colour by any process, and start again on the white ground ?—Amateur.

[47222.]—**Free Oil.**—I have to estimate the amount of free oil in a mixture of oil, soap, and rosin ? Will Mr. Allen, or some other kind chemical reader, favour me with the latest and most expeditious method ?—Old Railway Grease.

[47223.]—**Birdcage Making.**—Will any reader kindly mention the necessary tools for bending and cutting wire for birdcage making, or give some general instructions ?—C. H.

[47224.]—**Affection of the Heel.**—To Dr. Edmunds.—I suffer from a painful affection of the tendons at the back of one heel when walking, with slight contraction; no enlargement—the result of chronic rheumatism. Can Dr. Edmunds help me ?—Adonis.

[47225.]—**The Cup-and-Ball Microphone.**—I think great praise is due to the gentleman who devised this form of microphone, and placed it unfettered at the disposal of the public. But the "public" is not usually very demonstrative of its gratitude in cases of this kind. I have found it a wonderful and most useful general transmitter. My pair have been lying idle a few months, and latterly, on trying them, they are less sensitive than they were. Can anyone kindly give a hint ?—Beta.

[47226.]—**Picture-Frame making.**—Is the plane and shooting-block still the best way for making picture-frames commercially ? In mitreing with a jack-plane I find difficulty in working true—often too much taken off the heel. Is my plane too light, or what is probable cause of failure, which is usually in the hard woods more than others ?—Beta.

[47227.]—**Size and Power of Boilers.**—Would "J. H." (letter 20117, p. 287), who answered the question on the size and power of boilers, or some other kind reader, please say how the figures ·693 (used in calculating the h.p. of engine in the question) are arrived at and oblige ?—J. H. W.

[47228.]—**Telephone.**—What quantity of No. 36 wire on bobbins will give the best results, and what should be the dimensions of the bobbins to receive this quantity, the soft iron core on my magnets being 5/16in. in dia. ?—R. Kanthack.

[47229.]—**M.R. Engines.**—Can any of your readers give the wheel-bases of the new Midland express (No. 1501, Neilson), loads on each axle in working order, height of boiler centre from rail, and distance of driving-axle centre from firebox front, and trailing axle from back of do. ?—G. M. M.

[47230.]—**Unhealthy Trades.**—Which is considered the most unhealthy trade, or which shortens life most ? Is it glass-blowing ? Is it considered impossible to remove the evils of glass-blowing by the introduction of machinery ?—J. W. B.

[47231.]—**Insulating Material.**—I should be glad to be informed whether there is any material or composition that can be used as a substitute for indiarubber or guttapercha in insulating underground telegraphic wires, and if so, what is the nature of it ?—B.

[47232.]—**Merlin Patent Bicycle.**—Can anyone explain how the silent pawl acts in the above machine, and the means by which the clicking caused by the pawl running over the toothed wheel is prevented ?—C. F. S.

[47233.]—**To Mr. Lancaster.**—Can you kindly help me ? I want to obtain a steel band ¼in. high, [illegible]in. in dia. It must be a perfect circle, and will be required to undergo a constant variety of deflections from the circle not to exceed [illegible]in., but to return to the perfect shape again. Do you think some of the bandsaw makers would be able to make this, as, if successful, I should probably require a large quantity ?—E. P.

[47234.]—**Weight of Girder.**—What would be the weight and dimensions of a box-girder, length 12ft., to break under a load of one ton, to be made of plate and angle iron ? Any reliable information will oblige—E. P.

[47235.]—**Immersion Objectives.**—Please describe in the same way as "Carpenter," p. 17, describes the construction of objectives, how a Parkes 1-16 immersion is built up, and what would be the effect of adding an additional combination at the back, its construction, focus, &c. It appears from "Carpenter," p. 18, that the American objectives have three achromatic combinations and a single front of crown.—Zeta.

[47236.]—**Object Mounting.**—Would any of your good-natured microscopic correspondents kindly answer the two following questions ?—How can I best mount anatomical specimens—e.g., section of lungs of rat, &c. ? Secondly, in mounting botanical objects, how to avoid the natural juice or moisture contained therein from exuding, and thus spoiling the slide completely ? I have tried mounting both the above classes of objects in Canada balsam (previously having soaked them in turpentine), but have been very unsuccessful. I shall be very grateful for any hints on this subject.—A Constant Reader.

[47237.]—**Medical.**—To Dr. Edmunds.—I am 38 years old, and single. This last two years I have suffered with an occasional rash, which attacks my body in various places, but especially in the hands and bottoms of my feet. It is painful and very irritable, especially so at night-time. It comes in small and large flakes or patches, raises up the skin, and gets very red. I drink beer and stout, but no wine or spirits; am a hearty meat-eater, preferring fat to lean. I should be greatly obliged if Dr. Edmunds would state a diet, or suggest some medicine that I could take when the rash indicates an appearance; for sometimes my hands are so bad it is painful to hold my hammer or file. I may say I weigh 11½ stone, and am 5ft. 7in. high; take plenty of exercise, and am a smoker, and by trade a—Working Whitesmith.

[47238.]—**To "Aldebaran"—Astronomical Telescope.**—I must express my thanks for your comprehensive reply to my query on telescope lenses. I may say I have succeeded in making a telescope with a 2¼in. o.g. of 36in. focus, and that so far as I can judge it seems to define very clearly, though, for the want of a knowledge of proper test-objects, I have not been able to test it in any other way than by trying at what distance I can read small print with it, and I find I can very easily read the query column at 25ft. distance, and do not notice any coloured fringes at the edges. Perhaps you will be kind enough to give me an easy star test suitable for this aperture. Any other hints you can give me will be much appreciated. Also what would be the best kind of eyepiece, and a rough-and-ready method of calculating its magnifying power when it is used with this o.g. ? I forgot to mention that I could not get a plano-convex lens short enough in the focus (one ¼in.); the one I have seems to answer very well, but I suppose the other would have been better.—J. L.

[47239.]—**Deafness.**—Will Dr. Edmunds kindly give me the following information ?—I have suffered from a discharge of the left ear since I was about four years old, from the measles. The doctors at King's College Hospital advised me never to try to stop it and it would probably get well as I got older; but I took to placing cotton-wool in it and am now totally deaf with it. A short time ago I had a severe cold and was deaf with the other one. It has gone away, but I have had it twice since then, attended with a humming noise in the head. I wished to know if I could get into King's College Hospital, or where there is a clever aurist. The doctors down here (Worcester) say they can do no more. I did not want to have my journey up for nothing. Hoping you will oblige—An Old Subscriber.

[47240.]—**Oil Silk.**—Would some correspondent give directions how to make what is called oil-silk ?—An Amateur M.

[47241.]—**Thief Detector.**—Last autumn some thieves got into my garden and stole my fruit. In order that I may be made acquainted with the presence of these malefactors should they pay me another visit, I am fitting up an electric bell from my garden-gate (through which they gained access to my garden) to a bell in my house, and I have completed my work except the providing of a contact-maker to set the bell in action when the gate is opened. I should be glad if anyone would give me a sketch or particulars of what I require. I have seen various kinds of thief-detectors for doors, windows, &c., but none answer my purpose. The contact-maker I want will have to be of a trigger or lever-like construction to be fitted on the opening side of the gate (not the hinge side) to break contact by the action of the gate closing, and to make contact and continue ringing the bell as long as the gate remains open.—H. H.

[47242.]—**How to Get Rid of Mites.**—Will some reader be good enough to assist me to get rid of those "little pests" ? I have a loft over my shop where I store meal and flour. The ceiling of shop underneath is sheeted with boards and rebated into each other (not tongued and grooved). The mites work down through the upper floor and sheeting of shop ceiling and destroy a great deal of goods in shop. I wish to paper shop ceiling; but what should I do before papering to prevent the "little pests" from coming through ?—Church-Hill.

[47243.]—**Dry-plate Photography.**—To W. Robinson, Junr.—I am obliged by your ready answer to my queries. Can you have patience to answer the following ?—Can the difference between the visual and actinic foci be found by calculation ? When found, would it be well to have the ground-glass screen as far behind the position of the plate as the one focus is from another ? Will you, or any other reader, tell me how to make a double dark slide, with working drawings, if possible ? I am not a skilled cabinet-maker, so the simpler the better.—F. J. N., Liverpool.

[47244.]—**To Mr. Lancaster.**—Will you please to give me instructions to make a galvanic battery ? I saw one some time ago worked by a three-pint bichromate battery, which was very powerful. The magnet was a bundle of fine iron wire 6in. long and 1in. thick, and was inclosed in a box about 7in. by 6in. There were four powers on the machine, also a brass rod, which drew out. A sketch of the above to work from, also the number of coils of copper wire and the gauge, would oblige.—W. Wright.

[47245.]—**Electric Bells.**—In connection with my telephones I have put up a pair of call-bells; distance is about 250 yards, line wire copper, return wire iron, two Leclanché cells at each end. Telephones answer well, and so do bells sometimes, but sometimes again they will not. For instance, one day lately I put on switch at station A to call station B; no bell rang at B. I left it on, and in about thirty minutes, all of a sudden, without being touched by anyone, the bell at B commenced to ring. Again, at present moment, I have done same thing, and bell at B will not ring, although yesterday it would; but I have discovered that if I, with a bit of loose wire or my silver pencil-case, bring the two cells at B into work also, the bell at B will ring very strong, and then, after half a minute, the battery at A will ring bell at B, and so reversing it, bell at A can be made to ring, which it now will not do. Can anyone kindly explain this ?—Meme.

[47246.]—**Private Telegraph Wires.**—Some considerable time since I sent a query which was inserted as No. 46634. "Sunlight" kindly replied to it, but did not answer same at p. 160. Under same number I addressed further query to him at p. 179, to which no answer has been given. I, therefore, venture to repeat—i.e., How to strain outdoor wires to insulators ? and how, when strained, to keep tight ? Also, how near wires may be carried to a wall without fear of leaking ?—Meme.

[47247.]—**Product in Brick-burning.**—On opening a kiln of newly-burned bricks preparatory to drawing same, the surfaces exposed to the free draught are found to be covered with a grey deposit, which, on examination under the microscope, appears to be of a sub-crystalline character arranged in stellate-shaped masses of about one hundredth of an inch diameter. The slightest contact of the bricks is sufficient to prevent the formation of the substance and the true colour of the clay is preserved. Some parts of the kiln appear more affected than others. The substance is not acted upon by hydrochloric acid, and must not be confounded with the usual efflorescence due to the presence of salts of soda, potash, &c. All the evidence points to the mischief being done by the vapour; but what can the substance be ? The kiln is a down-draught one, the clay a pure silicate of alumina with crushed spar, the sand used pure silica. Can there be actions of heat and moisture going on during any stage of the burning sufficient to account for this deposit.—as I have read if colourless rock-crystal is heated red hot and quenched in water, it becomes opaque and friable, a description applying to the substance referred to ? If any of "ours" can assist me with an explanation, I shall esteem it a favour.—Didymograpsus.

[47248.]—**Wind-Pressure.**—I should be very glad of a solution to the following problem:—The wind blows at the rate of C miles per hour upon a rigid rectangular plane, fixed by its four corners, whose length is *a* and width *b*. The direction of the wind is inclined at the angle A to the direction of the length of the plane, and at the angle B to the width. What is the direction ? and what is the amount of each of the pressures produced on the four corners ?—A. W.

[47249.]—**Putting Steel Tongues in Concertinas.**—I repair concertinas, and when any tongues are broken, replace them by steel reeds for the sake of durability, and knowing steel to keep in better tune than brass or any other metal. I get the tongues ready hardened, but otherwise in the rough, from the manufacturers of English as well as German concertinas; nevertheless, some tongues I put in break immediately when played on, while others, put in the same instrument by me and at the same time, stand splendidly. I am careful in the filing, leave them as heavy as is consistent with the quality of tone, and can, therefore, in no way account why it happens. Can anyone confer a great favour on me by informing me of the cause and what I must do to effect a remedy ? and put under great obligation—New Zealander.

[47250.]—**Galvanising Boat-irons.**—I have been trying to galvanise some irons for my boat, but cannot get them smooth and bright. I first had them pickled in dilute sulphuric acid, then scoured with sand and coke, immersed in lime-water, and from this into chloride of zinc, then dried on a hot plate over a smith's fire. A piece of pipe stopped at one end served as a crucible into which I put a quantity of scrap zinc parings from plumbers, &c., covered with sal-ammoniac. Having the zinc nicely melted, I placed the articles in the crucible, dipped them a few times, and could not make them come out clean and smooth. Can any person help me ?—Yachtsman.

[47251.]—**Carriage Varnishing.**—What is the cause of copal carriage varnish, when put on, drying full of small holes ? and where the best varnishes are obtained ? Also, the best for a white job, and the simplest method of polishing it ?—An Old Subscriber.

[47252.]—**The Solar Protuberances.**—Would "F.R.A.S." kindly say whether there is any apparatus, at an accessible price, suitable for viewing the solar protuberances ? and whether there is any peculiar difficulty in making such observations ?—T. Loftus Wylde.

[47253.]—**Weakness.**—A man of 30 wishes to know of Dr. Edmunds if he can indicate any course of procedure which would perfect his physical condition. The fault is inability to bear the heats of summer, the digestive organs break down; whilst in the winter, though the cold does not make him ill, it inevitably brings an abundant supply of chilblains. Diagnosis is:—Height, 5ft. 4½in., moderate girth, lean but not skinny, pulse about 64 per minute and fairly strong, lungs and heart good, reasonably muscular for one following light employ, fond of walking, can do twenty miles very well, life teetotaller, never smoked, no proclivities for animal food, very regular in all habits, disposition studious, perspires somewhat tardily, nervous temperament. A query appeared once before on Chilblains, which I think was not answered, for I looked out for the answer with interest.—Rob. Crus.

[47254.]—**Electric Commutator for Intermittent Action.**—I should feel obliged if any correspondent would favour me with the following information:—I propose constructing a small Gramme dynamo to be connected with a windmill, and by it to charge a secondary battery. I understand construction of the whole affair, with the exception of the commutator, since as the power will be intermittent, the ordinary commutator brush will not do alone, as it would allow the battery to discharge itself through the dynamo. Is there any automatic arrangement to break circuit when the machine is not running, and remake it when well started ? A sketch of same would be very acceptable, and also of arrangement to indicate by electric bell when battery is fully charged. Would this idea be practicable on a small scale so as to charge, say, 3 quart Sutton's cells to drive a sewing-machine from two to three hours daily ? I may say I should try this as an experiment rather than as an economical method. A few Daniell cells would, of course, be best to use for this purpose.—Philolektron.

[47255.]—**Lacquer.**—In Napier's "Electro-Metallurgy" a method of depositing copper on flowers, &c., is given, but it does not mention any method of lacquering the deposit. Could this be done by immersion, as some parts of it would be very delicate and not stand lacquering with a brush? Also, a recipe for a cheap clear lacquer suitable will oblige—Philolektron.

[47256.]—**Surface Condensing Engine for Launch.**—Will some engineer kindly give me a little information on working the above? I have driven several kinds of high-pressure engines for the last eight years, but have not had any experience with condensing.—Simple Simon.

[47257.]—**Bookbinding in Vellum.**—I have lately been binding some books and pamphlets in parchment and vellum with limp covers and edges cut flush.

I went by instructions received from a workman forty years ago, and the books, when first out of the press, look very nice, but when quite dry they curl up like the petals of a turkscap lily, or the brim of a fashionable hat. I have tried re-pressing, but cannot permanently re-press this curly tendency. I shall be glad of advice. Perhaps parchment is unsuitable for limp bindings. I have succeeded with thick boards.—Argent Sable.

[47258.]—**The Coming Transit of Venus.**—Now that we are hearing so much about the coming transit of Venus, there are many who, like myself, have but little notion of the special purpose for which these observations are taken, beyond determining the Sun's distance, and are quite unable to see what is their real practical value. Would "F.R.A.S." give me some information on this subject, and in so doing I am sure that he will confer a favour on many other of your constant readers.—A Constant Reader.

[47259.]—**To Mr. Lancaster.**—I have made two electro-magnets and armature for small motor, but I can scarcely get any power in the magnets. Would you please to state where I am in fault? The magnets are flat pieces of soft iron 3½in long, ¼in. thick, 1in. wide. Two of these are screwed together 1in. apart with a piece of boxwood between to wind the wire on. The wire is wound on lengthways, the same as cotton on a shuttle. I have tried it with a ¼lb. of 22 silk-covered, also with 16 gauge, and six Bunsen ½ pint batteries, but can get scarcely any power in the magnets. I have made the armature the same way as the magnets, but I have not wound that yet, as it is no use till I find out my fault. If you would kindly help me I should be much obliged. The instructions you gave me to make the induction coil a week or two ago I followed out. I have just finished it, and it has proved a success, and am quite pleased with it. I thank you and Mr. Andrews kindly for your help. —J. A. W.

[47260.]—**Compound Engine.**—Will some kind friend please help me out of a few slight difficulties? What pressure can I run at with cylinders of cast-iron, low-pressure 2in., high-pressure 1¼in. bore? Cylinder covers ⅛in. thick. What size fly-wheel will be required? What is best form of surface condenser, bore of air-pump, and is ⅜in. thick enough for smallest part of steel crank-shaft?—W. J. P.

[47261.]—**Arsenic in Wall-paper.**—I have got some wall-paper with a green pattern, which I suspect contains arsenic. Could any reader kindly tell me the best way of detecting it? and oblige—Erin-go-Bragh.

[47262.]—**Wheel Grease.**—Can some of "ours" give me a good recipe for making the above?—Burnley.

[47263.]—**Boiler Cleaning.**—Will some of our chemical friends please tell me if 56lb. of cutch per month put into one boiler at the time of cleaning out be considered excessive? and what will be its action on the plates of the boiler? We put in the cutch to prevent boiler scaling. We have been told that our boilers are being injured by its use.—Jumbo.

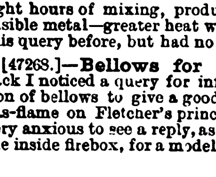
[47264.]—**Lightning Conductors.**—Would some of your correspondents say what is the best form and material to use as lightning conductors for a very tall chimney or other tall structure? And how should the conductor be fixed to the building? What arrangement should be made at the upper end for the attraction of the lightning? and what at the lower end for conveying the electric current into the earth? Any information on this important subject, founded on recent experience, will be thankfully received by—Shropshire.

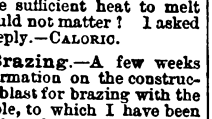
[47265.]—**Forecast of Storms.**—Having taken a little interest in the above, and having tried two experiments with reference to the above subject, and I may say with little success, I should be extremely obliged to W. M. Gardner (letter 20163) if he would give us a short description of his barmometer.—Home-Made Barometers.

[47266.]—**Locomotive Engines, &c.**—I would like to have some particulars on the following points:—1. Indicated h.p. of different classes of engines. 2. Weight of various trains. 3. Frictional resistances of trains. 4. Air-resistance to trains.—Wm. John Grey, Elswick Science School.

[47267.]—**To Chemists.**—Will someone please say what chemical mixture of materials will, within six or eight hours of mixing, produce sufficient heat to melt fusible metal—greater heat would not matter? I asked this query before, but had no reply.—Caloric.

[47268.]—**Bellows for Brazing.**—A few weeks back I noticed a query for information on the construction of bellows to give a good blast for brazing with the gas-flame on Fletcher's principle, to which I have been very anxious to see a reply, as I have been trying to braze the inside firebox, for a model locomotive made of copper 1-32 thick; it is 3½in. long, 1¾in. broad, and 3in. deep. As I could not get enough force out of a pair of kitchen bellows, I have commenced making one 18in. by 13in., with rounded corners with a separate feeder and reservoir on top, which can be loaded with weights to obtain the needful pressure. The valves I have made of india-rubber 3in. diam. and 3-16in. thick fixed to the boards in the centre, and covering a number of holes ⅜in. diameter. What I want to know is, what sort of leather to use, and if any composition is used to put between the latter and the boards (which are elm ¾in. thick) to make it air-tight? Or, whether it is simply nailed to the wood? I should be very glad if anyone would give a few hints on brazing, as occasionally I have got the spelter or silver solder to melt, but it would not run into the joint, although scraped clean previous to applying the borax and spelter.—E. L. P.





[47269.]—**Electric Motor for Tricycle**—Will any readers of the Mechanic, who are acquainted with the working of electric motors, inform me whether it would be possible to fix one to a tricycle in such a way, as from the rotary motion of the wheels whilst on the level or going down hill, sufficient power could be accumulated to make it easy going up hill? I have read that on the Brighton Railway some of the trains are lit up by electric light produced by power derived from the motion of the train wheels, and it seems to me quite as feasible that electricity can be produced from the motion of tricycle wheels, if there is any way of storing it. Or, would it be possible, by using a small steam-engine to produce both electricity to light up a shop, and also to accumulate power for a tricycle motor. I see in *Chambers's Journal* for this month that the French are bringing out electric-driven tricycles, but no particulars are given, and I shall be glad if some reader will be good enough to give me a practical answer to the above, or any practical suggestion or particulars as to a motor. I should be satisfied if I could get one that would make going up hill easier work. —A. J. C., Winslow.

[47270.]—**To Mr. Lancaster.**—I have a portrait lens, the two front glasses of which are cemented together; the cement has gone cloudy. Can I take them apart and clean them without fear of breaking? If so, how?—W. Brown.

[47271.]—**Waterwheel Grease.**—I shall be thankful for a good cheap grease for a waterwheel 30in. diameter, and partly working in water.—L. H. S.

[47272.]—**Drill for Boring Fireproof Floors by Machinery.**—Can any of your readers inform me what is the best kind of drill to use for the above purpose, as rose and taper drills knock too much brickwork, &c., into the room below? The mill is quite a new one, and the mortar, &c., has not had sufficient time to set.—A Subscriber.

[47273.]—**Lines of Force.**—Will some reader of the Mechanic be so kind as to give some explanation of what is meant by a "coil cutting lines of force," and a "coil adding and subtracting lines of force"? Of course, I have seen the experiment of iron filings on a piece of card producing lines of force, but I have sought in vain for an illustration of the way in which lines of force are cut by a coil of wire revolving between the poles of a magnet. And, also, how the iron ring influences the lines of force in a dynamo-machine? I have learned many things from the Mechanic, and wish to learn this.—S. C.

ANSWERS TO CORRESPONDENTS.

◆

⁂ *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

⁂ Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, June 21, and unacknowledged elsewhere:—

Capt. Ternan.—Lt.-Col. Fendall.—W. A. Ryan.—Capt. Guyon.—J. Chown.—J. Noble.—E. C. Ames.—Rev. T. E. Espin.—W. Walker.—E. J. Warmington.—Gymnastic.—An Amateur.—C. H. Romanes.—A. Matthews. —W. A. French.—J. R. Brown.—J. P. H.—W. D.—J. H. Huxley.—John Bond.—H. S. Frost.—Rev. S. Mills.—M. Jonson.—J. H.—Collodion.—F. Walker.—Beetle Crushers.—W. Baldwin.—E.—A Fellow Workman.—W. McAndrews.—C. R. Beaumont.—A Fellow of the Royal Astronomical Society.—Svenska.—Light.

Sans Sanitas. (Dyspepsia; try lighter meals, and especially lighter suppers.)—Carino. (Thanks; shall appear next week. It seems as you suppose with regard to the other matter, but we doubt it. If it be so, and the Editor is troubled as we were, he will, and probably with regret as we did, have to dispense with the help rendered.)—Nil Desperandum. (Work hard and learn all you can. If possible, get into a civil engineers' office in some subordinate capacity, and show by your work that you are capable of better things. 2. Several textbooks are published giving general rules for such calculations. Templeton's "Workshop Companion" is as good as any. If there is any special case, we are always ready to answer or insert a query, but we cannot be always repeating elementary rules.)—T. McDonald. (Yes, forty years at least. Of course in older, and far more imperfect patterns.)—Enod. (Have you tried the Dichroic ink? The subject has been several times previously discussed.)—C. F. Lloyd. (The ink is made of equal parts of tallow, wax, soap, and shellac, with sufficient fine Paris black. It is cast into sticks and ground up with water. For price, apply at the dealers.)—H. T. B. (To what is your letter a reply? Where is the question?)—S. H. (We believe it can be had of Messrs. Hachette, King William-street, Strand, W.C.)—Walter R. Herring. (The manufacture of coils has been fully described again and again in our last 25 volumes. Possibly the instructions given on pp. 15 and 16 of present volume will suit you. If not you are sure to find something that will in back volumes.)—Telewag. (Join one of the art classes, and procure some of the handbooks of the art.)—Electrician. (Two would no doubt be sufficient, if properly made. 2. The solution is not decomposed if the zinc is withdrawn. 3. A very simple affair. You will find some hints on p. 180, present volume.)—Argent Sable. (If blasting is out of the question, perhaps the readiest way is to bore holes and fill with petroleum or naphtha. After that has soaked in, the stumps are fired. Saltpetre will do, but takes longer to soak in. Blasting is the cheapest method.)—Young Clerk. (They can be bought at bicyclists' outfitters, and at many other shops. You must choose for yourself.)—Amateur Electrician. (Whichever way you want them. Zinc to zinc gives what is called quantity, and makes one large cell. Zinc to tinpot gives E.M.F., or intensity as it used to be called.)—Semper Fidelis. (You have nothing to do but to purchase one of the lamps and a suitable battery, and connect up with copper wires. You will find it very expensive. A dynamo is a machine for generating current; but it is too late in the day to ask for an explanation here. You will find all about them in our back volumes. 2. Dr. Edmunds answered the question on p. 324, last week. 3. It is cream of tartar in the proportion by weight of 3 to 4 of tin.)—P. (It is prepared from the stomach of the pig by a series of processes which cannot be carried out without suitable plant. The other is made from the pancreas, and the same remarks apply. If you are prepared to go in for the manufacture, you should consult the files of the *Pharmaceutical Journal.*)—Intending Emigrant. (It depends entirely on the emigrant himself, that is, on the money he can afford and the time that he can devote to the journey. The appointments of some of the sailing vessels are quite equal to those of the steamers, but the duration of the voyage is longer.)—François. (Kindly read up recent back numbers. See answer to "Semper Fidelis" above.)—Alnwick. ("Roads and Streets," published by Lockwood and Co., Stationers' Hall-court, E.C., is the best we are acquainted with.)—Paulatim. (Certainly you require a battery. Read up the subject in back numbers.)—Florence. (Yes, hot-water heating is the best and most trustworthy.)—A Poor Irish Boy. (Search the indices under head of Silvering. The usual plan is to place tinfoil on a flat table, pour quicksilver on it, and spread it over, then push the clean glass on, and weight down.)—M.R.C.F. (We do not know of such a book.)—Beginner. (You will find a number of recipes in back volumes for beverages of the kind. The query is not of sufficient general interest to insert.)—Tapeworm. (All druggists make up suitable preparations; but it would be unwise for a person of 60 to take any without the advice of a medical man. A remedy that would be effectual and harmless in the case of a strong hearty youth might not be adapted to a feeble old man.)—A User. (Pebble is colder to the tongue than glass; but a definite test is to place the lens between two pieces of glass and hold up to the light. If pebble, rings of colour will be visible, owing to polarisation.)—A Young Civil Engineer. (See p. 595, Vol. XVIII. Find out the cause, and then perhaps some one can give a remedy. You can do no harm by washing frequently with cold water to which a solution of borax has been added; but the cause is probably constitutional.)—C. E. Peek. (Thanks, we had noted it. You will find a brief description of Clamond's burner on p. 304. The *Times* has made the mistake of confusing magnesia with magnesium wire. Lewis's improved burner, of which we give a description this week, contains a basket of platinum wire: hence, probably the error. We have the book referred to. We believe Bourbouze's idea was based on something that preceded it.)—An Amateur M. (Seidlitz powders are made usually of Rochelle salt 2 drachms and bicarbonate of soda 40gr., mixed, and put into a blue paper. In a white paper are 35 grains of tartaric acid. The quantities are sufficient for half-pint of water.)—Red Cobal. (We presume you mean ebonised—*i.e.*, stained and polished; but if paint, the latter is mixed with varnish. 2. Try the coaguline again, or else shellac, heating the parts to be joined. You might stain it red.)—Beginner, Commercial-road. (See pp. 237, 251, 381, last volume, for many practical hints on electro-plating. The Bunsens will do; the bichromate is not economical or good, and the Leclanchés are no use at all for the purpose. The Daniell is the best arrangement for electro-depositing. However, you will find all information in the pages mentioned.)—A. H. B. Olney (The copper cups will not do. See recent letters. American potash properly prepared will do; but you can easily make the soda solution by boiling solution of common washing soda with some lime. See p. 308. Four shillings a pound for caustic soda is absurd.)—A Workman. (We believe that treacle is the best medium for moulding up carbon plates; but they are very inferior, and you certainly will not make "filaments for arc lamps" by that means. What was meant about the odds and ends being used for batteries was that they can be broken up and used with manganese for the Leclanché batteries. Much secrecy is observed in the manufacture of "rods," not filaments, for arc lamps; but of one thing you may be certain—that very powerful presses are needed, and the rods are baked in a furnace where no air can reach them.)—W. R. C. (A coil is not required, only a battery. A piece of thin platinum wire is inserted in the circuit, which becomes red hot, and so fires the powder.)—An Amateur. (See recent back numbers, and the index of the last volume.)—A Watchmaker. (Rub up the surface with a bit of sandstone or emery-cloth, and try again.)—Kent. (Either by attaching the contact piece to the hinged part of knocker, or by making the hammer drive in a spring pin when it falls on the door. 2. The best remedies are antimonial emetics and change of air, the latter to be preferred.)—F. H. Harrap. (Why not write to the patentee? A patent agent would supply it for a small fee.)—One in a Fix. (What do you mean by "all the rates and taxes"? They cannot have charged house duty, for instance? You are bound to pay land tax and poor rates, if that is what you mean.)—W. H. RICHMOND. (We should be glad to hear from you at greater length as to the proposed series.)—THOMAS CLEARY. (Probably from £8 to £10 10s., including agents' fees for provisional protection. 2. You would have to employ a patent agent to make a search for you at the Government Patent Office, which is in Southampton-buildings. You had better write to one of the patent agents whose advertisements appear in these pages, for a copy of their instructions to inventors, which will give you all necessary information.)—G. W. H (We know of none that we care to recommend.)—RUST. (We do not know. Possibly a note to the secretary would obtain for you the information. 2. The advantage claimed is in the economy of tin used, but we have no practical knowledge of the process. We see no advantage in using the double process, except for goods where an extra thick coating is wanted.)—T. PEMBERTON. (See index to any back vol.)—E. S. (Cleanliness and the use of water or air beds is the only means of prevention, but with long sickness and much loss of flesh they are almost inevitable.)—AN ENGLISHMAN. PROBLEM DCCLVII.—By F. C. COLLINS.

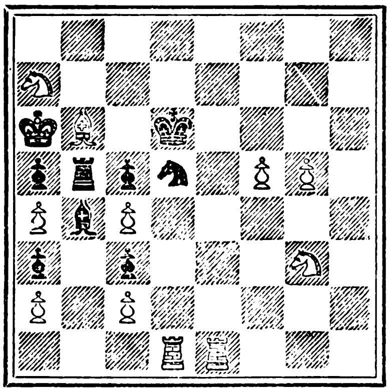
Black.

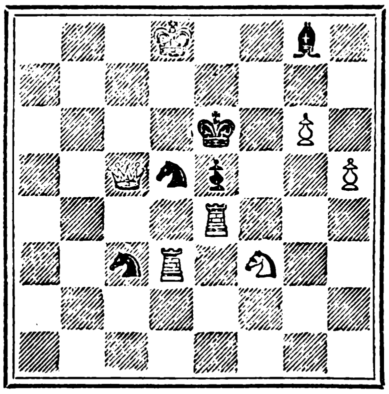


White.

White to play and sui-mate in two moves.

PROBLEM DCCLVIII.—By A. BRIGGS.

Black.



White.

White to play and mate in two moves.

SOLUTION TO 753.

White.	*Black.*
1. R to Q Kt 2 (dis ch)	1. Q to Q 7
2. Q to Q Kt 8	2. B to K R 2
3. R to Q B 2 (ch)	3. B takes R mate

SOLUTION TO 754.

White	*Black.*
1. Kt to Q 2	1. Anything
2. B, Kt or Q mates accordingly.	

NOTICES TO CORRESPONDENTS.

THE author of Problem 751 informs us that it can be made sound by adding a Black Pawn at K 13 4. The Pawn at K B 2 can be removed.

SCHMUCKE.—A sui-mate problem is one in which white compels black to mate him (white) in so many moves. The strategy involved in such is quite distinct from that in ordinary problems, and well deserves attention when exemplified by such masters as Kidson, Slater, Gilberg, and others. Problem 753 is a capital example of the kind. We intend to give others from time to time. Try the one above. Your solutions to 754, 755, and 756 are correct. As to the problem, it is a very fair one for a first attempt; but it is rather too easy for publication, on account of the check threatened by black. Moreover, there is a dual in the main variation.

Every Workman connected with the Building Trades requiring a situation should advertise in "THE BUILDING NEWS," published every FRIDAY, price Fourpence, at 31, Tavistock-street, Covent-garden London, W.C.

"THE BUILDING NEWS" is the Principal Journal, representing Architects and Builders, and has the largest circulation of any Professional Journal in the kingdom.

Every Workman should insist on seeing "THE BUILDING NEWS" every week at his Club or Coffee House. He will find more "Lists of Tenders" for new work in it every week than in any similar paper, and can thus judge where work is likely to be had. He is also specially invited to make use of "Intercommunication" if he wants to know anything about his trade; to write to the Editor if he has any suggestions to make and to advertise in the paper when he wants work.

The charge for Advertisements for Situations is One Shilling or Twenty Words, and Sixpence for every Eight Words after.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post-free to any part of the United Kingdom. For the United States, 13s., or 3 dols. 25c. gold, to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 3d. each to cover extra postage.

Messrs. JAMES W. QUEEN and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post-free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. XXIV., XXVI., XXVII., XXVIII., XXIX., XXX., XXXI., XXXII., and XXXIII., bound in cloth, 7s. each.
[Vol. XXXIV. Now ready.]

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in March and September, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d each, through any bookseller or newsagent, or 2½d. each, post-free from the office (except index numbers, which are 3d. each, or post-free, 3½d.)

Indexes for each half-yearly volume up to Vol. X. (except Vols. II., III., IV., V., and X.) inclusive, 2d. each. Post free 2½d. each. Indexes to subsequent vols., 3d. each or post-free, 3½d. Cases for binding, 1s. 6d. each.

⁂ Subscribers are requested to order Cases and Vols. through their booksellers, and not to send direct. The regulations of the post-office prevent their transmission through the Post.

CHARGES FOR ADVERTISING.

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen Words	0	6
For every succeeding Eight Words	0	6

⁂ It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions; and in cases where the amount sent exceeds One Shilling the publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement and charged for.

Advertisements *must* reach the office by 3 p.m on Wednesday to insure insertion in the following Friday's number.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a PINK Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

Holloway's Ointment should be well rubbed upon the pit of the stomach and region of the heart in that particular form of indigestion which gives rise to palpitation, shortness of breath, and a suffocating sensation. Every distressing symptom soon yields, digestion becomes easy, the spirits light, and good health returns.—ADVT.)

OUR EXCHANGE COLUMN.

The charge for Exchange Notices is 3d. for the first 24 words, and 3d. for every succeeding 8 words.

A pair of well-finished **Needle Instruments** in good order, platinum contacts, new coils, thoroughly reliable. Offers.—LOGAN, St. Cross P. O., Winchester.

Oil and Limelight **Dissolving View Apparatus** for Screw-cutting Lathe, Twist Drills.—D. W. N., Ernest Cottage, Peyton-place, Royal Hill, Greenwich.

A one-horse **Water Motor** in exchange for a good Perambulator (rubber tires), or offers.—WM. O BRIEN, 113, Haddington-road, Dublin.

Sociable **Tricycle**, for two or three persons, cost £24 nearly new condition. Exchange good Photographic or Dissolving View Apparatus, or offers.—WRIGHT, Photographer, Northampton.

Wanted, a good **Plane** and Shooting Block for picture-frame making.—BELL, Belbroughton, Stourbridge.

Half-horse and one-horse **Engine Castings**, cylinders bored, &c.; or two-horse ditto. Offers.—JAMES SUTCLIFFE, Engineer, Princess-street, Granby-row, Manchester.

Medical Coil, Galvanic Battery, Engines, and Lathe Castings, Field Glass, Screw Press "English Mechanic," "Engineer," &c. Offers.—JAMES SUTCLIFFE, Princess street, Granby-row Manchester.

Organ Pipes, new, flute stop, 5 oct., cost £3 10s.; for Telescope or Violin equal value.—G. J. R , 2, Claremont-terrace, Blackpool.

Mahogany folding **Camera**, upright and horizontal motions to front and back, hinged focussing screen, double slide, &c., takes 7½ by 4½, 6½ by 4¾, 5 by 4, and 4¼ by 3¼, plate's weight, 5½lb.; perfect; instantaneous spring shutter. What offers?—BEAUMONT.

Mahogany full-plate folding **Camera**, with improvements, dark tent to use either as changing box or for developing, 4½ by 18 by 24in. when closed, very light and portable. Wanted, Magic Lantern.—BEAUMONT, Withington, Manchester.

"**English Mechanic**," Vols. XI. to XV., bound, clean. Exchange for Pocket Revolver or Telescope.—287, Crystal Palace-road, East Dulwich, London, S.E.

Wanted to exchange, about 9 years of "**Engineer**" and 12½ years of MECHANIC; for Bicycle, or what offers?—Address, Mr. S. BOUL, Mr. T. Malden's, Park-lane, Donington, near Spalding.

"**English Mechanic**," 1875, to May, 1882, unbound, clean, few numbers short.—W. RICHARDSON, 59, Varna-road, Birmingham.

Achromatic **Telescope**, 3in., good quality, garden and tripod stands, finder, star diagonal, two celestial, one terrestrial eyepieces, rack motions.—Above address.

Bicycle, 50in., central fire double Gun, 16ft. pleasure Boat, quarter plate Camera, lens and chemicals, Gun Case, Lathe Exchange Launch Engine, boiler, &c., or offers.—CARLEY, Mt. Trenchard, Foynes, Limerick.

Orguinette, with tunes, cost 52s. three months' since. Will exchange for Metal Organ Pipes.—HURSNELL, Plumtree Station, Notts.

Will exchange Scott Burn's "**Carpentry and** JOINERY," strongly bound, cost two guineas, for Lathe Heads, Telescope, Microscope, or offers.—ALEX. MILLER, New Prestwick, Ayrshire.

Vols. I. and II. "**English Mechanic**" (bound), 35 parts, October, 1881, to date; 82 parts "Gardening," August, 1880, to date. Exchange Fern Case, or offers.—THORNTON, 280, Cumberland street, S.S., Glasgow.

Two horse-power **Vertical Engine**, with two cylinders, complete, equal to new. Will exchange for good Bicycle about 50in.—SIXSMITH, Jackson-street, Oldham.

Superior 7½in. back-geared **Lathe**, with tools, face-plates, chucks, &c. What offers in exchange to £10 value in Tricycle, Bicycle, &c.?—F. UNDERWOOD, Beverley.

American Organ, cost £8, for other **Musical** Instruments, or something useful.—W. J , 15, Ullin-street, St. Leonard's-road, E.

New **Vertical Engine**, cylinder 3in. bore, 6in. stroke, massive ornamental turned flywheel, 54lb.—Offers to ROBERT VENNER, Lynton Villa, Erith.

Stanley Heads, pair Rubbers, steel Hub, 56in. and 18in rims, backbone, and numerous other sundries. Exchange anything.—ROBERT VENNER, Lynton Villa, Erith.

THE SIXPENNY SALE COLUMN.

Advertisements are inserted in this column at the rate of 6d. for the first 16 words, and 6d. for every succeeding 8 words.

For Sale.

Lantern Photographs, 12,000, with readings, from 6d. plain, 1s. coloured.—A. PUMPHREY, Emily-street, Birmingham.

Gelatine Films for photographs, reduce cost and labour of photography to minimum.—A. PUMPHREY, Birmingham.

The **Filmograph** carries 100 films or 12 plates! Lightest Photo. Apparatus. Illustrated tests.—PUMPHREY, Birmingham.

Filmographic Manual, free 6d., with photograph from Film Negative. Full instructions. Films, Filmograph.—A. PUMPHREY, Birmingham.

100-Fold **Filmograph Slide**, can be used with ordinary camera. Plates changed anywhere.—A. PUMPHREY, Birmingham.

Collographic **Photographs** for Machinery and Trade Patterns. Sample and list for 2d.—PUMPHREY and DAY, Birmingham.

"**The Night-light Clock.**" Illustrated and described on page 370, No. 848. Price, carriage free, 5s. 6d.—P ROBERTSON, 13, Greek-street, Soho, W.

Lathe, 3½in., 3ft. bed, screw-cutting, slide-rest compound, set change wheels, chucks, &c., second-hand, good as new, £11.—MAKIN, Cupola, Sheffield.

Stocks and Dies, now in extensive use. List one stamp.—F. M. ROGERS, 21, Finsbury pavement.

Electric Lighting.—Inventors wishing to perfect, patent, or sell inventions connected with electric lighting should communicate with F. M. ROGERS, 21, Finsbury-pavement, E.C.

Minerals, 100 good specimens, including sapphire, ruby, topaz, emerald, opal, all named, different, 10s. Apply for list. Also many finer, rarer specimens.—COLLECTOR, Richard's Library, 42, Tachbrook-street, Pimlico, London.

Metallic "E" **Violin Strings**. Infinitely superior to gut. Four post free 1s.—SMITH, 2, Bedford-street, Plymouth

Micro. Photos.—List of 350 one penny stamp.—E. and A. DANCER, 436, Stockport-road, Manchester.

New loud **Violins**. No back or soundpost, 15s., 20s., by "FIDDLER," 19, Edward-street, Burdett-road, E.

Lathes, Lathes, cheap good screw-cutting, from £10. Easy payments. Hire system. First-class tools.—MAKIN, Cupola, Sheffield.

Electrical Depot and Manufactory.—MILLAR'S, 126, Chapel-street, Salford. Handiest shop in the trade for amateurs.

Electric Lamps, 5s.; Bells, 5s.; Batteries, 2s. None better or cheaper. Instruments repaired.—MILLAR, as above.

Gas Compressing Pump, hand lever, 500lb. sq. inch, perfect order £7 10s.—C , 29, Oberstein road, Clapham Junction, S.W.

AND

WORLD OF SCIENCE AND ART.

FRIDAY, JUNE 30, 1882.

SPIRAL APPARATUS.

By J. H. Evans.

In continuation of the spiral apparatus, I am now about to show and describe it as seen at the rear or back of the lathe-head, which is really the proper place for it, by reference to page 101, Oct. 7, 1881, of this journal. The apparatus is there figured as fitted to the front of the lathe-head, and I may say that the present arrangement is virtually a return to the actual original plan of fixing it—viz., at the back, with several improvements, and one reason for its being abandoned at that time was the fact that it could not be applied to any other than lathes with traversing mandrels. The apparatus, as fitted to the front, of course can be fitted to any lathe, therefore it is obvious that those amateurs possessed of a back-centre lathe must be content with it so arranged; but to a lathe with a traversing mandrel I should certainly advise having the apparatus at the back of the head for many reasons, which I will point out. As the various details of the arbors, &c., were fully described in the preceding article, I need not occupy space by going over them again, as they will be exactly the same. One of the chief advantages derived from the present arrangement is that it can be used in conjunction with the oval chuck, and from this some very beautiful work can be accomplished, and, again, except when the screw guides are required to be used, the fittings can all be left on their several places. The fact of having to remove the eccentric carrying the guide for screw-cutting was also another objection to this arrangement at the back, but it is impossible to have a multiplicity of apparatus without having to make changes in the setting up of the same, and as this occupies such a short time, I think it cannot be regarded as an objection, especially when the results obtained by it are so appreciative.

The engraving, illustrative of this apparatus as now shown, gives two views of it, the back face showing the chuck with the wheels in gear, and a side view disclosing the mode of connecting the slide-rest to it; and here I will point out that the joint being made to work upon two separate centres, which is my own introduction, does away with the necessity for such absolute accuracy in the adjustment of the socket which carries the connecting rod, to the height of the centre of the slide-rest, and another advantage in this universal joint is that tapers or cones may be turned by setting the slide-rest to an angle, and it works perfectly in every way that could be desired. I do not claim anything new in the invention of this joint only as applied to this particular apparatus; I merely point this out because I do not wish my readers to credit me with a desire to fall back upon anything that has been done before, and endeavour to claim it as my own. This joint, however, although nothing new in itself, is, as applied for the present purpose, my own original idea, and has met with

FIG. 1.

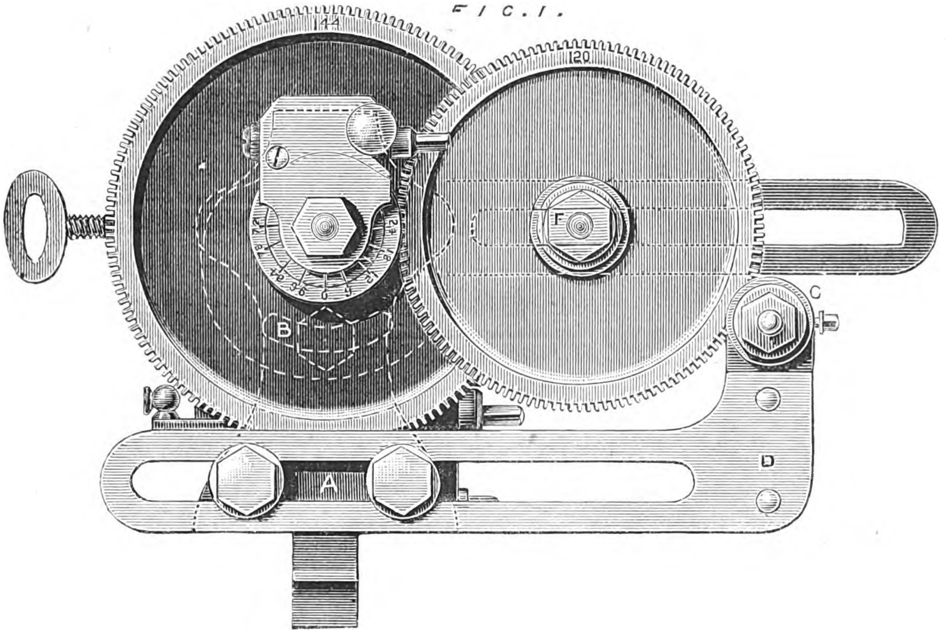

FIG. 2.

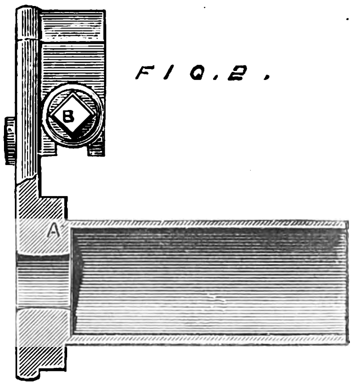

FIG. 3

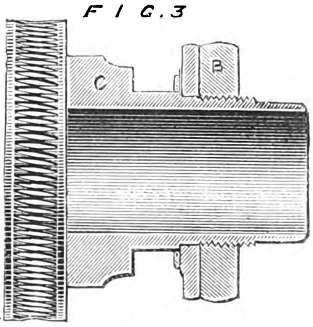

FIG. 5.

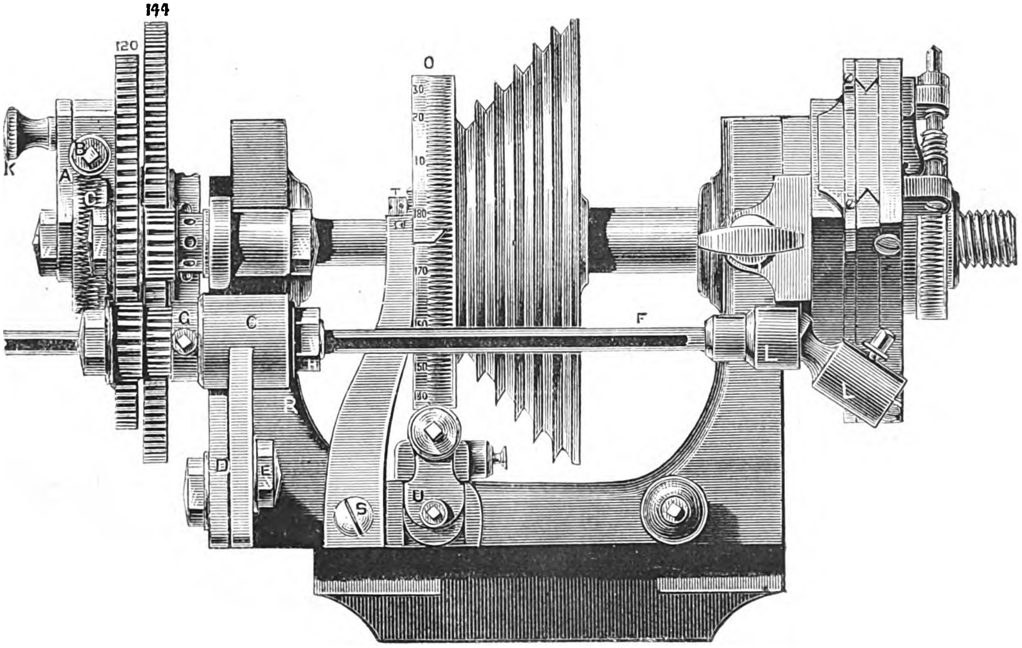

FIG. 4.

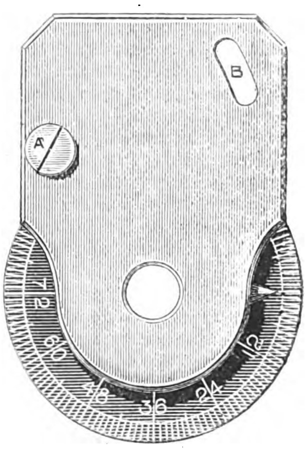

every appreciation from very many amateurs for whom I have made it, and who use it a great deal. As the question has been asked several times through the columns of this paper if I am going to finish the articles upon the spiral apparatus, I will endeavour to show our readers the best way to make it, or to transfer it, if they already have it fitted to the front. Letter A, Fig. 1, shows the outline of the mandrel-frame; this is shown by a dotted line, as the wheels nearly cover it. The first part to do will be to cut out a circular recess for the radial arm to work in. This must be cut out with the aid of a boring bar and cutter, which is shown in Fig 9, page 4, Sept. 9th, 1881, and, in order that the recess may be cut perfectly true to the collar, bushes must be fitted one in each collar to guide the bar; boxwood will answer very well for this purpose. The radial arm, if being transferred from the front, must have the projecting ring taken off the side that it is on, and another fixed on the opposite side. The best way to do this will be to fix the arm on to its place and cut out a recess exactly the same as that in the cast iron; in fact, it may be done at the same setting of the bar—that is to say, having cut the cast iron, place on the metal arm, and cut out the recess in it, about 1-16in. deep, and into it fit a ring of metal, which will, of course, then fit into that cut in the lathe-head. It may either be soldered or screwed on: the former is the least trouble, and as it is simply a guide, will be sufficiently strong. The radial slot B is arranged so that the same hole that receives the bolt for the eccentric of screwing apparatus may be used. This being the case, it is simply to make a new bolt, with hexagon head, to tighten the radial arm, in whatever position the gearing of the wheels requires it to be fixed. The wheels shown in the engraving are those which are used to produce the coarsest pitch that the series of 15 wheels will produce—viz., 144 on the chuck-gearing with a pinion of 16 on the middle arbor F, which is the double one; the 120, also, on this same arbor and the latter gearing with a pinion of 15 on the lower socket, which, in this case, takes the place of that on the slide-rest, and answers the same purpose, the actual pitch or rise of this spiral cut, by aid of these wheels, is as near as possible one turn in 7in. Such a pitch would only be used in ornamental turning. To proceed with the making. The next part to do will be the lower arm D, which is straight, and has a long slot in the centre to admit of its being adjusted with the slide-rest. It is fixed to the lathe-head by two steel bolts with hexagon heads, as seen, which have loose washers underneath. The plain part of the bolts will form sufficient guide for the slot to work on without its fitting down on to the bed; also, it will prevent the necessity of moving the head forward—by the way, an old objection when the bracket was fixed to the bearers. There is no necessity to move the head at all under any circumstances connected with this apparatus. The spiral chuck, of which I give two separate views, will form the best part to proceed with,—I mean, provided the whole is being changed from front to back. If being made, the arbors should be made first, in order that the line of gearing may be more readily got when making the chuck. To make the latter, the body (Fig. 2, A) should be chucked by the back-plate on to a surface-chuck, and held tightly by two clamps and bolts; while the hole is turned out, which it must be, to fit on the mandrel, and a hole made at the bottom for the steady-pin, which prevents the steel guides for screw-cutting turning round to fit into. This fitting must be very carefully done, and when screwed up quite tight, the mandrel must work freely, without any shake. Fig. 3 shows the tangent-wheel, which has 96 teeth; on the body of this the wheels are placed when in use, and are held firmly to it by the circular steel nut B, Fig. 3, against the face of the shoulder C, Fig. 3. A hole through the centre, Fig. 2, is for the purpose of allowing the steel screw to pass freely, usually used for fixing the steel cap for ordinary turning. This same screw will do, if long enough, and it generally is; but in lathes that have been made for a considerable time, this was not thought of, and the screws are sometimes too short; it is, however, an easy matter to make another. B, Fig. 2, shows the end of tangent-frame and screw; and Fig. 4 gives an end view, showing how the centre upon which the tangent-frame works is obtained. The screw A, Fig. 4, having a plain part, which fits into the hole, and is screwed as tightly as possible to a shoulder when the frame bears well against the inner face of the plate; the radial slot B is that in which the fixing-screw works for tightening it when in or out of gear. This chuck I introduced to obviate the difficulty of dividing the work, as the original plan of raising the radial arm and wheel out of gear, and shifting the mandrel or slide-rest screw round, was indefinite. This, of course, I saw in a moment was most deficient in accuracy, and so set about making the present one, which obviates all risk of inaccurate work; the face of the body of the chuck C, Fig. 3, must be turned away until the wheels on the chuck, line correctly with those on the arbors, and that should be the centre of the pinions, which are half an inch wide, the wheels being $\frac{3}{8}$, and the difference is made up by the thickness of the blanks which fill up the large holes in the wheels. The adjusting of the various parts to work well is rather a troublesome job, as there is very little room to spare.

We now come to the metal bearing C, Figs. 1 and 5. This is fitted to the straight arm D, Figs. 1 and 5, by a steel piece, $\frac{1}{2}$in. wide and 2in. long; the depth of the metal is a little less than the projecting piece, screwed with a steel nut on the end E, Fig. 5. This is made to adjust up and down, to admit of the connecting-rod F, Fig. 5, being raised to the height of the slide-rest screw; the metal C has in the centre a steel socket, fitted to it, with a collar, G, on it, to form a shoulder bearing; it is made taper, to fit the hole in the metal, and has a steel nut, H, on the other end; also a loose steel washer, which is screwed tightly against the face of the steel socket, and so forms a bearing, the socket revolving freely between the two shoulders G and the face of the washer in front of the nut H. It will be seen that the long connecting-rod F passes through this socket, and is fixed in the desired position by the square-headed screw, and I find that it is an improvement to have a long V-slot made in the rod into which the point of the screw should fit; this effectually prevents any chance of the rod moving without carrying the wheels with it.

I have had the whole of the lathe-head engraved, in order to show the apparatus as arranged, also to illustrate the oval chuck at work; the latter being on its place will show clearly how it works in conjunction with the spiral apparatus, and as this head has the segment apparatus fitted to it, it forms a second subject in one article, which will save the space at another time. Before describing this latter, I will finish spiral, however, in Fig. 5, the side view of the chuck, Figs. 2, 3 and 4, A being the back, B the tangent-frame, C the tangent-wheel, the large wheels being tightened on to the chuck by the steel nut and washer, seen more plainly in B, Fig. 3, K, Fig. 5, being the screw with a milled head to fix the tangent-wheel in or out of gear. There is a great advantage in being able to do this, as it saves a deal of time if the wheel is required to be divided into, say, four or six; but where a much larger number of divisions are required, the tangent-screw must be used, one turn of it being equal to one division on the face of the wheel. The joint L, before mentioned, is composed of three separate pieces: in the first, that fixed to the rod, a semicircular piece, is fitted to move freely, and works upon two small steel centres. In the centre of this the ball attached to the loose piece is also hung upon two steel centres at the opposite sides. This latter piece is bored out to fit on to the end of the slide-rest screw, and it has a hole bored through both, and then broached taper, and the screw is turned down, just leaving sufficient screw to take effect on the outer part of the steel and the plain part fitting the taper hole. A plain pin would answer the purpose, but a screw is always preferable to having to tap out a pin with a hammer. When not being used, the rod may be pushed right home to the socket out of the way, the radial arm raised, the arbor taken out of gear, and the chuck may be allowed to form the collar to keep the mandrel in its place instead of replacing the steel cap, so that, as I have before said, the apparatus need not be taken down. If not likely, however, to be used for any considerable time, perhaps it is as well to do so; but it will not be found in the way if left on. I think there is little left to be said upon this except that should anyone desire to do so, it can always be seen, and further explanation obtained at my works.

Having so far finished, I will now proceed to give the various details of the segment apparatus as seen in the engraving. On the back of the pulley a projection is generally left for the purpose of adding this at any future time. The segment-wheel O, is turned out to fit on this projection, and is fixed to the pulley by four steel screws, the plain parts of which should fit well. The wheel is cut in the same way as all other tangent wheels, which method I have explained before. It has 180 teeth, and is divided on the edge to the left side at every tooth, and figured at every tenth division; on the side the segment holes are drilled, generally 72 in number, and about 3-16th in diameter. Before fitting in the pins every hole should be made slightly taper, and the best way to do this is to make a taper half-round bit with a stop to it, to insure every hole being exactly the same size; the pins should have a small round hole in the end to facilitate their removal; and having used this apparatus, be sure and take them out before putting on the foot-band, or some damage may be done. The pillar is made in iron from a forging, and fixed so that the side of it will be close to that of the wheel. When fitting this up, the cast iron must be filed away to get a flat bearing for the pillar to go against, and should be fixed firmly to the cast iron with a steel screw S, and it is better not to finish shaping it until it is so fixed, and the two stop screws T are in their places. In the top of the pillar a hole is tapped through, and two screws as seen, one on the top, the other underneath; their object being to enable the distance of the segment being cut, to be compensated the distance of the space of the holes. This part done, we may proceed to fit up the tangent-frame, which is made either of steel or gun-metal, the length being the width of the frame. At the back of the head a space is filed out and a metal frame let in and fixed with a steel screw as in the case of the pillar, and this metal frame has in it two steel centre-screws, upon which the tangent frame works when placed in or out of gear, which operation is performed by an eccentric actuated by the square-headed screw. In the centre of this part of the frame a recess is cut out a

¼in. wide, and a steel eccentric fitted to it, sufficient eccentricity being given to allow it to throw the screw tightly into gear with the wheel; but when used it should be so adjusted that it will work freely with a winch-handle, in order to give a better bearing for the cam to work on. I always have a steel piece fitted to the cast iron: it forms a better bearing and wears better. On the top of the frame at the back a steel ball is screwed, through which a centre screw is fitted for the point of the main screw to work in, by which also it is kept against the metal shoulder. On the front of the screw a square is filed, and metal collars with different divisions are fitted; but I think one will be found sufficient, and that should be divided into 10: it will serve every purpose, and saves a multiplicity of different parts, which are seldom, if ever, used. I sometimes make the main screw to pass through double bearing, so that it can be worked from either side of the head. This is convenient; but not, I may say, necessary. In the centre of the head will be noticed two steel projections, which are for the purpose of keeping the tangent-frame steady. They are simply screwed into the cast iron and filed away, the side of each one until the frame fits well when working upon its centres. This will be found a most useful addition to an amateur's lathe, as it forms a means of holding the mandrel firmly while heavy cutting is being performed. One amateur told me that he found it exceedingly useful if a chuck got jammed on the nose, as he could fix the mandrel by it, while he forced off the obstinate offender; but I would beg of any one possessing it not to use it for such a violent purpose; but retain it in a state of perfection as long as possible for a better purpose. When using the dome-chuck, it will be found of great service, especially when doing heavy drilling.

The method of finding the Sidereal Time at Mean Noon for any other station will be found on p. 390 of Vol. XXXIV.

At 9 p.m. on July 3rd the Sun will be in apogee, or, in other words, the earth will be in that part of her orbit at which she is at her farthest from him. If we accept the Solar Parallax as 8·85″, we shall, at that instant, be separated by an interval of 93,910,166 miles from our great centre of light and heat. There will be no real night in any part of the United Kingdom until after the 20th. The usual indications of solar disturbance continue to manifest themselves.

The Moon

Is Full at 6h. 8·3m. a.m. on July 1st, and enters her Last Quarter at 9h. 51·8m. in the evening on the 7th. She will be New at 7h. 1·3m. a.m. on the 15th; enter her First Quarter at 10h. 17·5m. on the morning of the 23rd; and finally be Full, for the second time during the month, at 2h. 1·5m. in the afternoon of the 30th.

Occultations of (and near approaches to) Fixed Stars by the Moon.

Day of Month.	Name of Star.	Mag.	Disappearance.	Moon's Limb.	Angle from N. Point.	Angle from Vertex.	Reappearance.	Moon's Limb.	Angle from N. Point.	Angle from Vertex.

6	20·7	4	23·3	a.m.
11	25·7	8	45 2	,,
16	1·2	0	59·6	p.m.
21	6·2	4	31·5	,,
26	11·2	8	33·9	,,
31	16·2	*12	24·9	,,

* After midnight of the 30th.

The Moon will be in conjunction with Saturn at 5 p.m. on July 10th; with Jupiter at 2 p.m. on the 12th; with Mercury at 5 p.m. on the 13th; with Venus at 7 p.m. on the 18th; and with Mars at noon the next day.

Mercury

Is a Morning Star during the entire month, attaining his greatest elongation West (20° 5′) at 5 a.m. on the 20th. He may now be well seen in the east before sunrise. His angular diameter diminishes pretty rapidly from 11·6″ on July 1st to 5·8″ on the 31st.

Day of Month.	Right Ascension.		Declination North.		Souths.		
	h.	m.	°	′	h.	m.	
1	6	19·2	18	40·8	11	41·5	a.m.
6	6	10·7	18	43·7	11	13·4	,,
11	6	9·8	19	17·7	10	52·8	,,
16	6	18·2	20	12·0	10	41·6	,,
21	6	36·4	21	9·7	10	40·1	,,
26	7	4·0	21	48·7	10	47·9	,,
31	7	39·6	21	45·1	11	3·8	,,

As shown by the above ephemeris, Mercury never travels out of Gemini during the entire month. On the 14th he will be some 2½° south of μ Geminorum, and on the 26th in the same low-power field of view with δ. These are the most conspicuous stars he will approach.

Venus

Is an Evening Star throughout July, and may be seen after sunset in the West. Her angular diameter increases from 12·6″ at the beginning of the month to 14·6″ by the end of it. She is still gibbous, and forms by no means an interesting object in the telescope.

Day of Month.	Right Ascension.		Declination North.		Souths.		
	h.	m.	°	′	h.	m.	
1	9	1·7	18	47·3	2	23·6	p.m.

21	10	33·4	10	33·2	2	36·4	,,
26	10	55·0	8	10·5	2	38·3	,,
31	11	16·3	5	43·0	2	39·8	,,

So that Venus will travel from the most easterly portion of Cancer across a considerable part of Leo. On the evening of the 3rd she will be close to the 6th magnitude Star 83 Cancri. She will be rather more than 1° north of Regulus on the 14th, and about 1½° N. of ρ Leonis on the 19th. On the 27th she will be in the same telescopic field of view as χ Leonis. She will be in conjunction with Uranus (17′ N. of him) at 9 a.m. on the 30th. This is a month quite remarkable for the absence of the Major Planets from the night sky. MARS, JUPITER, SATURN, URANUS, and NEPTUNE being none of them visible. The Minor Planet

Juno

will, though, come into opposition to the Sun on the 18th, and may be seen by anyone who cares to regard a seeming 8th magnitude Star of orange hue.

Day of Month.	Right Ascension.		Declination South.		Souths.		
	h.	m.	°	′	h.	m.	
10	19	49·1	4	15·5	12	33·8	p.m.
20	19	40·4	4	53·5	11	45·8	,,
30	19	31·7	5	45·4	10	57·9	,,

Hence Juno must be sought in a perfectly barren part of Aquila.

Shooting Stars

Are more numerous than they were during the previous month. Watch should be kept for them especially on the 17th, 20th and 29th.

Greenwich Mean Time of Southing of Seven of the Principal Fixed Stars on the Night of July 1st, 1882.

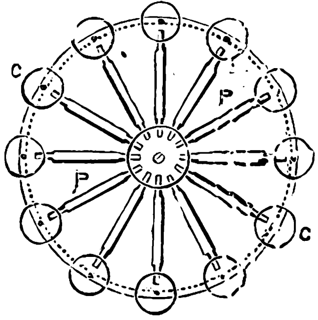
Star	Souths. h.	m.	s.	
δ Ophiuchi	9	28	54·87	p.m.
Antares..	9	42	53·97	,,
a^1 Herculis	10	29	51·07	,,
α Ophiuchi	10	49	59·18	,,
γ Draconis	11	14	19·50	,,
Vega	11	53	17·86	,,
δ Aquilæ	12	39	46·83	,,

The Method of ascertaining the Greenwich Mean Time of Southing on any other night in July of either of the stars in the above List, as also that of determining the instant of its Meridian Passage at any other station, will be found on p. 392 of Vol. XXXIV.

BARNEY'S IMPROVEMENTS IN TELEPHONES.

AMONGST recent patented improvements in telephonic instruments we find as specially deserving of notice, those devised by Mr. W. C. Barney, of 53, Bernard-street, London, whose specification (No. 4905, 1881) describes several forms, the most useful of which have perhaps to be discovered; but excellent results have, we understand, been obtained with one form already tried. The invention comprises both transmitting and receiving instruments. In microphones heretofore constructed the quantity of electricity passing through them is extremely small, and represents an almost infinitesimal part of the electric power emanating from the source of electricity employed. The current which passes through a microphone used for telephonic purposes should be as great as possible, having due regard to the sensitiveness of the microphone to the action of sound-waves upon it, because the variations of the intensity of the current produced by the action of the sound-waves are in proportion to the variations of the resistance of the microphone. Various forms of microphone have been devised, some in which the variations of the contact-points of the several parts of the microphone are caused by means of a spring or springs, others by means of a tympan. The microphone invented by Professor Hughes is simple and effective. In a microphone constructed on the principle of Professor Hughes, the greater the number of points of contact the greater will be its conductibility, which is a great desideratum. The microphones devised by Mr. Barney offer the least possible resistance to the passage of an electric current, and, at the same time, possess the greatest sensitiveness to the action of sound-waves; consequently, the current induced in the secondary wire of the induction-coil, to the primary wire of which the microphone and battery are connected, has great variations of tension, and its action on the coil of the receiving instrument is proportionately great. In one form of the microphone, which we select for illustration, Fig. 1, a number of pencils, P, of hard coke-carbon, or other equivalent material, are used, the ends of the pencils being held loosely in blocks C of carbon. A block of carbon B, to which is connected one terminal of the primary wire of an induction coil, about one inch in diameter, and about half an inch thick, forms the centre of the series of blocks of carbon placed around at a distance of about two inches from it; this periphery of blocks is connected together by any good conductor, to which is connected one pole of a battery, the other pole thereof being connected to the other terminal of the primary wire of an induction coil. The centre block has a series of holes around its circumference, equal in number to the blocks surrounding it, and in each of these blocks is a hole, in which lies loosely one end of a carbon pencil P, the other end of which lies loosely in a hole in the centre block. Each pencil is covered with a metallic sleeve, which must not be in contact with any of the blocks; this metallic sleeve increases greatly the conductivity of the pencil, and also increases its specific gravity, both of these effects being advantageous. Another form is made with carbon pencils and carbon bars in the following manner:—Two carbon bars about half an inch thick, having a length proportionate to the number of pencils used, are placed parallel to each other about two inches apart. They have a series of holes in the sides facing each other, in which holes lie loosely, the ends of carbon pencils, thus connecting electrically the two bars of carbon, one of which is to be connected to one terminal of the primary wire of an induction-coil, and the other bar to one pole of the battery, the other pole thereof being connected to the other terminal of the primary wire. A third carbon bar may be added with carbon pencils connecting it electrically with one of the other bars; in this arrangement the two outer bars should be connected together by a good metallic conductor, to which one terminal of the primary wire should be connected, and the centre bar should be connected to one pole of the battery. In another form the patentee dispenses with carbon, and uses pencils of wood, bone, ebonite, or any equivalent suitable material, placing on each end of the pencil a small capsule of hard tin, or of any hard metal, preferably platinum; the capsules on each pencil are connected together by a metallic conductor, such as fine copper wire or tinfoil; the capsule ends rest loosely in similar capsules placed in holes in blocks or bars of wood, ebonite, bone, cork, or any suitable non-conducting material. The exterior surfaces of the capsules on the pencils are roughened, and the interior surfaces of the capsules in the holes of the blocks are also roughened. The connections of this microphone with the induction-coil and battery are made in the same way as above described for carbon microphones. In order to confine the movements of a microphone to the direct action exclusively of sound-waves, and to avoid any secondary movements of it which must occur when sound-waves act upon a microphone through the medium of a tympan or of any vibratory plate, which movements interfere materially with its faithful response to the sound-waves, the blocks or bars are firmly secured to a flat surface of a non-resonant, non-vibatory, sound-absorbing material, such as cork. This material may or may not form one side of a box made of the same material. If inclosed thus in a box, or not inclosed, the material on which the carbons are fixed must not be fastened to any other material, but should rest loosely in a narrow frame of wood or other suitable material, or it may be suspended in any convenient manner; when pumice-stone is used the bars or blocks may be clamped between two pieces of pumice-stone. The sound-waves may fall directly upon the carbons or other pencils, or upon the obverse side of the material to which they are fixed. The object of leaving the material to be kept in its place by its own *vis inertiæ* only is to allow the whole mass to be moved by the impact of sound-waves upon it. The molecular movement in these light, porous substances being much greater than in dense compact substances, will communicate to the fixed blocks or bars a much greater movement than denser materials would. Microphones thus attached to porous substances will be affected by the molecular movement in these substances, as well as by the movement of the mass, and there cannot be any compression of the carbon; but the effect of sound-waves upon it is to vary the surface contacts by a shaking or jolting, or molecular motion; it may be possible that there occur rapid makes and breaks of the circuit; but these, however, are so rapid that an undulatory current flows, corresponding faithfully to the sound-waves, which is not the case when sound-waves act on the microphone through the medium of a tympan or vibratory plate, because the vibrations of a tympan or plate produce secondary motions.

FIG. 1.



In order to protect a microphone from the secondary action of any vibrations which might occur when the fixed parts of a microphone are attached to the surface of any material whatever, the patentee attaches the series of blocks surrounding the centre block, Fig. 1, to a narrow flat ring of copper, or other suitable metal, and the centre block is attached to a narrow strip of wood, ebonite, or any non-conducting equivalent material, lying across the centre of the ring, to which its two ends are secured.

The efficiency of microphones constructed with pencils and blocks or bars depends in a great measure upon the angle of inclination which the pencils make with the perpendicular. When the pencils stand perpendicularly their *vis inertiæ* is almost entirely at their lower ends, and when they lie horizontally their *vis inertiæ* is equally divided between the two ends. In this latter position the force of the sound-waves necessary to overcome their *vis inertiæ* is the maximum force, and in the former position the force required to overcome the *vis inertiæ* of their upper ends is the minimum force; but the contacts there being very slight, the current passing through these ends will be very feeble, and consequently the variations of the current passing through the microphone would be very slight, inasmuch as the current passing through the lower ends of the pencils would be almost uniform. The greater the variations of the quantity of current passing through a microphone used in a telephonic circuit, the greater will be the effect on the coil of the receiving instrument; hence it is necessary that a microphone should combine great sensitiveness to sound-waves with the bearings of the contacts of its several parts so arranged as to present the greatest surfaces of contacts where the variations of the current are produced.

A microphone composed of from eight to ten pencils connected together for quantity, inclining at an angle of about 20° from the perpendicular, gives excellent results. The microphone can be placed in a box of wood, ebonite, brass, iron, or any suitable material, about one inch from one of its sides, in which there is the usual hole with a mouthpiece, care being taken to have a hole in each side of the box between the microphone and the side of the box to which the mouthpiece is attached.

In the case of telephones, the patentee asserts that a plate, or diaphragm, or tympan must be held in close contact with the pole or poles of a magnet, and the plate, diaphragm, or tympan need not necessarily be made of iron or steel, or of any material capable of inductive action, but may be of cork, wood, ebonite, glass, or brass. Words spoken in any good transmitting instrument are reproduced in a clear, loud, and distinct tone in his receiving-telephone placed in the same circuit with the transmitter.

The action of the magnetic force in his telephone seems (he says) to be of a totally different character from that in the Bell telephone, in which the magnetic force acts directly by attraction upon the plate armature, whereas the magnetic force cannot possibly have any direct magnetic effect on the plate or diaphragm when this plate or diaphragm is not made of any material capable of inductive action, nor with any such material attached to it. The diaphragm, tympan, or plate may be made of cork, wood, cardboard, ebonite, ivory, glass, brass, iron, steel, mica, or their equivalents, and must be held by a constant pressure applied upon its edges, corners, or points, as the plate is made round, oval, square, star-shaped, or triangular, against the spiral end of the magnet. One function of the diaphragm or plate seems to be to confine within a narrow range the molecular elongations of the magnet produced by the passage of an electric current through a helix encircling the magnet, and it doubtless serves to intensify the sounds emitted by the magnet at this time.

The patentee was led to use a spiral wire for an extension of the core in the helix on an electro-magnet, from the results of numerous experiments made with a thin strip of iron, having one end firmly secured to a board and the other end slightly bent over by a weight attached to it, with a helix placed on a strip of iron. When a current of electricity was sent through the helix, the strip of iron instantly made efforts to resume its normal position, and sounds were emitted during the passage of the electric current.

In constructing his telephones, Mr. Barney uses several combinations of a spiral wire with electro-magnets, the spring being sometimes continued around the core and fastened to the shoe.

In Fig. 2 a bar of iron or steel, which may or may not be a permanent magnet, has one end fastened to a shoe S of soft iron equal in weight to about five times the soft iron elongation E of the other end, on which is placed a helix H. To the end of this elongation is fastened a short spiral spring G of iron extending about one half an inch above the end of the core of the helix. The end of this spiral spring may be capped with a disc of iron or steel, D, the same size as the end of the core, or larger; or the terminating convolutions of the spiral spring may be wound in a plane gradually diminishing to a centre.

FIG. 2.

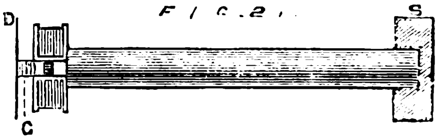


FIG. 3.

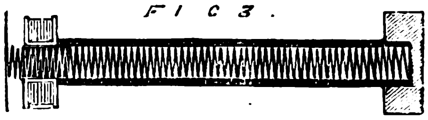


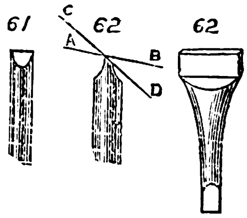
In another form, inside of a tube of iron or of steel, Fig. 3, upon one end of which is fitted a shoe of soft iron, is placed a spiral wire of iron or steel fastened to the soft iron shoe, the spirals being in close contact with the inside of the tube throughout its entire length, and extending above the end of the tube. On the spiral wire above the top of the tube is placed a helix, and a soft iron plug is placed inside the spirals encircled by the helix—the end of the spiral wire being arranged as in the first form. The connections are those usual with other telephones, and the cases may be of any suitable material.

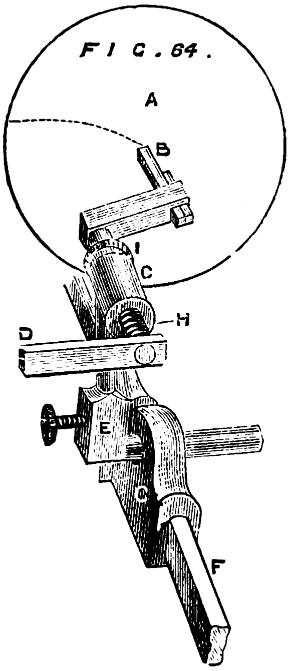
WATCH-CLEANING AND REPAIRING.

By "A FELLOW-WORKMAN."

(*Continued from page* 301.)

YOU must be careful and enlarge the right hole. As I said before, there are two barrels, but the *top* hole is always the largest, that would be the one nearest the chuck, and, of course, would be the last hole. Now you must see that the new bush does not protrude beyond the surface of the plate; to level it, use a tool, Figs. 61, 62, 63 instead of a drill; you must bring the rest up in front of the hole, and let the blade of the tool rest upon it to keep it firm; but for counter-sinking, you will find Fig. 64 a good substitute for a slide-rest. If you fix it firm and take pains in making it, it will do the work very well. A is plate in turns, B piece of a graver, C is a piece of tubing soldered on to a piece of brass wire; D is the handle for turning tool B, E is part of rest of turns, F body of turns, G part of rest, H wire-spring, I thumb-screw for putting tool deeper or fleeter, and works on a screw, so that you can cut any depth to a nicety. I think the drawing will sufficiently explain how it is made; but if any one who wishes to make one finds any difficulty, I will explain more fully.





Now to return to Fig. 53: B should be screwed on to the arbor, and the top hole should be larger than the bottom.

There are several different kinds of click-works: there is the circle-spring and dog, straight-spring and dog, the one as shown Fig. 51, and several common ones, but they are all more or less easy to repair, and as there is no particular rule attached to them, so long as they do their work and are firm, they will do.

Centre-wheel (F, Fig. 51): If the wheel breaks or is spoiled, you must send circumference and number of teeth, but it is difficult to get this unless you have a good gauge, so it would be best to send the old wheel. Fix the new wheel on a piece of plate with shellac, then fix plate in chuck, same as shown Fig. 54, and work by rule (Fig. 57), in the same way as explained for barrel. To put in a new pinion, get the length from shoulders, turn to fit wheel first, and then holes, place it on an arbor to turn it; but you will seldom, if ever, have this job to do; set square, and arbor can be bought in rough and only want fitting. The holes should be in the centre of the counter-sink, and you will generally find it so. I had one case where it was not so, but it was a common watch, and was made wrong in the first instance, and I think you may safely take the counter-sink in every case as a guide for your hole. If you have depth tools, of course, you can use them; but I have known jobbers to get wrong even then; however, we will suppose you have not got a depth tool and you want a new centre hole to pillar-plate: make old hole larger and "bush it," next place it in the chuck (C, Fig. 54), with the outside of the chamfer running true, then with your drill (H, Fig. 54) drill your hole.

I cannot say so much for the smaller wheels, as I have often found that they do not (in common watches) run in the centre of the counter-sink, but they should do; but to put new holes to 3rd, 4th, 5th, and top and bottom holes, you want a depth tool. I made a depth tool which answered very well, and I will give a description of it next week; but unless it is made with great care, it will be useless; a depth tool would cost about 12s. 6d.

(*To be continued.*)

THE ACHROMATIC OBJECT-GLASS.—III.*

By W. BRADBURY ("ORDERIC VITAL").

(*Continued from page* 344.)

DOLLOND, having found a remedy for the dispersion, could overcome the spherical error by practice. I have met with no account of the proportions of curves used by him, and it is probable that the calculations by which he found them, have never been published. But that he possessed a good knowledge of theoretical optics, will be evident from the following extract from a communication of his to the "Philosophical Transactions" for 1753:—

"If anyone would have the visual angle of a telescope to contain 20°, the extreme pencils of the field must be bent or refracted in an angle of 10°, which, if it be performed by one eye-glass will cause an aberration from the figure in proportion to the cube of that angle; but if two glasses are so proportioned and situated as that the refraction may be equally divided between them, they will each of them produce a refraction equal to half the required angle, and therefore the aberration being in proportion to the cube of half the angle taken twice over, will be but a fourth part of that which is in proportion to the cube of the whole angle, because the cube of one is but the eighth of the cube of two. So the aberration from the figure, where two eye-glasses are rightly proportioned, is but a fourth of what must unavoidably be, where the whole is performed by a single eye-lens. By the same way of reasoning, where the refraction is divided between three glasses, the aberration will be found to be but a ninth part of what would be produced by a single glass, because three times the cube of one is but one-ninth of the cube of three. Whence it appears, that by increasing the number of eye-glasses, the indistinctness which is observed near the borders of the field of a telescope may be very much diminished, though not entirely taken away."

The general construction of his double object-glasses was a double convex of unequal curvature—the shortest radius in front—combined with a double concave of similar character, with the longer radius posterior. This form is retained in the practice of the present day, with such alterations as the changes in the qualities of the glass have necessitated.

A difficulty appears to have been found in securing a proper balance of spherical error, owing to the excessive aberration of the convex lens; and as there were no theoretical rules for duly proportioning the curves, the task of final correction would doubtless be a very long and laborious one. This led Dollond to apply the same principle to object glasses, that he had recommended in the construction of eyepieces. Instead of a single convex, he divided the refaction between two convexes, and thus made his object-glass a triple by placing the concave between them. His son, P. Dollond, made a very many excellent instruments of this kind of various apertures and focal lengths. One of the earliest of these, of 46in. focus, was purchased by a French nobleman, who took it to pieces, and carefully measured the radii of the different lenses. As the foci are not mentioned, no inferences respecting the character of the glass can be drawn from the mere numerical radii: they were:—

1. Double convex.	2. Double concave.	3. Double convex.
1st radius 32·4	1st radius 22·2	1st radius 30·6
2nd „ 40·8	2nd „ 30·6	2nd „ 35·5

I have met with particulars of two other triplets by Dollond:—

No. 1.—FOCUS 46.

1. Convex.	2. Concave.	3. Convex.
1st radius 28	1st radius 20·9	1st radius 28·4
2nd „ 40	2nd „ 28	2nd „ 28·4

No. 2.—FOCUS 46·3.

1. Convex.	2. Concave.	3. Convex.
1st radius 28	1st radius 21·1	1st radius 28
2nd „ 35·5	2nd „ 25·75	2nd „ 28

Of his double o g.'s I have no particulars. About 5in. seems to have been the utmost limit of aperture obtainable at this period. Discs of good flint glass were very scarce, as its manufacture was not well understood, and any striæ or veins of unequal density rendered it useless for astronomical purposes. With regard to the glass used at this period, I am kindly allowed to quote from a letter of "our" excellent friend, "Prismatique."

"In Dollond's time, the crown-glass was generally made of the knot or part of the blown sheet where the pipe entered; they are now rare, as glass is rolled, not blown. The first mass of flint glass, out of which Dollond got some perfect object-glasses, was obtained from a firm now known as Powell's Whitefriars Flint Glass Works; it is very much the same as Chance's light flint in its refraction and dispersion."

As a conclusion to my short and imperfect account of the practice of the illustrious founders of the firm to which we owe the invention of the achromatic telescope, I will extract an interesting letter from Rees' "Cyclopædia." It is by G. Dollond:—

"The perfection of our object-glasses is in a great measure promoted by the great pains we take in selecting those glasses that suit each other the best, and also in adjusting them very carefully: yet that is not everything that is necessary to produce good object-glasses; they must be correctly worked, and the glasses be of perfect and proper quality.

"With respect to the surfaces used in our various object-glasses, it would be almost endless to enumerate them, as they depend upon and vary with almost every piece of glass that is used in their formation; and there are some nice points in the method of working them, which I should not wish at present to disclose. Our usual mode of proceeding is, in the first place, to calculate proportions that are requisite for the kinds of glass that are to be used, and then to select from our great number of tools those that come the nearest to the surfaces determined upon; and it frequently happens that we have not any that will answer, particularly for the spherical aberration. We do not enter into those very nice calculations that would be satisfactory to a theorist; we only aim at something near to what is required, for to practical men it is always more easy to produce what they wish by practical methods. Mr. Short, the celebrated maker of reflecting telescopes, used to proceed by first making his large metal as nearly correct or parabolical as he could, and then from a number of small metals to select by trial that which corrected the large one in the best manner.

"In all matters relating to the practice of optics, there is much uncertainty, and it frequently happens that with the very best endeavours, we cannot produce by the same means the same effect where extreme correctness is required, so that you may very readily conceive that very exact calculations, however requisite, will not always answer. In a rough way of taking the focal length and surfaces of an achromatic object-glass, composed of crown and flint glass of the usual densities, we should say crown, 1 to 3, and flint, 2 to 3; the outer surface of the crown shorter than that which is next to the flint, and the shortest radius of the flint next to the crown; and the nearer it can be brought without touching in the middle, the more perfect will be the performance, though this will, in a great degree depend on the aberrating power of the glasses used, for, sometimes we find it necessary to make the crown nearly of equal radii. The French opticians make the radii of the convex lens very unequal, and place the shortest radius next to the flint; and, instead of crown, they use Bohemian plate, which is nearly of the same refracting power, but of a different colour, their flint glass being of a much less specific gravity than the English.

"The great barrier to the further improvement, particularly in the extension of the aperture, is the want of good glass, which circumstance has ever been lamented; and from the excessively increased duties which act against the improvements of every manufacture, a prohibition is now likely to take place altogether."

After Dollond, the second great master of the art was Tulley. There does not appear to have been any very great difference in the practice of these distinguished opticians, if we may judge by a comparison of Tulley's curves, with the general account given in Dollond's letter. But his practice is the more interesting because he seems to have found the necessity of having some theoretical rule to guide him in selecting suitable curves for combination. The formula he employed, though necessarily an empirical one, gives results in close agreement with those yielded by much more elaborate methods; and was, therefore, quite near enough for a practical man. In his time the number of kinds of flint-glass was not large, and their refractive and dispersive powers were not widely different. The light flint glass previously spoken of was probably the most largely employed; as being of low specific gravity, it was the more likely to have the requisite purity for optical work.

(To be continued.)

ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.—XIII.*

(Continued from page 348.)

Making Gelatine Emulsion.

THE subject of gelatine emulsions and plates is one on which volumes might, and in fact have been, written, and here of course we can but give the briefest instructions. If the photographer succeed with these, he may with advantage take up the study of the advanced works which have been written on the subject. We do not propose to give the formula which has given the highest sensitiveness in our hands, but shall give one which has given us plates of fair rapidity, and of the very highest quality. The principal piece of apparatus necessary for making any number of plates is a drying cupboard or box. This is a box arranged so that the plates may be placed in it in such a position that a current of air passes rapidly over the surface of all of them. There are various designs of boxes, some of which are so arranged that the current of air is heated. This is not desirable if a fairly dry place can be had for the drying-box. The motion of the air is usually insured by burning a gas-jet at the lower end of a small chimney or flue. The defect in almost all drying-boxes that we know is that the air-passages are too small.

The other apparatus necessary is as follows:—

A large slab of plate-glass, marble, or smoothed slate, levelled accurately, so that the plates can be laid on it to set. The larger the slab the better, as more plates can be placed on it at once. A piece of coarse canvas or "scrim," such as ladies do worsted work on—say two feet square.

Several glass beakers or jam pots for mixing and boiling solutions in. The latter are preferable, as glass is very likely to be broken in the dark-room.

An ordinary hair sieve.

A vessel of such a size and shape that the sieve may stand in it, and that when it—the vessel—is full of water, the upper edge of the sieve will stand (say) half an inch above the surface of the water.

A large glass filtering funnel.

Several hock bottles. These, from their deep red colour, are useful for performing the various manipulations in.

An ordinary saucepan.

A Bunsen ring burner, on which this may stand to boil.

Let the following solutions be prepared, and each mixed in one of the jam pots.

A

Nitrate of silver	100 grains
Distilled water	2 ounces

B

Bromide of potassium	85 grains
Nelson's No. 2 gelatine	20 ,,
Distilled water	1½ ounces
A one per cent. mixture of hydrochloric acid and water	50 minims

C

Iodide of potassium	8 grains
Distilled water	½ ounce

D

Hard gelatine, such as that sold by the Autotype Company for dry-plates	120 grains
Water	several ounces

Let B and D stand till the gelatine is thoroughly soaked as indicated by its being quite soft. Let all the water be poured off D, and let as much water as possible be squeezed out of the gelatine.

The pots containing A and B must now be placed in hot water till the solutions are at about 120° Fahr., when B is poured into one of the hock bottles.

From this time all operations must be performed in the most feeble ruby light possible. A little of B is now added to the solution already in the bottle and the whole shaken. Small additions of B are made so that it is poured in five or six stages into A, the whole being shaken at each addition, and a very thorough agitation being given at the end. C is added, and the solutions, now forming an emulsion, are again shaken. The whole is poured into one of the jam-pots. This is placed in the saucepan, the lid is placed on the latter, and the water brought as rapidly as possible to the boil. A loose cover of some sort should be placed over the jam-pot during this part of the process to prevent condensed water from dropping off the lid of the saucepan into the emulsion. The emulsion is allowed to remain for half an hour in the boiling water. If, at the beginning of the process, a drop of the emulsion be placed on a piece of glass and a gas flame looked at through it, the flame will appear very red. The emulsion is said to be red by transmitted light. At the end of the boiling it will be a more or less near approach to blue in colour. At the end of the half-hour the gelatine D is placed among the emulsion, and the whole stirred to mix it. The can is then put in a cool and dark place to allow the emulsion to set. It will do so in from one to two hours on a moderately cool day, but it may be left for days if it be desired. This is the best period at which to break the process, which is somewhat lengthy to be performed at one time.

When the emulsion is set quite stiff the jam-pot is dipped for a few moments in hot water. If it be inverted the emulsion will fall out of the vessel in the same manner that a jelly for the table drops from its shape or mould. The sieve must meantime have been placed in its appropriate vessel full of water. The lump of emulsion is placed in the canvas, the whole is placed under water in the sieve, and the canvas twisted up, so as to cause the emulsion to pass through it in fine shreds into the water. It must now be washed for half an hour, either by allowing water to run into the sieve, or by frequently changing the water in the vessel.

The object of this washing is to get rid of the soluble nitrate and bromide, whilst the insoluble bromide and iodide of silver—the sensitive salts—remain in the emulsion.

At the end of half an hour the sieve may be removed from the washing vessel, and placed in any convenient position with one side somewhat tipped up, so that all superfluous water may drain off. The draining should go on for at least half an hour. At the end of that time the emulsion is finished, and only requires to be filtered. We have found nothing better for this than several folds of cotton such as pocket handkerchiefs are made of.

Three-quarter of an ounce of alcohol is now added, and the emulsion is ready to be used for coating the plates. The quantity will be about six or seven ounces. It may be kept in one of the hock bottles, wrapt in brown paper. A small earthenware teapot is the best thing to pour the emulsion on to the plates from. It should be very small; such a one as holds a few ounces, and is used by children at a "doll's tea-party," will do. The smallness of this allows a constant check to be put on the quantity of emulsion given to the plates by counting how many are coated by each fill of the teapot.

The glass plates must be thoroughly cleaned before before coated. This may be done by dipping the plates in a 5 per cent. mixture of nitric acid and water, then rubbing them under the tap with a wet cloth, and afterwards drying with a dry cloth. If they have been coated with emulsion before, they should be left at least twenty-four hours in the dilute nitric acid, and then rinsed with hot water.

Let us suppose the plates ready to coat. The dark-room lamp is placed within a few inches of the right-hand end of the levelling-shelf, and at back of it. To the left of the lamp is the pile of plates; to the right a glass measure or jam-pot or other convenient vessel, in which to stand a glass rod to be ready to hand. The glass rod should be about two inches longer than the breadth of the plates to be coated. Immediately in front of the lamp is placed the teapot full of melted emulsion. A plate is taken from the pile. It is placed as far forward on the levelling-shelf as possible, and in front of the lamp.

A pool of emulsion, about half-covering the plate, is poured from the teapot. The glass rod is taken between the fingers and thumb of each hand, and dipped into the pool of emulsion right across the plate. The emulsion will run between the rod and the plate to each edge of the latter. By a motion of the finger and thumb of each hand the rod is lifted the smallest possible distance from the plate, and is rapidly moved first to one end, then to the other, the tips of the finger and thumb resting on the level table as a guide. This, if properly done, will cover the whole plate with emulsion; and if the plate be small—under whole-plate size—it is sufficient to slide it to the far end of the table to set. If the plate be large, the coating will not be evenly spread unless it is lifted, balanced on the tips of the fingers of the left hand, and gently rocked for a few seconds. By this method plates may, after a little practice, be coated with great rapidity. There is no need to wipe the rod each time it is used. Each ounce of emulsion must not be made to cover more than six or seven quarter-plates or three half-plates

The plates will "set" in a few minutes—that is to say, the emulsion will stiffen like a jelly—and will not run off the glass, whatever position it is placed in. They are now transferred to the drying box. They will take from six to forty-eight hours to dry, according to circumstances. When dry, they are ready for use.

If a very rapid emulsion be desired, the boiling may be continued for from one to two hours, the emulsion, after washing, be rendered neutral or slightly alkaline by the addition of about twenty drops of the ten per cent. mixture of ammonia and water, and be kept for a couple of days before coating the plates. We would strongly advise, however, that the beginner confine himself to a slow emulsion.

ELECTRICAL ACCUMULATORS OR SECONDARY BATTERIES.*

By Prof. OLIVER J. LODGE, D.Sc.

(Continued from page 347.)

SO far we have investigated the amount of chemical action in a Faure cell, when a given current is passed through it; but though this is important it is by no mends all that we want to know, for the same chemical action exactly will go on in every cell through which the same current is driven, and the chemical work which a given current can do is, therefore, essentially unlimited. But, of course, the more cells we have in series, the more driving power—or electromotive force—do we require to send the current through them; and the chemical work that can be done by a given current generator is determined, therefore, by its available electromotive force and current strength conjointly. In this respect chemical work is precisely in the condition of every other form of work, and, in fact, it cannot be otherwise.

Consider now, as our source of current, a dynamo-machine driven with the horse-power P. Of this power some is wasted in friction and in churning the air; another portion is spent in warming the exciting magnets and armature, while the remainder, which we will call p, is available for maintaining the current through the external circuit. What fraction p is of P depends upon the perfection of the dynamo, and indeed the ratio $\frac{p}{P}$ may be called its efficiency. We may, perhaps, surmise that a probable value for this ratio is as much as ¾, but it is not likely to be more. To measure p, we have only to measure the electromotive force in volts between the terminals of the dynamo and the currents in Ampères, which it is at the same time producing in the whole outer circuit, multiply the two together, and divide by 746. We will, therefore, take p as a known quantity.

Now take N Faure cells and arrange them, n in series and m abreast, so that they are equivalent to n cells, each m times the size of a single one. Of course $m n = N$. Let the resistance of each cell with its connecting wire be r ohms—the resistance of the leading cables need hardly be taken into account if they are thick enough to keep cool—then the resistance of the combination of cells is $\frac{n r}{m}$ ohms.

---

* Condensed from the *Photographic News*.

* From the *Engineer*.

To drive a current of C Ampères through this resistance would require an electromotive force $\frac{nr}{m}$ C volts, which we may write nrc, if we put c for the current passing through each of the m series of cells. But this electromotive force is not enough to maintain the current for more than an instant; for directly the cells begin to charge, they each exert an opposition force e, which must be overcome. This opposition e may or may not vary during charging; but it probably does not vary very much after the first hour or so, and it may be considered as not far off $2\frac{1}{2}$ volts. It can be measured by connecting an electrometer to the terminals of a charged cell momentarily disconnected from the charging circuit. No time must be lost in taking this measure, or its value will diminish, and if the cell is short-circuited it falls off rapidly—probably because of the consumption of the hydrogen alloyed with the lead. It is its maximum value which is active in opposing the charging current, and this it is which we agree to call e in volts. The whole set of cells will offer an opposition force ne volts.

If the cells are not uniform we must determine the *average* values of e and r, but there is every possible reason for turning out the cells from the manufactory as uniform as they can possibly be made, and afterwards keeping them uniform by subjecting them to precisely similar treatment. Hence, the practice of replenishing the power of a working battery by occasionally adding an instalment of fresh cells is not to be approved on a large scale, unless it is carried on with regularity, a fresh one being put on at one end and a comparatively worn-out one simultaneously taken off at the other by some automatic time-keeper.

It is well known in ordinary voltaic batteries that if any of the cells are different from the others in any way, we get all the disadvantages which such difference may cause, and scarcely any of the advantages; in other words, one extra good cell in a series of poor ones is lost, and its effect swamped; while a single bad one among good ones chokes the lot. It is only like the links of a chain after all. Any difference—whether in size, or weight of lead, or closeness of plates, or time of charging, or of standing, or of discharging, or any temporary short circuiting of one cell more than of others—if it can produce harm it will, but if it tries to do good it can't. Hence every difference should be avoided.

Well, we were going to write down the E.M.F. necessary to force the current C through each of the m series into which we have supposed our cells to be arranged while charging, and it is

$$E = ne + nrc$$

the first term overcomes the opposition electromotive forces, the second drives the current against the given resistance.

The whole energy expended per second is proportional to E and to the whole strength of current, C, or mc, and is

$$EC = mnec + mnrc^2$$

The first term represents the useful work done, or the energy expended in overcoming chemical affinities, and in storing the current; or at least it represents this on the hypothesis that all the chemical substances decomposed assist the storage by being ready to recombine and drive the current back again whenever called upon to do so, and not before. If the cells are allowed to evolve gas while charging, or to stand a long time after charging, these conditions are not fulfilled, and some of the $mnec$ is lost. Hence, in saying that $mnec$ represents the useful work, one means that it does so under the most favourable circumstances, or that it represents its maximum value.

The second term $mnrc^2$ is certainly all wasted and goes to warm the cells. The proportion between the waste and the useful is therefore $\frac{rc}{e}$; and this shows the great desirability of keeping the charging current c weak, as well as for having the cells large and of low resistance. The horse-power available as current we have supposed to be p, and $p = \frac{EC}{746}$; hence, we may write the foregoing equation thus (remembering that $mn = N$):—

$$Nc = \frac{746\,p}{e + rc}.$$

This represents the total amount of chemical action going on in all the cells put together, for the current c is passing through each, and chemical action proportional to c is going on in each, therefore the total chemical action is N c. Looking at what N c is equal to, we observe that p is fixed and c is beyond our control; so again we perceive that the only way of getting the most effect at the least cost is to keep rc small. Now the resistance of a large Faure cell and connections need not exceed, I suppose, ·002 of an ohm, and the charging current sent through it may be kept as low as 4 or 5 ampères if desired; hence, as the value of e is 2·5 about, it is quite possible to make rc almost wholly negligible compared with e. We shall thus get out of the given horse-power the greatest amount of chemical action per second that we possibly can, viz.:—

$$Nc = 746\frac{p}{e}$$
$$= 300\,p \text{ say.}$$

The equations of last week, expressing the amount of total decomposition on both sides of a Faure cell when a given current is passed through it, may be now modified to express the decomposition produced in a whole set of similar cells arranged economically and subjected to the utilised horse-power p for T hours, by simply writing in those equations $300\,p\,T$ instead of C T.

As far as here appears, the number of cells does not signify, for if more cells are used, less will be done in each, and conversely. But we have just seen how important it is to keep c small, that is, to charge with a very low strength of current; hence the more cells charged at once the better. It seems difficult to use too many. The limit in series is reached when ne is nearly equal to the highest possible electromotive force of the shunt dynamo—that is, the number n must not exceed two-fifths of the maximum electromotive force available, expressed in volts. But it may be nearly as great as this with advantage There seems no limit to m, the number of cells that may be joined up in multiple arc, and apparently the more the better. But the "lead" wires and the armature of the dynamo must be of very low resistance, or they will get heated if m is very large, even though c, the current through each set of cells, is small. Edison's bar armatures seem just the thing therefore, or some of those machines which are made for electroplating purposes. The wire on the field magnets should be very long, so as to magnetise them strongly without shunting off too strong a current, even though it is driven with the highest available electromotive force.

The highest available electromotive force is the difference of potential between the terminals of the shunt dynamo when they are disconnected from the external circuit, so that the whole of the current produced in the armature passes through the field magnets. There must be some connection between the resistance of the wire on the field magnets, and on the armature, and the number of cells which will give the most economical result, though it is not a relation that is obvious to common-sense; but it can no doubt be worked out if we set to it, and I will try next week. Meanwhile let us put in a convenient practical form part of the result of this week's article, viz., that if the best arrangement is adopted in every way, no waste being allowed, and no secondary or useless chemical action permitted, the total amount of any substance of "atomic weight" w and atomicity k that can be decomposed or liberated, as the case may be, by p horse-power utilised as current in any number of cells, each of maximum electromotive force e, is

$$\frac{746\,p}{e} \cdot \frac{w}{12000\,k} \text{ pounds per hour.}$$

which becomes for Faure cells, whose e is $2\frac{1}{2}$ volts,

$$\frac{p}{40} \cdot \frac{w}{k} \text{ pounds per hour.}$$

For instance, 2·8 p pounds of litharge can be peroxidised, and also reduced, per hour, by the horse-power p applied to this purpose and to nothing else. Of minium the amounts are 2·1 p reduced, and 4·2 p peroxidised; that is, 6·3 p pounds of minium may be acted on altogether under the most favourable circumstances. Thus, if 5-horse power are utilised as current, 31·5lb. may be acted on in an hour, or a ton in 71 hours. To form 120 cells, each containing 28lb. of minium properly distributed between the two plates, cannot take less than T hours, where $6{\cdot}3\,p\,T = 28 \times 120$; which for $p = 5$ gives $T = 106$. But if the cells contain 14lb. of minium on each plate they will take longer—viz., at the very least $800/p$ hours.

ALBUMINOID SUBSTANCES.

RECENT researches by M. Béchamp on albuminoid substances, form the subject of an instructive report by M. Dumas, drawn up in name of a Committee of the Paris Academy. The gist of it is as follows:—

Among organic substances are those designated by the common name of albuminoid or gelatine-yielding substances; the liquid and coagulable, as egg-albumen, blood-serum, plant-albumen, milk-caseïn; the solid, as blood-fibrin, fibrous matter of muscles; lastly, the tissues that can be transformed into gelatine, and gelatine itself, at once the most interesting and the least known. As they are neither volatile nor crystallisable, their determination presents the greatest difficulties. Thus, their specific characters have been little known, their elementary composition is puzzling, the products obtained from them by means of strong reagents are complicated, and attempts to represent their constitution by a formula have proved unsatisfactory.

There has been of late, however, such strenuous endeavour to understand these substances, and results so important have been arrived at, that we may regard it as possible, and even probable, that ere long the real constitution of the substances, and the accurate definition of their constituents, will be discovered.

Though these substances do not crystallise, though they are not volatile, and though, finally, they enter into no well-determined combinations with bases and acids, yet they have a characteristic whereby they may be certainly distinguished from other matters: this is the action which they exercise on the plane of polarisation of light-rays. By the study of this property of different albuminoid substances, M. Béchamp has been enabled to divide them into species, which, while not absolutely determinate and comparable to those presented by volatile and crystallisable bodies, yet, at least, offer the first important results with regard to an orderly distribution of these interesting products.

The importance of this inquiry appears from the wide distribution of these matters in the animal and plant kingdoms. And when one considers that the analyses of these substances have led to the conclusion that there are in their molecules no less than 500 to 600 atoms of carbon, hydrogen, or nitrogen, one perceives how widely these bodies are separated from those whose study furnishes the groundwork of organic chemistry.

The first task in study of this group of substances consists in splitting up of the mixtures found in nature, and isolation of the individual bodies having determinate characters, such as one may consider as specific and essential.

Egg albumen contains at least three substances: one is precipitated by basic acetate of lead; the second by ammoniacal basic acetate of lead; the third is not coagulable in heat, is soluble in water, and insoluble in alcohol, with the aid of which it can be separated from its aqueous solutions. The first two substances have the general properties of albuminoid substances; but the third belongs to the group of ferments, and liquefies starch. The rotatory power of these three products is, respectively, 34°, 52°, and 78° to the left, and M. Béchamp has studied the compounds they form with acetic acid and hydrochloric acid, in which case they behave as bases.

The ferment discovered in egg albumen explains some phenomena during the period of incubation. M. Béchamp was led to seek it in other albuminoid products, and a general idea of his researches may be had when it is stated that he has succeeded in splitting up all albuminoid matters into two or three definite substances which have the properties of albuminous matters, and into a well-characterised ferment. "Why," he asks, "are all albuminoid liquids accompanied by these ferments? What relation exists between the abundant, coagulable, animal matters, which seem meant to furnish material to the organs, and those ferments, present in small quantity, which imply the approaching destruction of the alterable compounds with which they occur? Whence come these ferments? Whither do they go? What *rôle* have they to fulfil? All these are questions undoubtedly of deep interest, for one observes the ferments in the blood-serum of all animals, in the white and yellow of eggs, and in milk,—*i.e.*, in all liquids destined for formation and renewal of our organs."

The property of blood-fibrin, made known by Thenard, of decomposing hydrogen dioxide and oxygenated water, M. Béchamp has been enabled to refer to a certain constituent of the fibrin—viz., to the granular insoluble residue obtained after treatment of the body with hydrochloric acid; the part that is soluble in the acid does not possess the property. This insoluble substance is still albuminoid, and it loses its power of decomposing oxygenated water on boiling in water, but retains it unaltered an indefinite time when kept cold *in vacuo*.

M. Béchamp further gives the results of his investigations in extraction of the best-defined substances from the following albuminoid bodies:—Egg-yolk, egg-white, milk, blood-serum, peas-meal, white mustard, chick-pea, nut, almond, gluten, flour, red-blood corpuscles, muscle-flesh, and the crystalline lens. Similar investigations are worked out in bone and cartilage, which yield gelatine and chondrin. Lastly, there is an enumeration of all ferments whose presence has been observed in the products named, with which they so often occur, and their properties are specified.

While M. Béchamp has been engaged in these labours, the albuminoid bodies have been carefully studied by M. Schützenberger and, subsequently, by M. Bleunard. These have coagulated egg-albumen, exposed it at high temperature for a long time to an alkaline base, and analysed the products. It is known that, under these influences, urea is transformed into carbonic acid and ammonia, and oxamide into oxalic acid and ammonia. The researches of M. Schützenberger have proved that albuminoid matters behave similarly, and take hydrogen from water, to give up the nitrogen as ammonia; on the one hand, more or less complicated acids are obtained, which remain in combination with the baryta used; on the other, ammonia and complex bases, arising from the splitting-up of the albuminous substances, and from the hydrogenation of the nitrogen compounds they contained.

There are, however (the report points out), some difficulties about this action of alkalies, as indicating the constitution of albuminous bodies: one connected with the condition of the nitrogren present; another with the fact that the experiments are with mixtures.

The view has long prevailed that urea is a product of the destruction of albuminous substances of the blood and the tissue, and that this urea represents either the last combustion-product of these matters through respiration, or that it is connected with successive decompositions of them by ferments. Both processes might lead simultaneously to formation of urea. However that may be, M. Béchamp was shown, long since, that the oxidation of albumen by means of permanganate of potash furnishes a certain quantity of urea. In the present memoir he has taken up the question again, and he shows that all albuminoid substances possess this property; he also indicates reasons why several chemists have not recognised this fact.

The Committee desired that the principal experiments and results described in M. Béchamp's memoir might be repeated in their presence, and they were able to satisfy themselves of their correctness by personal observation.

EDISON'S ELECTRIC RAILWAY.

THE bed of Edison's Electric Railway at Menlo Park is as yet unballasted, so that a ride over its two miles of length is productive of unpleasant jerks and bumps. From the building next to the workshop at Menlo Park, where the steam-engine and dynamo-electric machines are placed, a narrow plank walk leads across the field toward the woods in the rear. In this are the wires running from the dynamo-electric machines to the railway track, distant perhaps a quarter of a mile. Here the wires are noticeable, emerging from their casing and communicating with the rails. At first sight the track appears to differ from an ordinary railroad only in its gauge, which is three feet six inches. But a closer examination reveals three distinctive features. Where two rails meet they are joined together on the sides. On each side of the joint is a strip of copper, the ends of which are nickel-plated. Outside these strips are screwed on flat bars of iron, the inner surface being also nickel-plated. Thus the current of electricity passes uninterruptedly from rail to rail. As this cannot be done at the switches, however, thin plates of copper are placed underneath the ends of both rails, so that the circuit is not broken. The frog in the switches is left out of circuit. It is only about 3ft. long, and as the driving-wheel of the engine is 4½ft. in diameter the wheel passes over the frog with no perceptible interruption. Near the improvised engine-house, which stands a short distance above the point where the wires connect with the rails, and about a quarter of a mile from that end of the track, the one passenger car of the railway stood. The engine was running up and down the track, conveying Charles T. Hughes, the superintendent, and dragging a small platform car loaded with rails and ties. In appearance the engine is peculiar. If an ordinary engine were cut in two midway of the boiler, the forward half discarded, and the cab reduced in size, it would present a tolerably correct representation of the electric engine. Its length is 15ft., and the height to the top of the cab 9ft. Of course there is no smoke-stack.

When a reporter took a seat in the cab the flat car had been left at the lower end of the track. Mr. Hughes raised the lever of the armature switch and the engine started. The engine ran evenly at the rate of eighteen miles an hour. No arrangement had been made for running at high speed, as Mr. Hughes was using the engine simply in construction work, and it had been dragging loads of three or four tons. The four dynamo-electric machines at the central station were arranged in a multiple arc instead of in series, as is done to attain a higher speed. Two miles of the road have been completed, extending toward Plainfield, and a mile remains to be finished. At the lower end men were engaged in ballasting the track. The road runs from an engine-house over a trestle about 12ft. high, through a swamp, and then through some fields, where there are cuts. Thus far the engine has done all that was expected. Yesterday, and on several previous occasions, it has proved itself equal to the task of drawing loads as heavy as could be applied, considering the character of the road and rolling stock. On Wednesday, with the dynamo-electric machines arranged in series, it ran at the rate of 41 miles and 4,000ft. in an honr, the highest rate that has as yet been reached. The rate of speed is estimated by the number of revolutions of the armature in the engine. The engine can be readily started, reversed, and stopped. In the cab, where the steam gauge is placed in the ordinary engine, is the armature switch. Raising the lever sends the current into the armature of the dynamo-electric machine in the front of the engine. If the lever is horizontal the circuit is broken, and if the lever is pulled down the current is directed into the armature in such a way as to cause it to revolve in the opposite direction, and the engine consequently moves backward. Mr. Edison intends to use an electric brake, but at present, in order to stop, the circuit is broken and an ordinary brake applied.

In examining the engine more closely, the reporter found two sheet-iron doors in the sides of what appeared to be the boiler, so that an inspection of the interior was easy. In front is a dynamo-electric machine; running lengthwise are the two legs of a large magnet, and the remainder of the interior is occupied with shafts and belting. An interesting feature is the course of the current and its transformation into motive power. It is taken up from the rails by the rims of the driving-wheels, and passes through copper clamps to the hub. Rubbing against the hub is a copper brush at the end of a horizontal rod, which has the position of the connecting-rod of an ordinary engine. The current taken from the hubs of the driving-wheels by these brushes passes along the rods to wires which lead to the armature switch in the cab. From this switch the two wires are conducted to the armature of the dynamo-electric machine in front. This machine may be said to fulfil a double function—in absorbing and storing up electric energy as well as in developing it. When the armature and bobbins revolve the power is transmitted by belting around a pulley on the same shaft with the armature to a pulley on a shaft under the cab. Thence belting runs to a pulley on the shaft of the driving-wheel. From the armature wires two smaller wires run to the coils of the magnet placed horizontally in the engine. These are the field wires, and through them the magnet becomes charged with electricity, and exerts a controlling influence on the armature which receives the greater force of the current. Without this magnet the armature would receive the full power of the current and would become so heated as to be useless; but the electricity in the magnet, which can be increased or diminished at will, tends to draw the armature toward it, and in reality causes it to revolve.

The total weight of the engine is four tons. The road, three miles long, will soon be completed and ballasted. One central station for every ten miles of track is Mr. Edison's estimate, the current being sent through the rails for five miles on each side of the station. After elaborate calculations in the case of the electric motor as compared with the steam locomotive engine, Mr. Edison claims that the ratio of mean economy for both is 4 to 8·93, or $55\frac{2}{3}$ per cent. in favour of the electric engine.—*New York Tribune.*

THE RELATION OF APERTURE AND POWER IN THE MICROSCOPE.*

By Professor E. Abbe, Hon. F.R.M.S.

I.—General Considerations as to Wide and Narrow Apertures.

THE question of the relative values of high and low apertures has been much obscured by the one-sidedness with which it has been treated. One party of microscopists—the "wide-aperturists"—having recognised that high apertures are capable of exhibiting minuter details than low apertures, conclude therefrom that *all* microscopical work must be done with very wide apertures, and that low-angled systems are worthless. Another party, relying upon the fact that there are many cases in which low or moderate apertures perform decidedly better than wide ones, generalise this experience and deny that there can be any essential benefit in very wide apertures, asserting that all observations, with the possible exception of resolving diatom striæ, can be done as well with low-angled objectives. The premises of both these views may be said to be true, but true *under conditions* only; and by disregarding these conditions both parties arrive at conculsions which are equally remote from a proper estimation of the requirements of scientific work with the Microscope. [As some suggestion appears to have been made when the above paper was read as to my views having undergone a change, I beg to remind my readers that the views above explained are those which I have professed since 1873—the date of my first paper on the subject. My advocacy of wide apertures for *minute* objects appears to have been interpreted as an advocacy of wide apertures for all purposes—a misapprehension which I am at a loss to account for, as nothing I have ever said or written could justify any such a supposition. All the catalogues of Mr. Zeiss issued since 1872 give practical evidence of this, as the objectives there specified (and stated to be constructed according to my principles and under my direction) include no low and medium powers, *except with low or very moderate apertures.*—E. A.]

My view of the question is based on the following considerations:—

1. Every given degree of minuteness of microscopic detail requires a given aperture in order to obtain a complete (or perfect) image, i. e. an image which is a *true* enlarged projection of the structure, exhibiting all elements in their true form and arrangement. The minuter the dimensions of the elements the wider an apertures is *necessary*—the larger these dimensions the narrower an aperture is *sufficient.* Structures whose smallest elements are measured by considerable multiples of the wave-lengths of light are perfectly delineated with low or very moderate apertures, and their examination with wide apertures does not improve their recognition. On the other hand, if we are dealing with objects whose dimensions (or structural elements) are equal to a few wave-lengths only, even the widest apertures hitherto obtained will not afford complete or strictly true images, but will show these objects more or less incomplete or modified. This general principle holds good in regard to objects of every kind, regular or irregular, isolated particles or composite structures, because the physical conditions of microscopical delineation are always the same.

The obvious inference from this principle is that the widest possible apertures must be used for the observation of objects or structures of very minute dimensions, low and moderate apertures for relatively large objects.

It may perhaps be said that the objects of microscopical research do not justify such a distinction of large and minute, since the works of nature are always elaborated to the minutest details, all coarse objects being composed of smaller elements, and these of still smaller ones, &c. This is quite true in regard to the objects considered as natural things, but not as objects of scientific research. The interest of research is not always directed to the ultimate elements, but is as often confined to the consideration of the coarser parts, and in such cases the observer is not only allowed, but sometimes compelled, to disregard everything which is not connected with the scientific aim of his investigation. To observe every object in nature throughout, from alpha to omega, is the privilege of dilettante microscopy only, which has no distinct aim. There are many lines of the most valuable scientific research (e.g. the greatest part of all morphological investigations) which have not to deal with very minute things. This kind of work can be completely done with low or moderate apertures.

To recommend the application of wide-angled objectives for every branch of microscopy, as has been, in fact, done by excited wide-aperturists, is no more to be supported than it would be to recommend the use of a magnifier to a painter for inspecting the tree which he proposes to delineate.

According to what has just been said, the only benefit of greater aperture is that it is capable of delineating *minuter* things. Now minute dimensions require high amplifications in order that they may be enlarged to a visual angle sufficient for distinct vision. Low figures of amplification cannot render visible (at least not distinctly visible) details which are beyond a certain limit of minuteness. Even if they are delineated by the microscope, they would remain hidden to the eye for want of sufficient visual angle. It follows, therefore, that wide apertures will not be utilised unless at the same time there is a linear amplification of the image, at least sufficient for exhibiting to the eye the smallest dimensions which are within the reach of such an aperture. On the other hand, a high amplification will be useless if we have small apertures which delineate details of dimensions only capable of being distinctly seen in an image of much lower amplification. We have here an empty amplification, because there is nothing in the image which requires so much power for distinct recognition. In the first case (deficiency of power) the large aperture cannot show more than a smaller one; in the other case (deficiency of aperture), the high amplification shows no more than a lower would do. Consequently:—

> *Wide apertures when high amplification is required; low or moderate apertures when low or moderate amplifications are sufficient or cannot be overstepped.*

2. The utilisation of a given aperture depends in principle on the amplification of the *ultimate* image which is projected by the entire microscope to the observer's eye. Now one and the same amplification may be obtained in very different ways since it is the resultant of three distinct elements: (*a*) focal length of the objective, (*b*) focal length of the

---

* From the *Journal* of the Royal Microscopical Society.

ocular, and (*c*) length of the tube. Any definite number of diameters (say 1,000) can be obtained with a low-power objective (say a 1in.) as well, from a mere dioptrical point of view, as with a higher power (say ⅛-in.), by applying a sufficiently deep eye piece and a sufficient length of the tube. It is, however, well known that there is a great difference in the optical qualities of images which are produced under these different conditions. Forcing a high amplification from a low-power objective is always connected with a considerable loss of sharpness of definition of the image, owing to the magnification of the residuary aberrations, which are inherent even in the most finished constructions. It is, therefore, a well-established practical rule that a certain amount of amplification requires a certain power of the *objective*—higher amplification a higher power (shorter focal length) —in order to obtain the image under these favour-conditions which are necessary for their full effectiveness. This considered, the inference of the foregoing paragraph may be expressed in these terms :—

> *Wide apertures with objectives of short focal length ; low and moderate apertures with objectives of low and moderate power.*

As a detailed discussion of this subject will be found in the second part of this paper, it will be sufficient here to point out some notable facts of experience by way of example only.

With objectives of, say, 1in., and ½in., focal length, the lower and medium eyepieces in use will yield 40-80 and 80-160 diameters only. In order to obtain 150 and 300 respectively, very deep oculars (or an extra length of the tube) would be required. So far now as such objectives are intended for the lower powers mentioned above, an aperture of about 0·15 (18°) in the case of the 1in., and of 0·3 (35°) in the case of the ½in., are at all events more than sufficient for showing every detail which can possibly be recognised by the eye under these amplifications, and therefore wider apertures are useless. In point of fact, no observer will see anything more or anything better with similar objectives of say 0·40 (48°) and 0·75 (96°) respectively, than with the narrower angles indicated above, as long as the low and medium oculars are in question only. These latter apertures would require for their full utilisation, i.e. for convenient observation of the minuter details which are within their reach, amplifications of much more than 150 and 300 diameters. With well-made objectives of those apertures, such figures may be realised indeed, and details may be shown by means of deeper eye-pieces, which remain quite invisible with the lower angled systems ; but no microscopist can deny the inferior quality of the images obtained in this way if compared to those of equal amplification, which are obtained with these same apertures when the objectives have double the power and the oculars the half only. Structures of so simple a composition as diatom striæ may perhaps be tolerably displayed under such forced amplifications of low-power objectives, but with objects of somewhat irregular and complicated structure the deterioration of the image attendant upon a considerable enlargement of the residuary spherical and chromatic abberations by deep eye-pieces, becomes at once obvious even with the most finished objectives. In point of fact, no experienced histologist will ever use in ordinary work even an ocular amplification of the amount necessary for obtaining 100 diameters from a 1-inch objective or 200 from a ½-inch. He would be unwise if he troubled himself with inferior images whilst good images of the amplifications required could be obtained with equal, or even greater, convenience with objectives of the same apertures but half the focal length.

The above is an example of waste of aperture, or lack of useful power ; waste of power and lack of aperture are exemplified by every objective of excessively short focal length, e.g. 1-50 inch. Such a lens, even if immersion, cannot be made with an aperture of much greater numerical value than 1·0, in consequence of the technical obstacles arising with such very short focal lengths. Now the limit of an aperture of that amount is entirely exhausted, at all events with a power of 1,000 to 1,200 diameters, inasmuch as nothing of the real attributes of an object can be seen with that aperture under a higher amplification, which could not be as well recognised under the lower. A 1-50, however, will yield 1,500-2,000 diameters with the lowest eyepieces which are usually employed. The lowest attainable power is, therefore, an empty power already, and every useful amplification available with the aperture in question could be obtained under favourable conditions and with much less inconvenience by an objective of half the power, or even less.

3. The preceding shows that wide apertures can only be utilised in the observation of minute details, under high amplifications obtained with objectives of short focal length. Wide apertures are therefore useless when those conditions are not fulfilled, because in this case the same result could be obtained as well with low-angled systems. But as abundance *primâ facie* is no detriment, the foregoing considerations do not enforce any positive objection to the use of the wide apertures for every kind of work. There are, however, other points of view from which it becomes obvious that the application of wider apertures than can be utilised is not merely superfluous but is a decided disadvantage, inasmuch as they prevent the utilisation of some really valuable benefits which are the privilege of low and moderate apertures.

The first disadvantage results from the reduction of the depth of vision (or the "penetration" of the Microscope) which is connected with wide apertures. I have given in another place* a discussion of the circumstances on which penetration depends, and the formulæ which afford an approximate numerical estimation of the depth of vision in microscopic observation. These theoretical suggestions show (in accordance with the experience of practical microscopists) the reduction of penetration with increasing aperture under one and the same amplification, and especially when the amplification is not restricted to very small figures. Now there are many objects of microscopical research which do not require, and, indeed, do not even admit of high powers ; but demand for effective investigation as much penetration as possible. This is always the case where the recognition of *solid* forms is of importance, and, therefore, a distinct (at least a tolerably distinct) vision of different planes at once must be possible, whether the observation is assisted by stereoscopic devices or not. The greater part of all morphological work is of such a kind, and in this line of observation, therefore, a proper economy of aperture is of equal importance with economy of power.

(*To be continued.*)

ON THE PHOTOGRAPHIC SPECTRUM OF COMET (WELLS) I., 1882.†

By WM. HUGGINS, F.R.S.

ON May 31, I obtained a photograph of the spectrum of this comet, with an exposure of one hour and a quarter. On the same plate I took a spectrum of α Ursæ Majoris for comparison. The comet's spectrum on the plate consists of a strong continuous spectrum extending from about F to a little beyond H. I am not able to distinguish any of the Fraunhofer lines in this continuous spectrum The slit was rather more open than was the case in photographing the spectrum of the comet of last year; this would make these lines less distinct, but the lines G and H are well seen in the star's spectrum taken under the same conditions. We may, therefore, conclude that the part of the comet's original light which gives a continuous spectrum is much stronger relatively to the reflected solar light in this comet, than was the case in the comet of last year, and for this reason the Fraunhofer lines are not distinguishable.

Observations of the visible spectrum had already shown that the comet differs remarkably from the hydrocarbon type common to all the comets, some twenty, which have appeared since spectrum analysis has been applied to these bodies.

The photographic spectrum shows, as was to be expected, that this essential difference of spectrum exists also in the more refrangible region. The very strong ultra-violet group assigned to cyanogen is not to be seen on the plate, and the bright groups between G and *h*, and between *h* and H do not appear to be present.

The head of the comet was in sharp focus upon the slit, and the continuous spectrum with defined edges corresponds to the nucleus which in this comet was very distinct. In this continuous spectrum at least five separate places of greater brightness are seen, which very probably represent groups of bright lines, though they are not sufficiently distinct in the photograph to admit of resolution. That this interpretation is correct, seems probable, from the circumstance that these groups project beyond the strong continuous spectrum on one side. This side corresponds to where the light of the coma, on the side of the nucleus next the sun, falls upon the slit. We learn, therefore, that the light of this part of the coma consists for the most part in this part of the spectrum of these groups, as here on the plate only an exceedingly faint continuous spectrum can be seen.

It is not possible to measure with any useful accuracy the beginnings and endings of the groups, as they are too faint at these points. Measures as accurate as the circumstances would permit have been taken of the brightest parts of the groups. The wave-lengths of these brightest parts are :—
λ 4253
λ 4412
λ 4507
λ 4634
λ 4769

In the visible spectrum, the bright lines of sodium appear to have been strong, and it may be that some of the light of some of the groups may be due to this substance.

Prof. A. Herschel and Dr. von Konkoly showed long ago that the spectra of the periodic meteors are different for different swarms, and it does not seem surprising that we have now a comet, the matter of the nucleus of which under the sun's heat shows an essential chemical difference from the long series of hydrocarbon comets which have appeared since 1864.

Mr. Hind has kindly furnished me with the distance of this comet from the sun at the time the photograph was taken. The comet was then 42,380,000 miles distant from the sun, while the comet of last year was 69,420,000 miles when I obtained the photograph of its spectrum.

† Substance of note read before the Royal Society, June 15, 1882.

SCIENTIFIC SOCIETIES.

THE METEOROLOGICAL SOCIETY.

THE closing meeting of this Society for the present session was held on the 21st inst., at the Institution of Civil Engineers ; Mr. J. K. Laughton, F.R.A.S., President, in the chair.

The following papers were read :—

I. "A new Metal Screen for Thermometers," by the Rev. F. W. Stow, M A., F.M.S. This screen differs from the ordinary Stevenson in the following respects : 1. It is somewhat larger ; 2. It has a single set of double-zinc louvres ; 3. It is partially closed at the bottom to cut off radiation from the ground. The advantages claimed for the use of zinc louvres are : 1. The conductivity of metal causes the heat derived from the sun's rays to be distributed over every part of the louvres ; 2. The louvres being much thinner than those of wood, the circulation of air through the screen is not only much greater absolutely, but much greater also in proportion to the bulk of the louvres ; 3. The zinc louvres, therefore, are much more sensitive to changes of temperature than wooden ones. Comparative readings of thermometers in this screen, along with those in an ordinary Stevenson screen, were made during the summer of 1881. From these the author is of opinion that the Stevenson becomes unduly heated when the sun shines ; but this may be as much due to its small size as to the material of which the louvres are made. The thermometers in it are only 3in. to 5in. from the louvres at the back of the screen against 7in. to 8in. in the zinc screen. The roof, too, is single, and the box is open at the bottom. The author also says that there is no need to condemn all wooden screens ; but there does seem to be some reason to think that screens with metal louvres might be better.

II. "On the Effect of Different Kinds of Thermometer Cribs, and of different Exposures in Estimating the Diurnal Range of Temperature at the Royal Observatory, Cape of Good Hope," by David Gill, LL.D., F.R.A.S. Meteorological observations were commenced at the Cape Observatory in 1841, when the thermometers were placed in a well-ventilated crib, before a south window, through which they could be read. The buildings were unfortunately burnt in 1852. A small wooden house, with double roof, and affording a free passage of air, was then erected on the site of the old meteorological observatory. The instruments were placed in the middle of the building, and observations were recommenced on the same plan as before, and continued until the end of August, 1858. On September 1st, the thermometers were transferred to a crib erected in front of the S.W. window of the transit circle room. This crib is well ventilated, except on the side next the transit-room window; but the great mass of solid masonry in the immediate neighbourhood of the thermometers appears seriously to affect the range of temperature. For many years a Glaisher stand has been in use, and at the end of 1880 the author caused a Stevenson screen to be erected in its immediate neighbourhood. In this paper, the author gives results of observations made in the window, Stevenson and Glaisher screens, during the year 1881 ; from which it is evident that the exposure of the thermometers in the window crib gives a distinctly smaller, and on the Glaisher stand a larger, daily range of temperature than in the Stevenson screen.

III. "Some Account of a Cyclone in the Mozambique Channel, January 14th, 19th, 1881," by C. S. Hudson.

IV. "Rainfall of Frere Town, Mombassa, East Coast of Africa, 1875–1881," by R. H. Twigg, M.Inst.C.C., F.M.S.

Analysis of Arguzoid.—The following figures are the result of an analysis by Herr Hans von Jüptner of "arguzoid" :—Tin, 4·035 ; lead, 3·544 ; copper, 55·780 ; nickel, 13·406 ; zinc, 23·198 ; iron, trace. Its density is 8·109.

SCIENTIFIC NEWS.

THE death is announced of Dr. Hjaltelin, the distinguished physician of Reykjavik, so well known to all scientific explorers of Iceland.

The *Daily News* correspondent at Maritzburg reports the observation of a brilliant comet near the sun.

The bright line of sodium seen by several observers in the spectrum of Comet Wells has been traced by Dr. Hasselberg, of Pulkowa, to some distance in the tail.

The new Egyptian Minister of Public Works, Mahmoud Pasha Fallaky, is the director of the Cairo Observatory, and was specially deputed by the Khedive to observe the recent total eclipse at Sohag.

Prof. Johnstone Stoney gave, at a recent meeting of the Royal Dublin Society, an account of some experiments made by his son to determine, by means of indicator diagrams, the energy employed in driving a bicycle. The machine was an 'Xtraordinary, one of the upper links of which was replaced by a spring, a board carrying a paper being so placed that a pencil indicated the difference of pressure on the pedal. Prof. Stoney and his son have travelled about 2,000 miles since the beginning of the year, and the average amount of muscular energy required is found to be equivalent to 7·3 foot-pounds per minute, a great difference being found between rough and smooth roads, mud and stones, up-hill and down, and with or against wind. Experiment has shown, according to Prof. Stoney, that there is no actual dead point in the machine.

Mr. B. H. Thwaite, F.C.S., suggests the formation of a British Society of Textile Industry, on the model of that at Mulhouse, which has undoubtedly had a beneficial influence on the industries of Alsace. Such a proposal needs only the support of some of our influential manufacturers to become an accomplished fact.

The Royal National Lifeboat Institution, having, during the past 20 years supplied first-class aneroid barometers to its different stations with a success that has been highly encouraging, has determined to offer similar instruments at a small cost to owners or masters of fishing vessels. As the sole object of the Institution is to benefit fishermen, the instruments can be obtained only by bonâ-fide owners or masters of fishing vessels.

Dr. W. B. Carpenter is to deliver the next Lowell Lectures in Boston, for which purpose he will soon visit the United States, and extend his journey to Canada.

From Mr. C. V. Shadbolt, of Beechcroft, Chislehurst, we have a photograph taken from a balloon, at an altitude of 2,000ft., last Whit-Monday. The spot depicted is a little north of Stamford-hill Station, and the photograph, which in parts is sharp and distinct, shows the junction of the Enfield branch of the Great Eastern with the Tottenham and Hampstead line.

M. Louis Clerc's "Lampe Soleil" was exhibited on Saturday last in the vaults beneath the Royal Exchange. This lamp, it will be remembered, is a combination of the arc and incandescent systems, two short carbons of large section being inclined to one another at an angle of about 40°, with a piece of white marble held in a fireclay block in such a manner that it becomes incandescent through the heat emitted by the arc. The carbons and marble will, it is said, last for 30 or 40 hours without renewal, but the chief claims made for the lamp are that the light is soft and agreeable, while the absence of mechanism renders it the perfection of simplicity.

The Committee of the London and South-Western Railway Institute and Club purpose holding an Industrial and Fine Art Exhibition during September next. The Exhibition, which is "under distinguished patronage," will be on the same lines as that held at Westminster, and as the Institute possesses in its rooms at Brunswick House, Vauxhall, and the Lecture-hall adjoining, ample space for the display of exhibits, there is reason to hope that the exhibition will be highly successful. Forms of application and particulars may be had of the Secretary of the Institute, Brunswick House, Vauxhall, S.W.

A prize of £2,000, open to all, has been instituted by the French Government, to be awarded to whoever, in the course of five years following July 1 next, invents the most useful application of the Volta pile.

It has been lately proved by MM. Bichat and Blondlot that the plane of polarisation may be rotated by action of the current of discharge of a Leyden jar. A transparent body (heavy flint or sulphide of carbon) placed between a polariser and analyser, had a coil round it through which the current passed, and (the apparatus being arranged for extinction of the light), there was a sudden reappearance of light at each discharge. The authors analysed the phenomenon thus: A small mirror was rotated on a vertical axis before the optical apparatus, and the image in it of a vertical slit in the polariser, was watched through a telescope at each discharge. One thus sees a series of broad luminous bands, with narrower dark bands between, quite recalling the phenomenon observed with the light of the spark. In the latter case the discharge is known to be oscillatory, the bands corresponding with alternating contrary currents; and it was proved in the other case that the plane of polarisation is subject to successive contrary rotations; it oscillates about the normal position. (On turning the analyser one way certain images brighten and others fade, while the opposite rotation gives opposite effects.) Further experiments by a very sensitive method proved that the electrical and optical phenomena are simultaneous.

The wire rope railway system of Bleichert, of Leipsic, has lately been applied in Istria between the coal-mines of Vines, at Albona, and the small harbour of Rabaz. This is one of the longest lines of the kind in existence. Its total length is nearly four miles (6,100 metres), with a descent of about 753ft. (The greatest rise for the loaded waggons is 15 per cent., and the greatest descent 26 per cent.) The intervals between the supports vary between 66ft. and 500ft. The line crosses some roads, two streams, a cascade, and the head of a bay. The driving machinery is placed about the middle of the line; it serves only to set the line in work after long rest. During work, the motive force of the down-going loaded waggons suffices to draw up the empty waggons. The line is constructed for a daily despatch of 5,000cwt. The loading and unloading is done automatically. Before the terminal station, the waggons pass a steelyard. Three other lines, on the Bleichert system are being made on Austrian territory. The line at Aich (Carlsbad), constructed four years ago, is in constant work, and is said fully to meet requirements.

A new form of telephone, recently patented in Germany, is the Schward-Scharnweber telephone. (It is figured in the *Zeits. für Ang. Elect.*, No. 2, 1882.) A long, flat horseshoe magnet has, at the open end, four small iron cores, with conically wound coils round them, fixed with screws within it, so that the ends of the cores are close to the membrane. The ends of the coils are so connected that the induction currents strengthen each other. At the bend of the magnet a circular spring tends to press the magnet towards the membrane, and a screw fixes in any given position.

In a recent note to the French Central Society of Horticulture, M. Boizard recommends the vaporisation of tobacco-juice for destruction of insects in hothouses—a method he has successfully practised three years. A little of the juice is boiled about two hours over a small fire, then water is added, and the liquid boiled more energetically, till all is vaporised. No injury was observed even in the tenderest plants, such as *Adiantum*, *Blechnum brasiliense*, &c.; but if such be feared, while yet insects have to be got rid of, one may guard against too strong action by syringing (*bassinant*) during the operation. Flowers of orchids, &c., may be protected, if this be thought necessary, with paper-bags. Some of the insects fall on the ground, and one need not trouble about those remaining, for they are dead. The plants thus rid of insects are exempt from attacks for six months, at least as regards kermes and coccus. Pucerons, acarids, and thrips return sooner, and one must operate oftener for them; but less vigorous treatment will do. It is essential that the temperature in the hothouse be as low as possible. M. Boizard suggests that the method might be applied in open air, the vapour being distributed through a tube.

A series of experiments have been made by Herren Wolffhügel and Von Knorre with a view to explaining a fact observed by Koch, viz., that oil-solutions of carbolic acid are far inferior to aqueous solutions, of the same concentration, in disinfectant action. For a disinfectant to have full action, it must be able to fully penetrate the object treated; and water, by virtue of its greater capillarity, has doubtless the advantage over oil in this respect. Again, it was observed that carbolic acid was more freely given up by carbolic oil in water than by carbolic water in oil. This may be accounted for by the greater solubility of the acid in oil. How far this peculiarity of oil, and its less tendency to penetrate porous solid bodies and to mix with liquids, is to be regarded as the cause of the inactivity of carbolic acid in oil-solution cannot yet be measured, since one cannot tell how oil and water behave with regard to giving up carbolic acid to minute organisms. The authors consider, however, that oil should not, in general, be used as a solvent for carbolic acid where one aims at killing, within 24 hours, fungi adhering to water-containing bodies, solid and liquid, whether as spores or bacilli.

The French Meteorological Expedition to Cape Horn, recently organised, may be expected to make important additions, not only to meteorological, but to other branches of science during its year's sojourn in those inclement regions. Full directions as to meteorology are given in a paper by M. Angot (*Comptes Rendus*). The expedition will have a complete series of registering apparatus (for some instruments two series), so that direct hourly observations are considered unnecessary. Six a day will be sufficient, and the order is indicated. Among other matters, special attention is to be given to austral auroræ when they occur (a good many have been observed at Cape Horn); by means of photographs, sketches, measurements, &c., the phenomena will be fully observed. It may be here mentioned that while the French Transit Commission gave up the island of Cape Horn in the extreme south (though the most favourable from an astronomical point of view), on account of the uncertainty of the weather, and have fixed on the entrance to the river Santa Cruz, in Patagonia, instead—they have recognised the value of the opportunity this meteorological mission affords, and urged that instruments for observation of the transit on Dec. 6th, be supplied to its members.

The temperature which seems most favourable to the bacterium of the disease called *charbon*, is that of mammalia (37° C.). Birds, having a higher temperature (about 42°), do not take the disease under ordinary conditions. M. Pasteur, however, has developed it in fowls by lowering the temperature (keeping the feet in cold water). M. Gibier has now experimented with frogs, and finds that they "do not suffer after inoculation in the normal state; but if kept, after being inoculated, in water at about 37°, they may take the disease (five out of twenty did—most of the others died soon after immersion). The bacteria developed were remarkable for their great length, and this is attributed to the slowness of the circulation.

There has been a falling-off lately in the attendance at technical high schools in Germany. The number of students has diminished from 6,433 in the winter session of 1877-78, to 3,900 last winter; or 60 per cent. This is partly accounted for by the depressed state of industry; but, according to Prof. Grasshof, there is a superabundance of academically-educated engineers (*Techniker*), which has also, doubtless, to do with the result. The estimated annual number of these in demand in 1875 was 660; to this a total number of 2,300 students would annually correspond, and the number might be raised to 3,000, on including foreigners. Thus even the attendance at present is about 900 over the actual requirements. Prof. Grasshof thinks there are too many technical high schools in Germany—six would suffice—and too few technical middle schools.

IN districts where water is largely impregnated with lime iron tubes will not answer for locomotives.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor *of the* English Mechanic, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made Payable to J. Passmore Edwards.

*** *In order to facilitate reference, Correspondents, when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."
—*Montaigne's Essays.*

COMETS AND A COMMITTEE—MOTION OF SIRIUS—FORECAST OF STORMS—SUNRISE AT STONEHENGE ON THE LONGEST DAY—PROJECTING SOLAR ECLIPSES—DURATION OF AN ECLIPSE OF THE SUN—ζ HERCULIS—THE PEDOMETER—VIEWING THE SOLAR PROTUBERANCES—THE COMING TRANSIT OF VENUS.

[20212.]—Once more, I should like to ask "Penelope" of the *Birmingham Weekly Post*, the gentleman who "does" the science for the *Leeds Mercury* (or, in fact, any of the "good advertising mediums" of the Sunspot and Meteorological quackery) for information. Here we have had two large comets in perihelion within a comparatively few days of each other, and, coincidently with this, as cold and bitter a June as I remember—the Atlantic being crowded with icebergs, and snow having fallen in Scotland only last Monday! How is it, then, I would ask, that these two visitants of our system have so hopelessly failed to exert "considerable influence on the sun"? and that neither separately nor in conjunction have they "stirred him up, excited him, as it were, to action, and moved his latent heat and fire into unwonted energy"? Or, possibly, some member or members of the Brummagem "Committee," who investigate "Solar Physics" (for the benefit of one or more of their own number at Brompton), will supply this information, and so make a show of earning a part of the annual £500 of which the national pocket is picked for the maintenance of a wretched sham.

In reply to the question of "Paugul" (letter 20157, p. 328), the revolution of Sirius round a distant companion—or rather, as he says, about their common centre of gravity—supplies the only feasible explanation of the curious change in the observed direction of its motion with reference to the Earth.

I do sincerely hope that no one will follow the advice given by Mr. Gardner in letter 20163 (p. 329), and "look at Dr. Herschell's Weather Table" at all. It is a compilation of utter trash, and was repudiated by Sir William and Sir John Herschel successively. Moreover, as an illustration of the trustworthiness of your correspondent's own rules, it may suffice to note that we have had wind and rain enough, and to spare, at the beginning of June this year, instead of at the end of it. No one living can predict the weather in these Islands 48 hours in advance; and no vaticination of meteorological change for that or any longer period is worth the ink it is written with.

Mr. Stooke (reply 47032, p. 336) will find that the Sun will rise at Stonehenge on the longest day 39° 24′ 34″ to the North of East. I must invite his attention to the caution given to "Neo" in my letter (20150) on p. 326, should he employ a compass to determine this point.

I may tell "A. B." (query 47177, p. 339) that Loomis's "Practical Astronomy" does not give the means of finding the true time of New or Full Moon, but that it does give detailed and illustrated directions for graphically projecting the phases of a Solar Eclipse for any given locality. The method of constructing the maps of the passage of the Moon's shadow over the Earth, which are found in the *Nautical Almanac*, is very fully described indeed, in Chauvenet's "Spherical and Practical Astronomy."

"A. B." (query 47180, p. 340) should always mistrust the statements of Dr. Lardner with reference to astronomical facts when they are either uncorroborated by or opposed to the assertions of recognised authorities on that subject. Keith is correct as to the maximum duration of total darkness during a Solar Eclipse at the Equator. The famous Eclipse of August 17, 1868, was total in India for a little less than 7 minutes. It is the longest one of which any record exists.

I cannot help thinking that Mr. Herbert Sadler somewhat over-estimates the present distance of the components of ζ Herculis, in letter 20179 (p. 349). It will be observed that Mr. Muschamp Perry's measurement of this star, made as late as May 31st of the present year (letter 20181, p. 350), shows the stars to be only 1″ apart; but this estimate certainly errs in defect as much as Mr. Sadler's does in excess. I must persist in the belief expressed on p. 326, that 1·4″, or thereabouts, will be found to represent the present distance of this star very nearly indeed.

The Pedometer, concerning which "Don Carlos" puts query 47210 (p. 363), simply registers the numbers of steps, or movements of the body, made by the wearer. If, for simplicity's sake, we conceive the possessor of a pedometer to take a step of exactly one yard in length, then, by pushing the regulator either to the right or to the left, he makes 1,760 beats of the pendulum register one mile upon the face of the instrument—and so on. Obviously, though, if he were to make 1,760 vertical jumps, always alighting on the identical spot whence he started, his pedometer would record a mile, albeit he had never really advanced the fraction of an inch.

Mr. Loftus Wylde (query 47252, p. 364), will scarcely obtain any apparatus "at an accessible price," for directly viewing the Solar protuberances on the uneclipsed Sun; inasmuch as the only means of so viewing them is by the aid of a spectroscope of very great dispersive power, and by opening the slit widely when the red or blue parts of the Spectrum in which the well-known hydrogen lines are situated are in the field. Under such circumstances, a red or blue image of the prominence will be visible. The red end of the spectrum is that most frequently used for this purpose; and the eye should be further defended by a dark glass transmitting light of the same refrangibility as that emitted by the protuberance. In saying this, I am, of course, speaking of seeing the Solar prominences in their entirety. The way in which they are ordinarily observed is by the aid of the spectroscope, with a very narrow slit, which exhibits the bright lines of their component gas or gases superposed on the ordinary continuous spectrum. The star spectroscope made by Browning, the optician, answers excellently for this purpose with a small or moderate telescope, if such telescope be only equatorially mounted (so as to keep the image of the prominence sensibly stationary on the slit). My querist may study Proctor's little shilling book on "The Spectroscope," published by the Society for the Promotion of Christian Knowledge, with advantage.

Apparently "A Constant Reader" (query 47258, p. 365) does not regard the determination of the distance of the earth from the sun as of any "real practical value." Considering the fact that this distance is the unit of all astronomical measurements, supplies the sole means of determining the scale on which the solar system is built, and furnishes the solitary method of ascertaining the distance of the fixed stars from our system, astronomers, rightly or wrongly, regard an accurate knowledge of the solar parallax as of the greatest possible importance. As the time for the occurrence of the next Transit of Venus approaches, I will, with the Editor's permission, give some details as to the preparations for the observation of, and the method of observing, this phenomenon. This, however, can scarcely be done in a single paragraph in a hurriedly-written letter.

A Fellow of the Royal Astronomical Society.

ζ HERCULIS AS A TEST FOR 3¼IN. TELESCOPE.

[20213.]—Allow me to thank "F.R.A.S." and Mr. Sadler for the information they have been good enough to give with regard to the distance of the components of ζ Herculis.

I think it cannot fail to strike your astronomical readers, in connection with the question of the aperture necessary to divide certain difficult double stars, that it is quite useless to lay down any hard-and-fast rule in connection with this matter.

I think this is clearly shown by referring to some of the correspondence that has appeared in your journal during the past two years in connection with ζ Herculis.

For example, in your 31st Vol., p. 382, Mr. Sadler proposes this object as a proper test for a 3¼in. telescope; and, again, in your 32nd Vol., p. 278, Mr. Gardiner, a gentleman residing in the State of New York, actually states that he *has* divided this star with a 3¼in. object-glass. It must be noted, however, that Mr. Sadler assumes the distance of the components at that epoch (about 1880·49) to have been 1·5″; and if this had been actually so, there would have been nothing very remarkable either in Mr. Sadler's having proposed this star as a test, nor in Mr. Gardiner's having divided it. But it now appears (see Mr. Sadler's letter 20179, p. 349 of your current number) that in the middle of the year 1880 the distance was only 1·31″, and, therefore, beyond the reach of a 3¼in. aperture on theoretical grounds.

The next letter to which I would beg to call the attention of your readers is one written by your esteemed correspondent, "F.R.A.S.," which appeared on page 59 of your 32nd Volume, about three months after the date of Mr. Sadler's communication, above referred to.

Commenting on Mr. Sadler's letter, "F.R.A.S." expresses it as his opinion that no telescope of 3¼in. aperture could possibly divide this star at the time he wrote (1880·73), and in support of this opinion quoted his own failure to do so, using a very fine Dallmeyer achromatic of 4⅛in. aperture, power 400.

It appears from the above that, if Mr. Gardiner was not mistaken about his having actually divided this star with 3¼in., Dawes' rule, $\frac{4\cdot56}{\text{aperture}}$, is, in certain cases, not reliable. Again, that "F.R.A.S.," who, we all know, is an observer of great experience, should fail, about the same time, to divide this star, using a telescope of undoubted excellence, and the object being theoretically well within the grasp of his instrument, also tends to show the impossibility of laying down any fixed rule on the subject.

Referring to what Mr. Sadler says (letter 20179, page 349 of the current volume) as to the visibility of the *comes* of this star with a smaller aperture than 4in., I took the opportunity of a clear sky last evening (June 23rd) to test the question experimentally, with the following results:—4in. Cooke achromatic, power 225, aperture reduced to 3in. by a stop; *comes* just visible with close attention, and about in contact with the disc of primary. I then tried a 3¼in. stop, which made the *comes* rather easier, and gave a clear separation of the discs. The present distance is, however, according to Mr. Sadler, 1·55″, and therefore the above observations agree very well with the accepted theory on the subject. Had the distance been only 1·31″, I feel quite sure I should not have been able to detect the *comes* with a 3¼in. aperture. I am, therefore, forced to consider Mr. Gardiner's observation as a very remarkable and unprecedented one.

In my opinion, a close and rapid binary like the one under discussion is a most unsuitable one to be quoted as a test: at one time it is beyond the reach of a 4½in. telescope, and in a couple of years it can be divided by a 3in. Many beginners are unable to obtain the latest measures, and are, therefore, quite unable to judge as to what their instruments should show them at any particular epoch.

David Simms.

Limavady, co. Derry, June 24.

P.S.—Under date July 9th, 1876, in Canada, and using a 4½in. "With-Browning" reflector, I have noted this star as pear-shaped, with power 280.

WELLS' COMET.

[20214.]—Mr. Lane, in his interesting letter 20180, states that by the application of the graphical method he has seen reason to believe that a sensibly brusque change in the orbit of Wells' comet took place about April 23rd, and that such change would long remain undiscovered by the mathematical method. Now, in this latter assertion I cannot agree. Whatever accuracy the graphical method may possess, the mathematical must possess still more.

Such an alteration as Mr. Lane suggests can only be demonstrated by means of the mathematical method, carefully applied, making it clear that the path before and after April 23rd cannot be included in the same orbit. If Mr. Lane should do this, he will, I believe, be the first to point out the actual existence of anything of the kind.

I quite agree with Mr. Lane that such a change is quite possible from more than one cause as regards comets, and even—although to a less extent, owing to their small surface—planetoids may be found some day to exhibit such changes; perhaps also the major planets. **W. C. E.**

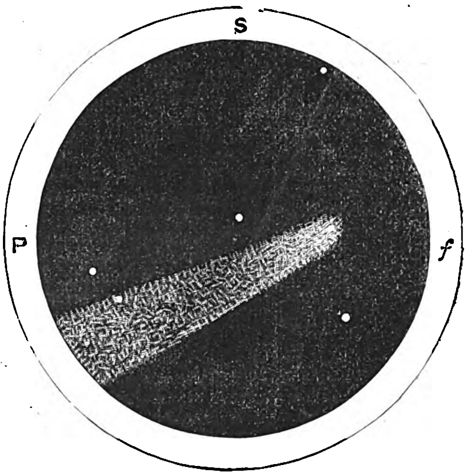
[20215.]—Being away from home for some weeks, I have not received my English Mechanic regularly, and, therefore, have been unable to reply to the remarks made by several correspondents with reference to my sketch of the comet as seen on the 13th May (letter 20037).

I think I can best reply to all by furnishing another sketch made on the night of the 20th May, when I had a most beautiful view of this interesting object.

Your valued correspondent, "F.R.A.S.," letter 20088, very justly remarks that my illustration, as it appears in the engraving, exaggerates the visible breadth of the coma in proportion to its length. It assuredly does so in a very disappointing manner. The fine shading off is utterly lost. Placing the nucleus on the edge of the field, I was able, on the 20th May, to trace the coma across the whole field of view, but so beautifully and so finely shaded off that I greatly fear be impossible for the engraver to do it justice in a wood-engraving.

May I take this opportunity of stating that a letter written to me from Oxford on this subject was accidentally destroyed before it came into my hands, and that, in consequence, I have not been able to reply to it? I very much regret this seeming want of courtesy on my part. **S. Mills.**

6, St. Mark's-road, St. Helier's, Jersey, June 19.



AN ENGRAVING-MACHINE.

[20216.]—SEVERAL years since a correspondent of the ENGLISH MECHANIC re-asked for the description of a machine for engraving. Frequent attacks of illness, and other circumstances, have prevented me from replying to the inquiry till now. About 60 years ago I constructed a simple apparatus of the usual kind, for taking silhouettes—viz., a brass rod passing through gimbals, and having at one end a wire for tracing over the profile, and at the other a pencil for drawing the silhouette on a piece of paper fixed to a hinged support, having a spring at the back to insure contact. This apparatus I converted, in 1872, into a somewhat rude machine for engraving. I forward a description and photographs for insertion in the ENGLISH MECHANIC, which may perhaps meet the wishes of your inquiring correspondent.

Fig. 1 is a photograph of one end of the machine, having a back or frame in which the words or figures to be copied are slipped. The figures, &c., are written on cardboard. This back is hollowed so as to curve the card according to the radius of the rod, and thus in some degree, at least, in one direction, to compensate distortion. The frame can be adjusted by the dovetail slide, so as to bring the tracing-point nearly into contact with the figures.

FIG. 1.

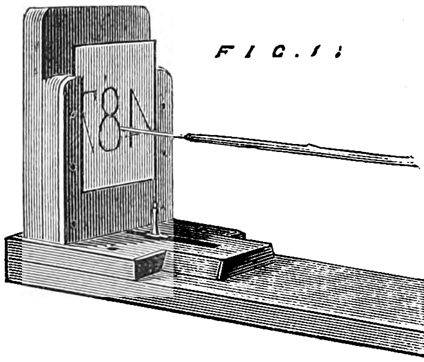


FIG. 2.

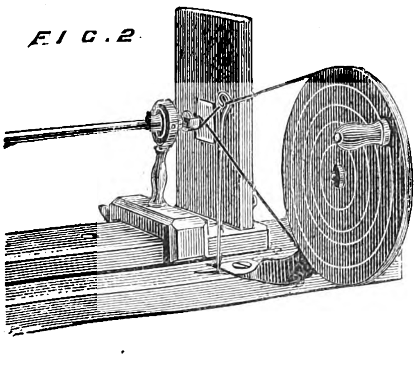

Fig. 2, which is supposed to be separated from Fig. 1 at some distance, in order that the representation may not be too large for your page, is a photograph of the other end of the machine, showing the rod passing through the gimbals, and carrying a small pulley and drill fixed to it by a brass frame. The pulley is, of course, driven by the large wheel and cord. The seal or metal, &c., to be engraved is fixed to a hinged back, and is kept in contact with the drill by the action of a spring behind.

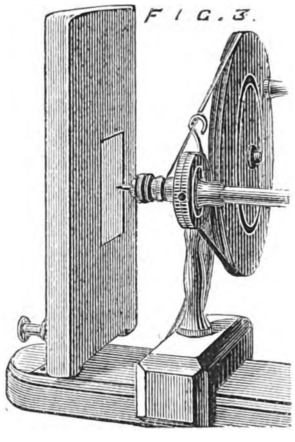
Fig. 3 shows the drill and pulley, &c., on an enlarged scale, and from the opposite side. The length of the rod (staircase wire) which I have used is 2ft. 9in.

FIG. 3.



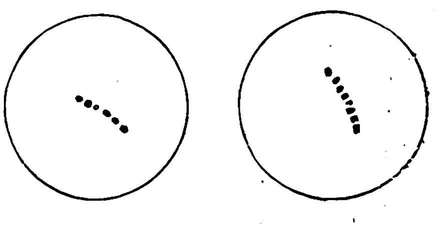
With this I forward a specimen of the work done by the machine, and also a zinc plate engraved by it, for the editor's inspection, to show the capability of so simple an apparatus. The elaborate and effective engraving machines of various makers are probably known to your readers. They are, in fact, pantagraphs, with attached drill. Your readers will also be aware that the exquisite microscopic engravings on glass by Peters are produced by a modification of the old silhouette tracer. In connection with the above subject, I may add that a simple, though rude, substitute for a pantagraph may be constructed on the above principle by merely supporting a light rod of wood (an arrow, for instance) on a pointed wire driven into a board, the rod having a tracer at one end and a pencil at the other. The subject to be copied is to be fixed to the cover of a book and brought into contact with the tracer by its weight, thus in some measure correcting distortion, at least, in one direction. The paper to receive the copy is also fixed to the cover of another book, and then in like manner meeting the pencil. An elastic band over the rod where supported by the pointed wire will prevent it from slipping.

N. S. Heineken.

TUBERCULOSIS.

[20217.]—As the bacillus of tuberculosis is engrossing such general attention at the present time, I send you the inclosed note and pictures (drawn with a camera from the microscope by Mr. Edgar Thurston), in the hope that, if published, they will interest a number of our readers.

The resolution into distinct beads, alluded to in the note, is an original observation. The lens was specially constructed for me by Messrs. Powell and Lealand, for the purpose of investigating micro-organisms, and may fairly rank as the greatest achievement in the science of microscopical optics.



The fine adjustment to the substage, referred to in the note, will be found most useful by those engaged in observations with wide-angled high powers.

THE ROYAL SOCIETY, Burlington House, June 21st, 1882.—Tubercle bacillus, showing beaded structure, from human sputum, × 2,300 diameters. Oil-immersion objective, by Messrs. Powell and Lealand, 1-25th, N.A. 1·38 (130° in glass). Microscope stand has a fine adjustment on the substage.

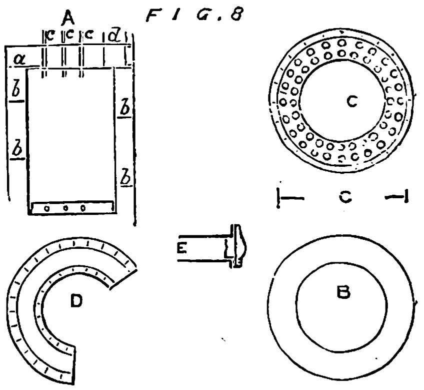
Edward M. Nelson.

THE TURKISH OR HOT-AIR AND VAPOUR BATH, AND THE SCIENTIFIC PRINCIPLES ON WHICH IT SHOULD BE CONSTRUCTED.

(Continued from p. 356.)

[20218.]—I REMOVED the cover of the large drum and fitted the small one inside it, so as to place it in the centre and have a space all round it. It only differed from Griffin's hot-air bath by being of a different shape and being constructed of different material. To keep the inner one in its place, I got a piece of thin sheet-iron, such as is used for making stove-pipes, and cut out of it a disc a little larger than the diameter of the larger drum, and out of the centre of it I cut out a circle 1½in. less in diameter than the smaller drum. This is so far illustrated in Fig. 8, A and B. My next step was to cut the edge of the large disc through, as shown on C of same figure, and to turn these snips alternately up and down; and by bending them out and in the disc was made to fit the inside of the outer case tightly. The next step was to rivet it to the bottom of the small chamber. Out of the same iron I cut three or four segments of rings, which, if complete, would have exactly fitted into the space between the two drums. These, as shown on Fig. 8, D, were rather over three-quarters of the circle. By placing them at equal distances apart, arranged so that the spaces in the ring left deficient, should always be over a portion that was perfect, they acted as checks to the passage of the heated air and products of combustion, and caused them to circulate round the inner chamber and heat the air contained in or passing through it. The outer surface of the big drum also yielded heat to the room in which it was placed by radiation. The disc at top, which I riveted to the top of the inner chamber, had a number of small holes punched in it. I next cut a hole 3in. in diameter in bottom of the outer drum—or, I might say, the top as it now

FIG. 8



A, two drums, one inside the other; △, inner chamber; *a*, iron disc shown in plan by C in situ in section; *b*, portions of rings shown in plan by D in situ; *c*, tubes through which the pure heated air escapes, shown also Fig 12; *d*, hole with flanged pipe to take stove-pipe; *f*, furnace, detail shown on Fig. 11; C, perforate iron disc; B, iron disc, before fitting and perforating; D, sectional stops to make air circulate round inner chamber; E, tube fastened in wall to take stove-pipe high up in bath-chamber.

stands in Fig. 8, and to it I riveted a gas-pipe of that diameter with a flange on it, which I also picked up for a few pence at the old iron-store; this was for fitting a 3in. stove-pipe, which served to convey the foul air and products of combustion to the chimney of the room through a hole made for that purpose through the wall. This hole was fitted with a similar flanged pipe, into which a plug, with a turned ornamental cover, fitted when the stove-pipe was removed. In rooms without a fireplace this could be passed through the outer wall.

I shall now describe my furnace, which I constructed out of an old gas-stove (see Fig. 9, A). I used it for long with the ring burner B; but after a time I removed the old ring burner and substituted for it one of Bunsen's burners as made by Griffin, and illustrated in Fig. 2 (974). I fitted the rose portion of this burner on an iron chamber, which fitted into the centre of the old gas-stove. This casting I made out of a casting from a pattern of my own invention, by which I was enabled to place the rose burner referred to in the centre, and when I required extra heat to light from one to three Bunsen burners with single flames, so arranged as to converge, and send a large volume of heat into the space between the two chambers. It soon burnt away the cover of the inner drum, into which I had fitted bent iron pipes, through which the fresh air from without was conveyed by connecting them by indiarubber tubes with the iron pipes, illustrated in Fig. 6, B.

FIG. 9

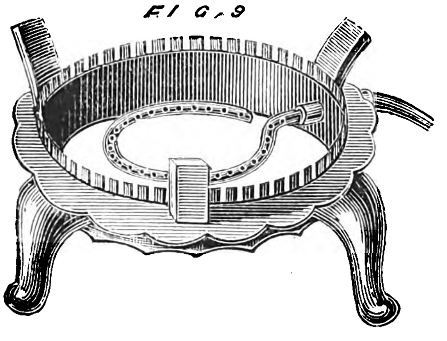


Fig. 9b.

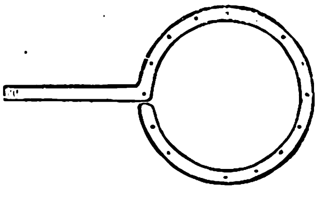


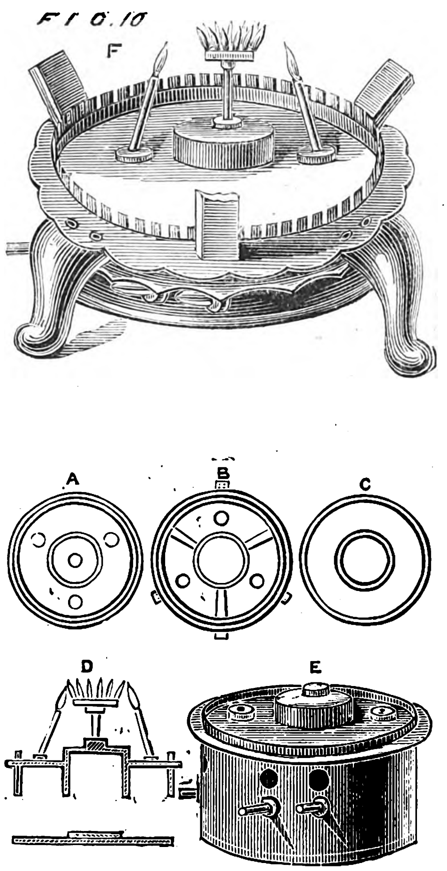
In Fig. 10 is shown the iron casting which made the chamber for the four burners. It was made in two parts, so that I could turn up the faces true in the lathe, and fit them together gas-tight. Each of the four burners had a separate supply of gas. With it any amount of heat could be procured; but I fancy it was very wasteful of gas, as during the time it was used the gas-bills were much higher than usual.

I have already stated that the bottom of the inner chamber soon burnt out. I replaced it with an iron casting which I had cast on three pieces of iron tube ¾in. in diameter. These were arranged parallel to one another across the casting, the upper portion of which was turned to fit tightly in the inner drum or chamber. It is illustrated in Fig. 11. A is a plan showing how the tubes were arranged; B is a plan showing its appearance from inside, and the holes for admitting the fresh air.

Through its inner surface I bored inch holes into each of the iron pipes through which the outer air passed into the chamber. This casting and its pipes could be made nearly or quite red-hot, but it should not be so—a lower heat is sufficient; it heated the air as it passed through. The stove-pipe had a damper for regulating the current, as the rose burner could be used alone with the smallest row of beads of gas visible, or with 12 large flames, and could also be supplemented by the three single-flame Bunsen burners, any heat from the mildest warmth to a heat far too intense for a bath could be produced at will.

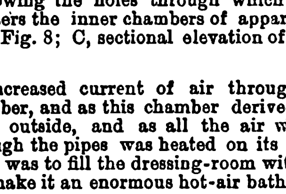
Having provided for the supply of pure air, I attached a long stove-pipe to the upper end of the outer chamber; this I led into the chimney of the room, as will presently be described, it acted like the chimney *c''* when fitted on *a* in Griffin's apparatus, already described and illustrated. The air which had warmed the inner chamber as it rushed through the chimney, created a draught which carried away the impure air of the dressing-room. As the doors and windows were carefully stopped and padded, the effect of this was to create an increased current of air through the inner chamber, and as this chamber derived all its air from outside, and as all the air which passed through the pipes was heated on its passage, the effect was to fill the dressing-room with heated air, and make it an enormous hot-air bath.

FIG. 10



A is a plan of the top of the gas-chamber, looking down on it, showing the four bosses to be drilled for the burners. B is a plan of the same from below, showing how the cylinder was divided into four separate chambers, so that each Bunsen burner might have its separate supply of air and gas; the bosses to be bored for the supply-tubes are shown (*a*). C is the plan of the lower casting, which fits into B; its section is shown at E. D is a section of upper casting, showing how the burners were fitted to it. E, elevation of compound burner, shown in section and apart in D. F, compound burner, fitted to gas-stove complete.

FIG. 11.



A, plan of furnace through which the air passes to be heated in part section, showing tubes imbedded in casting; B, inside view of casting showing the holes through which the hot air enters the inner chambers of apparatus, see △ of Fig. 8; C, sectional elevation of furnace.

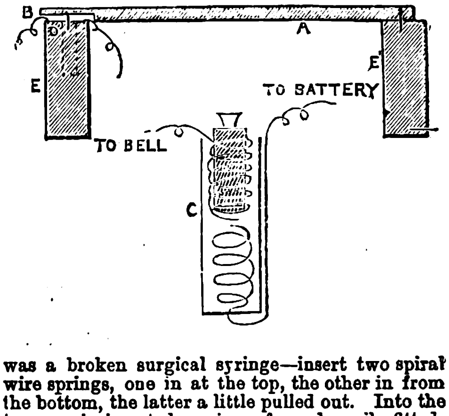
(*To be continued.*)

BURGLAR-ALARM PLATFORM.

[20219.]—I see that you notice in the Mechanic of the 16th a recent American invention, called a "burglar-alarm platform." I have had one in operation for some months, which is satisfactory, details of which might be of use to some of our readers, the mechanism being very simple and compact.

At the parts of the room required for alarming the burglar, a plank is taken up, and a piece cut off the length of the distance between two, or three, or more joists, with 3in. or 4in. extra. This piece, A, must be cut so that each end rests on a joist; it must be planed down at the side a little, so as to fit in easy, one end to be cut down as shown in sketch at B. I take a glass tube, C, nearly 4in. long, and, say, 1in. diameter—mine was a broken surgical syringe—insert two spiral wire springs, one in at the top, the other in from the bottom, the latter a little pulled out. Into the top one is inserted a piece of wood, easily fitted, with a screw to regulate the movement of the higher spring. A hole is made in the joist E with a centre-bit 1¼in. diameter and 4in. deep, in which is fixed the tube C. The action is as follows:—On the floor being depressed by a person stepping on it, the screw which should be touching the floor underneath is pressed into the tube, the pencil of wood attached to it pushing the spring down, making contact with the lower spring, causing a bell to sound, which, if made continuous-ringing, will be an efficient burglar-alarm. This alarm is very easily made, and not liable to get out of order, the two springs reducing disarrangement of those parts to a great degree.



J. W. Fisher.

A DOUBLE TRICYCLE.

[20220.]—I would by no means advise "A Littlemore Mechanic" (letter 20177) to construct his tricycle to carry the riders abreast. This method, I think, will prove itself unsound, and quite go out, except for machines to carry four persons.

I have an idea as to the position of a second rider which I could scarcely state at length in these columns, but shall be glad to hear from "A Littlemore Mechanic" at my address here.

Winslow, Bucks. **W. H. French.**

GAS-ENGINES—ELECTRO-MOTORS.

[20221.]—I have chosen the subject of gas-engines in order to show to our two correspondents who have made calculations on my projected electro-motor, that they may be quite right "according to Cocker," and that yet, when an experiment is made in a different way, they may find out that their calculations have only been dealing with part of the truth. Let us assume they are testing power of a certain sized cylinder as a gas-engine. A proper amount of gas and air is admitted, and then exploded; they find this equal to so many pounds lifted so many feet high, and adding power lost by friction, might say this was one horse-power, and quite right too, as far as the truth had been ascertained on the matter. Let, now, the gas and air, previous to explosion, be compressed to a certain degree; they would then find (after deducting the power used to compress), that instead of one horse-power, three horse-power had been developed. But where has this power come from? At all events, we may be satisfied that that power had been latent in the gas and air; otherwise it could not have been given out. But our first experiment did not develop all the power existing in the mixed gases, neither can we measure the possible extent of power therein, until the utmost possible extent of compression is ascertained also. Then again, take chloride of nitrogen: here, to make this, we place a jar of chlorine gas over a solution of chloride of ammonium; the gas is absorbed, and a drop of liquid like oil is found to have formed. Take this, touch it with a certain substance, a most fearful explosion ensues, and no compression has been used. Now calculate the value, in power, of the two ingredients, used in the way of ordinary combustion; how small a fraction would it be of the explosive power referred to? So much for calculation. It seems to me not unlikely that substances containing nitrogen will yet furnish "the power of the future" under proper management; for explosion is supplementary to the ordinary calculations on combustion.

To return to the electro-motor, all I contend is, that to use the direct power of the electro-magnet (if practicable), must be more economical than part of the power delegated to an armature, or other extraneous body of iron.

Barry-road, S.E. **J. H. Huxley.**

VARIATIONS OF SPEED ON STEEP GRADIENTS.

[20222.]—The following timings of two of the up Midland expresses during last summer may prove of interest, as showing the difference of the running of a heavy train up steep gradients as compared with that of a light train, and the slight variation in their times down bank. From Luton the driver of the light train had time well on hand. Like many other correspondents, I should be glad if "C. E. S." could see his way clear to give us a diagram of the gradients on the Midland, and if you, Sir, would let it appear in our columns.

MEDICAL REPLIES.

[20223.]—(17212 and 47237.)—Each querist will probably find help from five drops of "Fowler's solution" taken in water twice a day (after the first and last meals). The drops must be measured accurately, and if the medicine disagrees, it must be left off. Otherwise it may be taken for some weeks, until disagreement occurs, or the disease is relieved. "Whitesmith" should eat less flesh food, and more vegetables.

(47224).—Probably a form of rheumatism of the tendon or bone, which will be relieved by taking five grains of iodide of potassium, and five grains of bicarbonate of potash twice a day in water.

Deafness (47239). — Unless querist has an accumulation of hardened wax in his ear, he had better put up with his infirmity. The best treatment for hardened wax is first to soften it, and then to wash it out with a finely-pointed syringe, so held as not to injure the membrane of the ear, which is stretched across the bottom of the passage like the head of a drum. To soften the wax use a mixture of half sweet oil and half paraffin lamp-oil, and instil ten drops into the ear every night for several nights running. Follow this by syringing out the ear with comfortably warm soap and water before going to bed. The passage of the ear should be quite clear down to the membrane, which is nearly an inch inwards from the external level, and can be distinctly seen like a disc of thin parchment when the ear is held gently open, and a good light falls into the passage. This is practically all that can be usefully said in regard to deafness and noises in the head, and cases not curable by skilful syringing after softening obstructing wax, rarely get much benefit from medical treatment. It is most unlikely that querist will get, by coming to London, any benefit which cannot be given by one of the best doctors in Worcester.

Weakness (47253). — Querist is probably a nervous, worrying fellow, much given to introspection and thinking of his ailments. Among such patients, there is a regular class who may be described as "worriers"—people who, although there are always plenty of other people to worry them, must take to worrying themselves and worrying every one around them. Such men are never any good until they stop reading medical books, and what they call "studiousness," and take to methodical, thorough-going *work*, and "do something." Many such men have a propensity for preaching; others—who have not time or strength to keep their own business going, to insure their lives for their families in case of their own premature death, or to build themselves up a permanent and comfortable home, instead of making the Sunday a "day of rest," can not be content without figuring in some didactic office on that day, instead of fitting themselves by rest and recuperation for doing their next week's business like model citizens. Read Carlyle, and avoid running to wind and tongue. Querist used "diagnosis" where he should use the word *description*, and this is a symptom of just that kind of "studiousness" which tends only to muddle-headedness.

Grafton-street, Bond-street.

WILDBAD AND ITS CURES IN THE BLACK FOREST.—II.

[20224.]—To-day I am face to face with phenomena which entirely baffle my reason. Here is an instance. A man, wounded by a bullet, which was extracted, complains of much pain and distress in the healed region. Like many thousands, he bathes in these hot springs. After a time, the old cicatrice, or scar, dissolves; forth issues, in due time, a small piece of cloth which had been buried a long time in the flesh, and carried in by the bullet. What charm is this? How can the waters summon the old wound to reveal its secret, and dislodge the enemy? Why should diseased bones be often cured in the hospitals here, the huge swellings of chronic gout and rheumatism disappear, lameness from accidents be relieved, paralytic feet be recovered to such an extent, that Wildbad is seriously named the "cripples' bath"?

During the years 1840–1873, the number of baths given to poor visitors alone amounts to 447,642, of which 175,200 were taken in 1869. But in the year 1871, after the Franco-German war, 26,154 were administered; so that, including soldiers' baths, the free baths amount to 661,379. A fair argument for the goodness of the State arrangements, and the rare utility of the hospitals here.

One of the most interesting institutions of the place is the Herrn Hilfe (Herrnhilfe). Here, such a collection of pitiable objects I have never seen in the English hospitals. Most of them appear at once to my eyes utterly hopeless. I have the reports before me. Taking the year 1869 at random, there were, during the season, 161 patients of these—most of them—dreadful cases; 34 remained no better, 19 were cured, 23 greatly benefited, 85 much better.

The kind of cases were such as these—boys, girls, and women (avoiding technical terms):—

General weakness, scrofula (local), general scrofula, diseased bones, rickets, chronic disease of the joints (some rheumatic), enlarged throat, foot paralysis.

I shall now attempt to give some recent examples, which I have gathered either from the persons themselves or from their friends.

1. A gentleman had been afflicted with a stiff neck the whole winter, which resisted every remedy. Coming to Wildbad, *three baths* entirely cured him. (A case of local rheumatism.)

2. A lapidary had so violent a rheumatic swelling in both legs (to use his own words) he feared they would burst. This case was, doubtless, rheumatic gout. The Wildbad course entirely relieved him.

3. Mr. Robertson informs me his right foot and ankle were enormously enlarged with a similar attack. His Edinburgh doctor ordered him to Wildbad, with a most successful result.

4. A young lady was here totally lame from paralysis of the lower limbs, somewhat emaciated from long illness, and suffering. Mrs. M., of Frankfort, now here, informs me she was perfectly restored here; and the last time she saw her she had married, become tall, stout, and robust in a marvellous manner.

5. A gentleman is now here who is a walking marvel. Some years ago, when about twenty-one, he was struggling in play with a comrade at an open window some 10ft. above the parterre. He was suddenly thrown backwards, bent his spine over the sill, and toppled over into the garden. His injuries were severe, his limbs were paralysed; he lay helpless in bed for many months. He was brought to the Wildbad baths, and was almost completely restored; married the daughter of one of the leading physicians here, and is, indeed, quite a walking advertisement for the place.

I am informed by Dr. B., who resides here, that a very severe case of eczema, in which the leg and ankle were enormously swelled, and which had resisted all previous treatment for three years, was cured by the baths in less than a month. He partly attributed this result to the purity of the water containing so little salts as four grains to the pound. The result of twenty-seven years' experience here (he says) is very much in favour of the efficiency of the baths in cases of broken bones united, but attended with stiffness and pain—in all kinds of wounds, especially of a military nature, and in every case of chronic rheumatism, causing pain and stiffness. I could easily multiply recent cases of relief, but these are a very fair sample.

I have already detailed a few cases descriptive of the type of disease adapted for a trial of these baths. I shall now briefly recount what some other physicians have observed:—"Wildbad is to Schlangenbad what the reality of a place is to its panorama." . . . It is superior to most of the principal Spas of Germany in the beauty and romance of its environs. . . . Nature has done everything for the invalid in this Spa."

Dr. Granville relates: M. Berchthold, 26 years of age, after a severe fall, experienced an affection of the right hip. Four months afterwards, excessive pain accompanied his walk with crutches. In five months he could not press upon his heel, but in thirteen he experienced the most dreadful sufferings. The second bath at Wildbad caused him pains in the loins, the third increased it to excess; he was compelled to leave the bath and be placed in bed. In a few minutes a great sense of coldness was followed immediately by copious warm perspiration around the hips. In an hour he left his bed without a stick, free from pain. Herr Berchtholt now walks upright and straight, as though nothing had happened. He relates another. (Be it remembered his expenses at Wildbad were only eleven shillings and fourpence.) Cases of this kind must then have been very plentiful. I was returning from visiting the Royal Chambers. I addressed a lady with whom a boy of 14 years was walking slowly, with a hope that the invalid might derive all the benefit she could wish. Yes, truly she replied, "Mon fils vient de jeter ses béquilles aujourd'hui même; we are in high spirits. . . The physicians at F—— looked upon him as lost. . . I have reason indeed to bless these baths, and I am happy. . . . Il etait perdus de tous ses membres, et le voilà maintenant qu'il se promener!"

G. W. Royston-Pigott, M.D., F.A.S.

(*To be continued.*)

MR. WASSELL'S SPECULUM TESTING.

[20225.]—So many able writers have touched upon this subject, that it would be presumptuous in me to take up your space by more than a few remarks. I have been employed for many years in making specula, and for a long time felt the great need of just such a friendly union of talent and experience as Mr. Wassell has collected, and which I look upon as a remarkable instance of the *chivalrous spirit* an esteemed contemporary (*Musical Opinion*) has said the English Mechanic has done so much to foster among its readers.

I have tested my specula in every conceivable way, but have found the one mentioned by Mr. Bell as the most reliable. I am also quite of his opinion that an exquisite figure can only be obtained by a kind of intuition which is the result of long experience, rather than by any mathematical formula, though I do not underrate the advantages derivable from having a correct formula to start with, feeling as I do that if I had had the same advantages as will shortly be within the reach of our readers, it would have saved me years of uncertain plodding. It is, therefore, with great pleasure that I send a 6in. speculum for Mr. Wassell's examination, and wish him every success in his meritorious endeavour to place a reliable formula within the reach of amateurs.

D. Richards.

MR. SCOTT RUSSELL AND THE VIENNA DOME.

[20226.]—In reply to letter 20206, page 357, I may say that I feel very much surprised indeed by the conclusion arrived at—viz., that expansion and contraction are to be disregarded, as far as relates to atmospheric changes of temperature. I can state as a fact that when the first railway was laid down in Australia, from Melbourne to Geelong, that the rails were laid as is usual in this country, and when the sun shone upon them they expanded immediately, and having no room, some bulged inwards and others outwards, and the engine speedily got amongst the sleepers; the rails had to be almost all lifted, and space left for expansion. I am also confident that I read in the *Glasgow Mechanics' Magazine*, years ago, that the Britannia Tubular Bridge across the Menai Straits expanded and contracted no less than 11in. between summer and winter. But I think that it is easy to understand that in the case of a dome, the principal expansion would be upwards, and not outwards. I suppose that the writer is aware that it would be a very risky performance to go into a smithy early in the morning (before sunrise), and to pick up a bar of iron from the floor and attempt to straighten it by blows without first taking the chill off it, and that said bar could be proved to be shorter before it was warmed, which can easily be—Q.E.D.

June 23. **J. J. A., Liverpool.**

CHIME-CLOCK MAKING.—II.

[20227.]—The frames being mounted, we will next proceed to make the weight-barrels. These are each formed of stout tubing, 1½in. long and 2in. diameter, with caps to fit in each end. These caps have flanges cast on them, rather larger than the inside of the tubing, to allow for turning true when attached to the arbors. The arbors are made of 5-16in. round steel, roughly filed up to an octagon for about 2¾in. of their length; drill three of the caps truly with the flanges, using a drill that will allow the octagon portion of the arbor to be driven tightly into the caps. Centre the arbor, and set them as true as they can be got; turn the flanges to fit the tubing, the ends of which should also be turned true; drill the three remaining caps, and turn their flanges to fit tubing. These caps will form the ratchets for winding, and should be much thicker than the front ones. The barrels may now be put together, and pins put right through the tubing and flange to secure them. It is also advisable to run some soft-solder in to insure all being fast together; next put the barrels in the lathe and turn the whole true. The barrels are now ready to be grooved for the line, and the ratchets cut. The grooving may be done in a screw-cutting lathe or fusee engine. They will each require 16 turns for eight days, and are best cut with a left-handed thread, so that the weights may be out of the way of the pendulum when they are nearly down. The ratchets are, of course, best cut in a wheel-cutting engine. When this is not practicable, they may be cut with a three-square file, no very great accuracy being necessary, providing the click gets fair hold of each tooth. The teeth must be cut so that each barrel winds the same way that the hands of the clock travel. Having completed this, pivot the barrels into the frames, allowing a little end-shake between the shoulders of the pivots and the frames. The barrels for the hour and chiming-trains must be pivoted-in so that there is room between the caps on the winding end of barrel and the frames for the wheels next above them; but the going-barrel must be pivoted close up to the front frame to allow of the centre and third wheels being put behind the great wheel. Leave the front or winding ends about ¼in. diam., and 1½in. long.

The wheels and pinions are next wanted. The sizes of wheels may be taken from Fig. 1 (that has been reduced by the engraver to one-third the full size). The numbers of the teeths are as follow:—

Hour.			Going.			Quarter.		
144	pin.	12	144	pin.	12	144	pin.	12
80	,,	10	80	,,	10	80	,,	8
72	,,	8	75	,,	10	72	,,	8
56	,,	8	30 'scape			56	,,	8
8 pins in pin-wheel.						nut of 40 on chime-barrel.		

We shall also require a wheel about the same size as the pin-wheel of 80 in the hour striking train, cut with 78 teeth, to carry the locking-plate; also a brass pinion with 8 teeth to drive it.

W. Baldwin.

110, Richmond-road, Dalston, London.

ON THE FLOW OF WATER FROM A PIPE WITH A FLAP.

[20228.]—Trusting that a few further remarks upon this subject will not weary your readers, I venture to put the observations contained in my last communication into more of a mathematical garb, assuming, as the cause of the phenomenon, atmospheric pressure on the inner surface of the flap.

We will first consider case (1), and find an expression for the horizontal thrust of atmospheric pressure necessary to move the flap through a given angle (θ).

Let W represent the weight of the flap, and T_t the tension at the hinge. Then the tension at the hinge, when the flap is drawn out of the vertical through an angle θ, will be, $T_t = W / \text{sin.}\ \theta$. Resolving this tension into its two components, we have a horizontal thrust, $T_h = W \text{ sin.}\ \theta / \text{sin.}\ \theta_1$, where θ is an angle made by the flap with a horizontal line. If θ_{11} be the angle made between a line tangential to the curved surface of the water and the flap, we have for the atmospheric thrust, $T_a = W. \text{ sin.}\ (\theta = \theta_{11}) / \text{sin.}\ \theta_1$.

By applying these formulæ to the case in question, I obtained for the atmospheric thrust a pressure of 58·32lb. This result, it will be seen, does not tally with that stated in my last letter (which should be 570in. lb., and not 5·70lb.); but it must be remembered that in the present instance the pressure merely represents the actual force necessary to move the flap through a given angle, the force being supposed applied at the bottom, whereas in the former case the force was supposed to be distributed over the surface. This, doubtless, accounts for the variance.

Case (2) was that in which the flap was in contact with the water, and did not alter its position on the pressure being removed. There is nothing phenomenal with regard to this, as it may be attributed to molecular forces, which we will call T_c. In case (3) the flap was pressed close to the mouth of the pipe, and, on pressure being removed, returned to the same position as in (2). In this case there must be the inequality,

$$T_c \text{ cos. } \alpha > \left\{ \frac{W. \text{ sin. } (\theta - \theta_{11})}{\text{sin. } \theta_1} + I \right\}$$

where α is the angle of capillarity, as we may suppose the tension acting *ap* the flap, and I the moment of inertia of the flap, which, by using the notation of the integral calculus, is, $I = \int\int x^2 . dxdy$. (*Vide* Rankine's "Applied Mechanics," &c.)

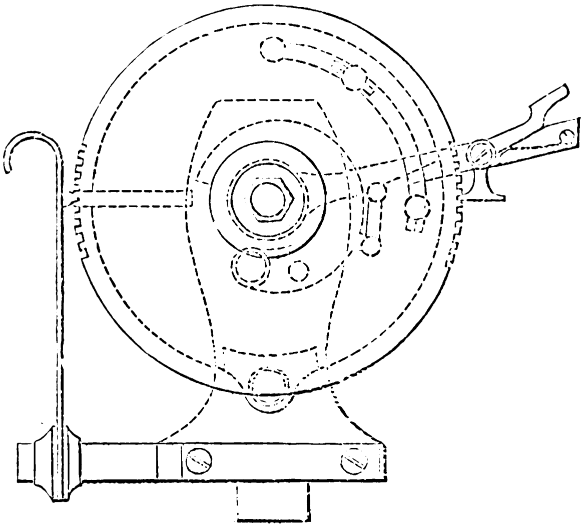
Case (4) can be accounted for in the same manner as (1).

C. H. Romanes.

Worthing, June 20th.

AUTOMATIC COUNTING APPARATUS.

[20229.]—The sketch represents the end-view of the Automatic Counting Apparatus, one-fourth actual size. The care and attention necessary in counting with the division-plate and spring-index pointer is familiar to all using the lathe for ornamental purposes; and many a beautiful work has been seriously damaged, or entirely spoiled, by an error in fixing the pointer in a wrong division, either through defective light, interruption, or other cause. To remedy this, various contrivances have been had recourse to, but all have failed in one respect or another. I have recently made an apparatus, designed by a member of the Amateur Mechanical Society,* and exhibited at the last Conversazione of the Society, which most completely effects the desired object of rendering an error impossible.



The apparatus consists of a sleeve fitting on to the mandrel, on which a handle moves freely. To it is connected a lever, acting on another forming a large portion of a circle. The latter, when at rest, is eccentric with the axis of the mandrel, but becomes concentric when the straight lever is pressed on. A wheel, accurately divided, also fits on to the sleeve, and is secured by a washer and nut; into the wheel gears a pawl connected to the handle. Against the lathe-head is a disc carrying two stops: on the one the handle rests, and by the other the required number of divisions is regulated. A detent, connected with a spring, fits into the space between the teeth, and keeps the whole perfectly steady.

In using the apparatus, all that is necessary is to raise the handle till the pawl drops into the required division, then to bring the movable stop on to the handle and fix it. Before depressing the handle the lever is pressed down, by which the detent is released from the wheel, and the whole moved downwards till arrested by the other stop, when the detent automatically falls into the proper division of the wheel, and the mandrel again becomes fixed.

The great advantage of the apparatus is that in working it is not necessary to look at it after it has been set, and the handle can be raised and depressed without the position of the lathe being changed. Mr. Ashton has since added two other levers, the one counting backwards, the other counting either way; but in the latter the detent is let into the divisions of the wheel by releasing the lever, and does not drop in automatically as in the others. Wheels of any number of divisions may be made, but one of 120 and another of 96 will accomplish nearly all that is required. I have also made from the design of the same gentleman a universal cutting-frame requiring no guide pulleys: it takes a much deeper cut than others, and will cut into shoulders and angles.

Henry S. Frost,
Engineer, Lathe, and Tool Maker,
45, Mortimer-street, Cavendish-square, W.

---

* Mr. Ashton, of Park-square.

SCREW-CUTTING IN AN ORDINARY LATHE.

[20230.]—To cut screws with an ordinary slide-rest we fit change-wheels to the face-plate or catch-plate of lathe. We lengthen the screw of the slide-rest, and upon it we fix corresponding change-wheels. A swing frame is required, and with a few change-wheels, a variety of threads can be cut accurately.

Thomas M. Bear.

Britannia Works, Colchester.

CHEAP BUNSEN BATTERY—COPPERING CARBONS.

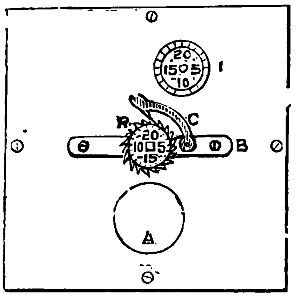
[20231.]—Cut a piece of sheet-copper to just fit in the bottom of a salt-jar; to this solder a piece of copper wire a foot long. attach this to the copper terminal of a Daniell or Meidinger cell; cover the copper for the depth of an inch with crystals of sulphate of copper, then fill to an inch above the crystals with sulphuric acid; dilute with 10 parts of water; twist a wire round the carbon and lead it to the zinc of the battery; place the carbon in the salt-jar so that it rests on crystals and leave for about three days, when it will be well coppered. The copper should be bright red. After coppering each carbon, add a few crystals of sulphate of copper. If this method is too slow, I will give one by which they can be coppered all at once; but the apparatus won't be near so easily made, and will cost more.

H. T. B.

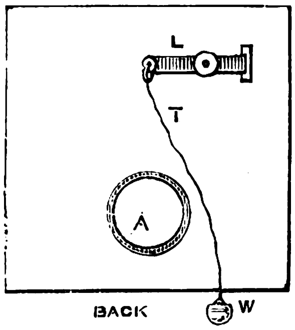
BEAUMONT'S PHOTOGRAPHIC SHUTTER.

[20232.]—Perhaps the following description of an instantaneous shutter I have just made may interest the photo. readers of "ours." It is made to suit a half-plate lens, and the revolving disc is shaped in the aperture so as to give the foreground of the picture about three times the exposure of the sky. There is an index on ratchet R, also on friction-screw I, for adjusting the disc to any desired exposure at will. To make the exposure, I have introduced a rather novel arrangement—viz., a piece of sewing-cotton, to one end of which is fastened a small button, weighing about ½ drachm, the other end of thread is attached to lever L, as shown. The button is not heavy enough to pull off the catch by its own weight, but when dropped from the hand pulls down the catch lever L, releases the disc, and makes the exposure. Description: F F are two pieces of mahogany, back and front respectively, 6in. square, ¼in. thick; these are screwed together, ⅛in. apart, between which the disc D revolves, disc 5in. diam.; A A A, aperture, 1¾in. in diam.; B, bar, carrying C, click; R, ratchet, fixed on the end of box containing spring, not shown; S, screw for tightening or slacking friction-spring inside shutter; L, lever, for holding disc ready for making the exposure; T, cotton thread, with small button or weight attached. There is also a small arm on the disc-axle in front of ratchet, not shown, for setting the shutter, and a catch for holding the aperture open while focusing.

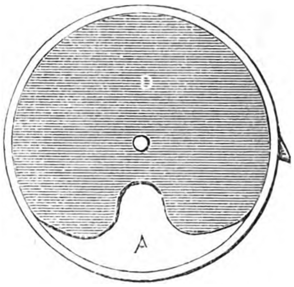
The above shutter, when made, is adjusted and indexed so that it can be set to go off in any desired fraction of a second. How to divide the indexes:—Take a circular piece of thin white cardboard about 6in. dia., and black it by means of a candle about ½in. from the outer edge. Make a small hole in the centre, and fix it on spindle of revolving disc. Now get a tuning-fork of known note (a C fork makes 256 vibrations per second) and on the end of one of the prongs gum a strip of pointed cardboard. The shutter is now set to go at its slowest speed, the fork made to vibrate is held with the paper point just touching the cardboard disc, and the shutter let off. The paper point on the fork will scrape away the soot in a wavy line, each wave representing one vibration of the fork. Now, if there are 25 waves to an inch, and the shutter at the same radius moves through the space of 5in. in opening and closing the lens, it will be 256 ÷ 25 × 5 = 2, or half a second. The indexes are now marked at this place. The shutter is then set to go off at its quickest rate. Suppose this gives 3 to the inch, then 256 ÷ 3 × 5 = 17, or the 17th of a second. The indexes are again marked, and the spaces between the two divided.



FRONT



BACK



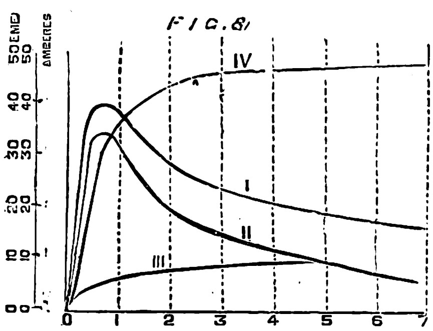
It will be seen that the exposure is adjusted to any desired time by merely turning the indexes to the figures required. I have tried to make the description as lucid hs possible, and anything not quite clear shall be glad to explain, or will make them to order. **C. R. Beaumont.**

Cooper-street, Withington, Manchester.

NOTES ON DYNAMO-MACHINES.—V.

[20233.]—39. In note 19 we have referred to the action of the shunt dynamo. This action is represented by the curves in Fig. 8. These curves result from a number of experiments with a Siemens machine, running at 500 revs. per minute, of these dimensions:—Helix 24 part commutator, 336 convolutions of 2·5mm. wire, ·4014 Siemens units resistance. Field-magnets 2,240 convolutions, 3mm. wire, 4·46 Siemens units resistance. Distances on the horizontal line represent resistances in the outer circuit in Siemens units, and the scales on the left-hand side measure the E.M.F. and current on the ordinates 1, 2, 3, 4, &c. Curve I. represents the total current flowing through the helix, which at the brushes is divided into two, a current represented by curve II. in the outer circuit, and a current represented by curve III. flowing round the field-magnets. Curve IV. gives the E.M.F. in volts.

FIG. 8.



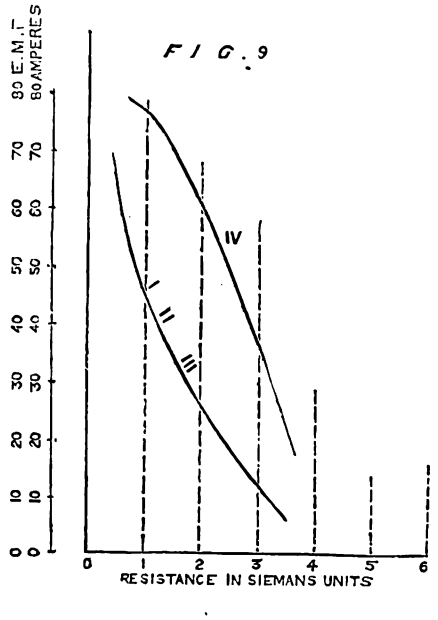
40. That we may be better able to compare the shunt with the ordinary dynamo, to represent the action of the latter, let us take curves, Fig. 9, drawn in a similar way. This dynamo is of the ordinary type, and constructed by Siemens to the following dimensions:—Helix 24 part commutator, 336 convolutions of 2·5mm. wire; ·4014 Siemens units resistance. Field-magnets, 512 convolutions of 5·5mm. wire, ·3065 Siemens units resistance. In this diagram curves I., II., and III. correspond the current flowing through helix, field-magnets and outer circuit being the same. Curve IV., as before, gives the E.M.F. in volts. As the resistance in the circuit is diminished, it will be observed that here the current rises much more rapidly than in the shunt dynamo (see Note 19). In Fig. 8 the current is fairly constant for a resistance of from 3 to 4 or 4 to 5 ohms, while in Fig. 9 the curve representing the current is very steep, and a small change in resistance makes a considerable difference in the current. A careful comparison of Figs. 8 and 9 will make the action of the two machines plain without further explanation. In the ordinary dynamo, the E.M.F. is greatest when the machine is short-circuited, in the shunt when the circuit is open, or, in other words, when the resistance is a minimum in the ordinary dynamo, the E.M.F. is a maximum; in the shunt, when the resistance in the outer circuit is a maximum, the E.M.F. is also a maximum.

41. Curves such as we have described ought to be supplied by the makers with each dynamo-machine. These provide all the formulæ necessary for the particular machine, and tell at a glance what the machine can do and what it can not do. The curves ought also to guide us in the choice of a machine. It is obvious that the shunt-dynamo gives the best results as far as steadiness of current is concerned when working under a varying resistance.

42. The shunt-dynamo is extremely useful for incandescent lighting, since, owing to the E.M.F. increasing with the resistance, any number of lamps, from one up to the maximum number, can be lit up. If the incandescent lamps are arranged in parallel circuit, and the current through each lamp is to be constant, the generator must be arranged so that the total current flowing is proportional to the number of lamps alight, or, in other words, C × R (where R is resistance in the lamp circuit), i.e., E.M.F. at terminals of machine must be constant, and something must be done to satisfy this condition.

43. To understand how the current through each lamp varies as the total number of lamps is varied, let us take the machine the curves for which are represented in Fig. 8. Suppose we have 30 incandescent lamps of 30 ohms resistance each, equal to a total resistance in lamp circuit of one ohm. According to the diagram, we will have a total current of 32 ampères, or a little over 1 ampère through each lamp. Let 15 lamps be extinguished; the resistance is now 2 ohms, and current through each lamp 1·3 ampère. If other five lamps be put out the current through each of the remaining ten will be 1·4 ampère. Finally, let the lamps in circuit be reduced to five—the current through each will now be 1·6 ampère. The light will vary in a much greater ratio than the currents, also, the resistance of the lamps will not remain quite constant, as we have assumed. The way in which the resistance varies with the current will be considered further on.

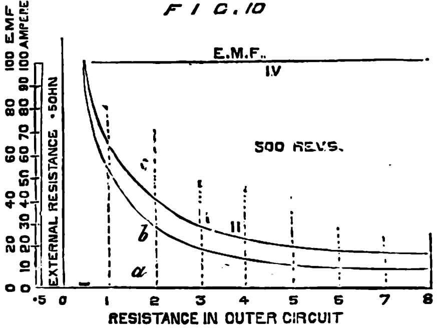
FIG. 9.



44. A comparison of Figs. 8 and 9 will show that, with the ordinary dynamo, on extinguishing a number of lights, those remaining will become dimmer instead of brighter; consequently, the speed of the machine will have to be *increased* and not *diminished*, as in the shunt dynamo. In Fig. 8 the current curve is not steep enough to satisfy the condition of Note 42, and in Fig. 9 the curve is too steep.

45. Fig. 10 shows the curve for a magneto machine or a dynamo, the F-magnets of which are excited by an auxiliary machine. The total E.M.F. is 100 volts. The current curve is somewhat similar to that for the shunt dynamo. Taking incandescent lamps of 30 ohms resistance each, for 60 lamps, we have 1·6 ampère through each; for 30 lamps 2 ampères, for 15 lamps 2·5 ampères, for 10 lamps 2·8 ampères, and finally, for 5 lamps, over 3 ampères through each. In drawing this curve it has been assumed that the E.M.F. remains constant; but, strictly, this is not true for all currents flowing through the armature. As the current in the armature decreases the E.M.F. increases a little, because the magnetic field produced by the current in the armature tending to neutralise that created by the current round the field-magnets is reduced. The case is then somewhat worse than appears from the curve. On the assumption that E.M.F. remains constant, however, a curve for speed correction has been drawn, represented by the dotted line. The E.M.F. is proportional to the speed consequently for a fixed resistance (say, 2 ohms), the current is also proportional to the speed. *a c* represents the current we obtain at 500 revols. with 15 lamps, but *a b* is the current we desire to have, so that the lamps may be of the same brilliancy as when there were 60 in circuit. Consequently, as *a c* is *a b*, so is 500 to the required speed.

FIG. 10



46. Where there is a number of machines, all working different circuits and driven from one engine, it is impossible to reduce the speed of any particular machine. The most convenient way to diminish the E.M.F. in the case of the separately-excited machine would be to switch a resistance into the circuit of the exciting dynamo. If working with a shunt-dynamo, the plan adopted by Edison, of introducing a resistance into the shunt-circuit might be employed. But in all these cases, that C × R may be constant, something must be done, either in the way of reducing speed, or introducing resistance. It is easy to have an instrument recording E.M.F. at terminals of each machine, which might ring a bell when the E.M.F. varied appreciably, and thus call attention, so that the requisite adjustment might be made, or some system by which the resistance might be introduced mechanically, might be devised. These details, we shall not, however, consider at present.

E.

CONNECTION OF BATTERY CARBON.

[20234.]—I beg to bring to the notice of the readers of the English Mechanic a simple and effective plan I have designed for the connection of battery carbon. A binding-screw may be used, or in lieu thereof, a piece of bright copper wire with the end flattened. But now for the description of the plan. Bore from the centre of the top of the carbon (a block is most suited for this plan) a ¾in. hole for about 1in. down, with a ¾in. drill or centre-bit. Then melt some lead over the kitchen fire, and pour it into the hole, filling it. The binding-screw may be put in the lead when it is still melted, or held while the lead is being poured around. The carbon, preparatory to the leading, should be slightly enlarged at the base of the hole, as shown at Fig. 1, or better still, as at Fig. 2, which has two holes bored at right angles to the large one, with their ends stopped up with any suitable material, such as a cork or piece of wood. This plan prevents the lead falling out, as it contracts when cold. The binding-screw may be easily removed, as it leaves a thread in the lead-top. This plan is a very simple one, and saves a great deal of lead, as in the other methods a lead cap is melted right around the carbon head, thus using a larger quantity than in the plan I have set forth. In a carbon plate which is too thin to allow of a hole being bored in the top, a hole may be sunk in the flat side right through (and countersunk each side), thus having the binding-screw at a right angle to the carbon. I hope this will be of some use to our readers.

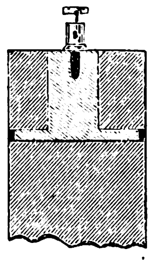

FIG. 2.

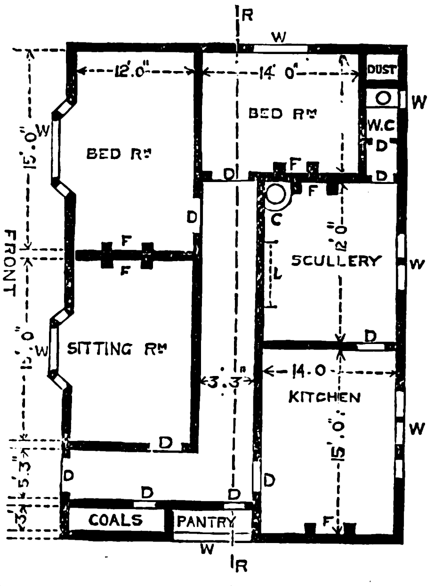
Beetle Crushers.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[46398.]—**L. and N.W. Engines.**—955, Charles Dickens, Feb., 1882, stationed at Manchester (16); know nothing of others.—DUBLIN.

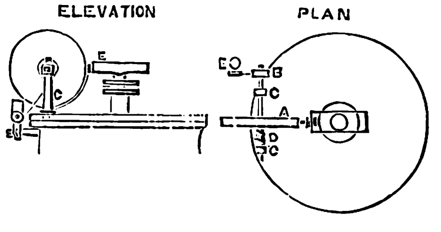
[46403.]—**Cottage Building (U.Q.)**—"Employment" has a very good notion of a cottage. Five rooms 14ft. square would, I should say, form a very fair sample of a house. Here is a possible arrangement of such a house. The various quantities of different materials may be easily computed by drawing out the sketch on a very elementary form. I should think the cost would be about £500, if put to competition.—DITTON.



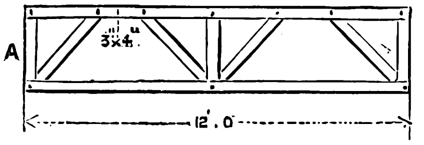
F, fireplaces; C, copper; L, borrowed light; D, doors; W, windows; R, ridge of roof.

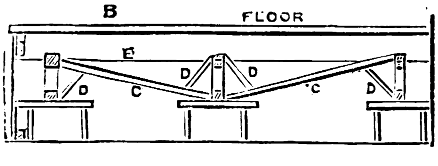
[46648]—**Chimney on Girder (U.Q.)**—If the chimney-breast does not project more than the thickness of the wall, it may be either brought out on corbelling in narrow steps, or built upon a 3in. York-stone landing, the full length of the breast and full width of wall. If anywhere in the Metropolitan district, do not forget the 20th section of the Metropolitan Building Act.—DITTON.

[46470.]—**Diagrams of Oscillating Engines as on London River (U.Q.)**—"An Old Fitter" will at once see by my rude diagram how the diagrams can be taken, as I have often taken them—but cannot say if as on London river, as I am too far North for that. A, large spider-grooved wheel, circumference a fraction more than length of engine-stroke; B, small grooved wheel, circumference sufficient to give indicator necessary travel; C are two brackets screwed into cylinder-cover, with bearings for spindle, on which the two grooved wheels are keyed; D, small spiral spring fastened on spindle and at C, so as to keep cord tight at F; E, supposed indicator; F, piston-rod head, with small pin where cord is attached to, and working over the large grooved spider-wheel.—CARINO.



[46505.]—**Movable Stage (U.Q.)**—For movable stage 36ft. by 24ft., frame together nine trusses, as A, of 3 by 3 timber for sills, uprights, and struts, and 3 by 4 heads; set these trusses upon the tables, as shown on B, and connect together with ties C, 3in. by 2in., three to each truss, firmly secured by hooks and eyes or pins, and stiffened by pieces D, 3 by 2, which are fixed to the trusses A by hinges, and secured to ties C by cabin-hooks. The joists E, 7in. by 3in., to be notched down over trusses so as not to shift, and placed 12in. apart. The floor may be of 1¼ boards, ledged and tongued in pieces, 3ft. by 12ft.; these pieces, if screwed down to joists, each with six screws, will keep all firm. The front can be filled in with boarding, ledged and tongued, and screwed at intervals to the ends of joists. Cost about £50, and will pack into space 24ft. by 4ft. 6in. by 4ft.—DITTON.





[46804.]—**Furniture Cleaning.**—Some cold tea, the leavings after your breakfast, if you have not been draining your teapot too dry, will remove a great deal of "nasty black stuff" from your furniture. Wet a small piece of soft woollen or linen rag in the tea, then wash your chairs, or tables, or bannister-rails; then dry with a very soft duster and plenty of "elbow-grease." It is a valuable remedy for cloudy spots. Never rub with "varnish" or "polish" without a washing first.—H. O'B.

[46828.]—**Railway Brakes.**—The G.W. vacuum brake is created by ejector, and maintained by pump, and, I believe, differs only from the Midland in the construction of the cylinder. It is a two-minute brake, but some cylinders take longer to leak off than others. I once timed a cylinder to four minutes, the wheel being locked for two yards when the train started. The only complaint the drivers make against this brake is that it does not "hold" long enough, which (as on the Midland), is the result of the power leaking away in so short a time. They are all of opinion that the brake would be much more serviceable if it would remain on until released. In order to apply the brakes on each carriage as nearly as possible at the same moment, a valve is provided in each van, so constructed that any sudden increase of pressure in the pipe instantly causes the valve to open automatically and admit a supply of air after which it closes again by its own weight. The driver is required to have 10in. of vacuum on starting, and not less than 20in. when the train is running, and in descending inclines the vacuum brake is to be used in preference to the hand brakes. I hear the L. and N.W. are fitting a vacuum brake to their Irish mails. Can Mr. Stretton say whether this is correct, and, if so, what brake it is? I think they have made a great mistake in not fitting the Westinghouse to their stock—a system we should like to see adopted by this company.—NORTH STAR.

[46847.]—**Equation.**—I do not think that the introduction of the arithematical progression into the solution of this interesting problem helps us in any way. By its aid, Mr. Davies proves that $zx = 9 + xy/2$; but this can be obtained directly from equations (c) and (d); so we have the same difficulty as before—viz., the *signs* of the two sides of the equation after completing the squares and taking the square roots. My meaning will be made clear by the following equation:—

$$(5 - 4) = -(3 - 4)$$

which is evidently correct; square both sides, and we get

$$(5 - 4)^2 = (3 - 4)^2.$$

Now take the square roots, and note the signs which I will put in words to prevent mistake.

$$\begin{array}{c}\text{Minus}\\ \text{or}\\ \text{plus.}\end{array}\left\{\;5 - 4\;\right\} = \begin{array}{c}\text{plus}\\ \text{or}\\ \text{minus}\end{array}\left\{\;3 - 4\;\right\}$$

This is only correct if we take the upper signs or the lower for *both* sides. It will not do to take the upper sign of one side and the lower sign of the other side, unless each side happens to be $= 0$; but in the problem we are trying to solve, we cannot take this for granted. This shows us that it is quite possible to solve a quadratic in the usual way, but that the result may be misleading unless we attend to the signs of both sides. As a further proof of the fallacy of this method of solving the problem, let us take the same original equations, but with different values for the symbols; suppose $x + y + z = 21$; $x^2 + y^2 + z^2 = 153$; $zy = 3x(z - y)$. It will be found that $x = 6$, $y = 6$, $z = 9$, will satisfy all the equations; but if the method of solution as given by Mr. Davies be adopted, we will obtain $xy = 24$, $zy = 72$, which is evidently wrong.—M.I.C.E., Bath.

[46847.]—**Equation.**—Mr. Lane Davies' second solution (p. 358) is identical with his first (p. 226); for, though by multiplication he obtains from (c) and (d) an equation (β) which is independent of either separately, he substitutes in it a value of zx, which is derivable from (c) and (d) jointly, and thus obtains an equation that can depend only on the result of eliminating zx from (c) and (d), viz., $\frac{1}{2}xy + \frac{1}{3}yz = 9$ (e). The substitution might just as well have been made at first, and then the equations to be multiplied together would have been, as in the first solution, merely varying forms of the single equation (c). The method is thus practically an attempt from one equation (e), of the form $\frac{1}{2}xy - 3 = +(6 - \frac{1}{3}yz)$, to obtain another $\frac{1}{2}xy - 3 = -(6 - \frac{1}{3}yz)$ independent of it, and shows that Mr. Lane Davies has not yet quite mastered the fallacy underlying the school-boy-proof, that $1 = 0$, which is of the same nature. His mistake in the second solution is in taking the value of zx from the "progression" without tracing its origin, the progression itself being absolutely useless. Mr. Lane Davies does not, however, quite understand (p. 312) when equations are identical, so that he may not at once assent to the above criticism; but that his method is wrong may be proved by showing that it leads to an infinite number of solutions. After substituting the value of zx in (β), reducing the square and dividing throughout by 3, he adds 36 to each side to make it a perfect square; if instead, we add $27 + n^2 - (n - 3)\,xy$, and $(n - 9)^2 + \frac{2}{3}(n - 3)\,zy$ to the left and right-hand sides respectively, n, being any number whatever, and these quantities being equal by virtue of equation (e), we again make both sides perfect squares, in the form $(\frac{1}{2}xy - n)^2 = (9 - n - \frac{1}{3}zy)^2$, whence the method would give $xy = 2n$, $zy = 3(9 - n)$, and so $xz = 9 + n$, their values being 6, 18, 12 only in the particular case when $n = 3$. That this special case should suit the original equations is only by accident; if for 11 and 49 in equations (1) and (2) were substituted $47/10\sqrt{5}$, and $769/20$, we should still get equations (b) and (c); but would have to take $n = 6$. We should get the above indeterminate values of xy and zy by directly solving (e) in the ordinary way: if then, having found that of xz by substitution in (c) or (d), we deduced the values of x^2, y^2, z^2, and substituted them in (2), we shall get $\frac{2}{3}n(9 + n)/(9 - n) + 6n(9 - n)/(9 + n) + {}^3/_2(81 - n^2)/n = 49$, or $49n^4 - 282n^3 + 1782n^2 - 23814n + 59049 = 0$ as the biquadratic equation whose four roots are required to give us the necessary four values of x, y or z. One of these is 3, another 6·977811 very nearly, and the others imaginary.—R.E.B.

[46859.]—**Indigo Blue Dyeing.**—The difference between R. Holliday and Sons' method, which was invented by Lalande and Shützenberger, and the woad vat consists in the use of bisulphite of soda, zinc dust and lime instead of woad, &c.; the process is protected by patent, and the only license fee required is an undertaking to buy the chemicals from R. Holliday and Sons, who give all particulars, and, if required, send a dyer to teach the process. The advantages are that one vat answers for both woollen and cotton by using it either hot or cold, according to the material to be dyed. The vat is set in a very short time, and the bath can be exhausted—*i.e.*, all the colouring matter can be made to combine with the fibre.—S. J. Simpkin.

[46875.]—**Model Electric Engine.**—The distance between the magnets being 5-16in. only, I should not make the keeper thicker than 1-16, which would leave a stroke of ¼in. This would make the mass of iron of the keeper objectionably small, and I advise you, therefore, to place your magnets 3-16 further apart and to make the keeper ¼in. thick, which would leave the stroke unaltered. Make the middle part of keeper 5-16in. thick, and screw into its centre a rod 3-16in. thick (B E in the sketch), the other end skewing into a boss at the lower edge of the beam. B E should have a projection of the side turned towards F and M M M, with a 1-16 hole for a pin, to which is connected by means of a fork-joint one end of a 1-16 wire. This wire, I believe, is what "R. W." has denoted by N. The other end of N is similarly connected to a boss and pin on F, the latter turning on a pivot, which may be formed by a stud screwing into one of the fly-wheel standards (I I in the sketch). "R. W." has indicated the pivot in Fig. 3 just above wires 2; find its best position by trial. All the connections are distinctly shown by "R. W." in Fig. 2. The length of your crank should be half the stroke of C, which is about 3-16in. (Rather small, I think.) I hope these few remarks will be useful to you, although it is more likely that by this time "R. W.'s" engine made many a thousand revolutions.—R. Kanthack.

[46929.]—**Iron in Water.**—As no one else has replied, I venture to suggest that, as ferrous carbonate is held in solution by the presence of free carbonic acid, the addition of milk of lime to the water would precipitate it very quickly. Probably, if arrangements could be made for blowing air through the water, the same effect might be produced; but that might be more expensive than the adoption of Clark's process for softening water. Nun. Dor.

[46932.]—**Telegraphic Engineering.**—If Mr. Shone would write to the Secretary to the Postmaster-General, or to Mr. Graves, the engineer-in-chief, he would no doubt obtain an intimation of whereabouts he would find the information as to the telegraphs engineering service. Failing a reply from either of those gentlemen, which is unlikely, I should write direct to the Civil Service Commission, Cannon-row, S.W.—Nun. Dor.

[46936.]—**Steam-Launch.**—On p. 410, No. 875, you will find some details which may assist; but in the last three or four volumes there have been many replies about steam-launches.—Nun. Dor.

[46940.]—**Soap-Making.**—Many thanks to "Pygmalion Phibbs" for his able assistance. I have now got the book he recommended, and find it will be of great service. I should be glad if he would give me an instance of a "standard acid solution." That would be of use to me. Mr. Edward Thomas Scott's warning has surprised me, as I understood the duty was taken off some years ago.—Svenska.

[46947.]—**Lesson in Assaying.**—In Vols. XII. to XV., there are several papers on assaying, chiefly lead, copper, and silver, which appear to be just the kind of hints the querist wants. As to a book, I suppose he could have nothing better than "Mitchell's Manual of Practical Assaying," published by Longmans.—E. G. M.

[46950.]—**Composition Gas-pipe.**—This piping is made of an alloy of lead and tin, but the proportions vary in different factories, and are kept as trade secrets.—E. G. M.

[46955.]—**Marine Steam Boiler.**—This querist should consult the indices of the last four volumes or so; he will find a great many hints about launch-boilers, some of which may assist him.—Essar.

[46960.]—**Model Electric Lamp.**—The engine and boiler described could not be made to give sufficient power to work a dynamo-machine capable of supplying current to an electric lamp.—Nun. Dor.

[46982.]—**Colouring Screw-Heads.**—If "Steadfast" will refer to p. 54, No. 861, he will find full directions for blueing watch-screws—an art that has been frequently described. As to the blueing-pan, anything in the shape of a thin iron pan, to be held over gas or a charcoal fire, will answer.—T. P.

[46989.]—**Stoppage in Pipe.**—The best remedy is to prevent the accumulation. The pipe should be 4in., laid direct to the drain, without the slightest bend, if possible. A "small quantity of water running day and night" is exactly the mistake so frequently made in sanitary arrangements. A thorough flush at intervals of, say, six hours or so, would be immensely preferable. The spirits of salts is good, but it is the "flush" of water that should be seen to in all cases of drain-pipes. The application of driblets, or constant trickling, is both wasteful and useless.—Nun. Dor.

[46993.]—**Consumption and Homœopathy.**—There are, no doubt, special hospitals for consumption, but scarcely one in which a specified drug is used. Above all things, avoid becoming an inmate of a consumption hospital; but seek rather to increase the strength by fresh air, good food, and, if there is any truth in Koch's hypothesis, by inhaling the vapours of antiseptics. You may take the whole contents of a homœopathic medicine-chest without deriving any benefit.—Oxon.

[47023.]—**Sea-Sickness.**—A pinch of saffron, folded up in thin paper or muslin, and worn next the skin, just upon the pit of the stomach, is a remedy for this troublesome and ofttimes dangerous malady. It is surely worth trying.—H. O'B.

[47050.]—**Hot-Air or Vapour-Bath.**—If Isabelle Stuart will write to me direct, I will send her the full description of a simple, costless system, by means of which instantaneous cold, warm, hot-air bath, cold, tepid, warm, shower, or pulverised water, or steam-bath, can be obtained at will in every house, either plain, perfumed, or medicated, without extra expense; also the the means of modifying, ventilating, perfuming, medicating, warming, refreshing, drying, &c., the atmosphere of any apartment at will—it being the object of a patent of mine. She will be at liberty to work it in a hygienic establishment, or to use it personally, and make it public.—Ch. Rabache, Morchain, par Nesle, Somme, France.

[47070.]—**To Mr. Allen.**—I should like to make a remark on the statement made by Mr. A. H. Allen that arsenic is such a common impurity in aniline colours, that it is hardly fair to the English manufacturers, since they use the arsenic method for the production of magenta: the poisonous body is, however, removed before the magenta is in a saleable state, and the hydrochlorate of rosaniline formed. It would be interesting and instructive to hear what quantity of arsenic has been found in samples of the aniline colours produced by any one firm of "coal-tar dye manufacturers." Besides this, the greater number of aniline colours are produced without arsenic; among them I may mention the azo colours, of which the consumer has a variety of colours or shades, from yellow to red and also brown; the greens are not produced by using arsenic, neither is eosine and its nitro-derivatives, both beautiful reds, some having a fine blue shade: bromine is present in these. Saffranine is not made with arsenic—another pretty red. Diphenylamine blues, and the blues derived from methyl, benyl, amyl, and ethyl diphenylamines, are free from arsenic, since none is used in their production. Arsenic acid is not used in making violets. May I ask what colour is produced by the use of arsenic beside rosaniline?—S. J. Simpkin.

[47098.]—**Engine Queries.**—To find the angular advance of an engine, draw a circle (Fig. 1), A D B, to represent the path of the crank-pin, at a scale of 3in. to 1ft.; draw also a smaller circle, whose diameter, E G, shall be the exact stroke of the slide-valve, and represent the path of the eccentric. Now, let A C be the crank, erect a perpendicular, B C, at right angles to A C D; now, with dividers, mark off a distance C H in C D, so that C H equals the lap and lead added together; erect H *h* parallel to C B, join C *h*, then the angle D C *h* represents the angle of advance. To find angle of crank and corresponding position of piston entails a long explanation, taking up too much space here. If the angularity of the connecting-rod is to be considered, however, if "Phenix" only wants an approximation, the following diagram will do, leaving out the connecting-rod or considering it of infinite length:—Let the circle A B D (Fig. 2) be drawn to any scale of the path of the crank-pin, then A D will represent the stroke of the piston. Assume that B C is the crank at half-stroke, the piston will be at half-stroke also, and C will represent its position; let now the crank move to positions E and F, and draw lines, E *e* F *f*, parallel to B C; the points *e* and *f* will mark the position of the piston, and C E C F the angularity of the crank, and so for any position of either required. With regard to the third question, either I have misunderstood it or you have not put it clearly, for hydrostatic pressure depends upon the height of the water; therefore, I do not see what the inclined base has to do with it. A column of water, no matter what diameter, 33ft. high will indicate about 14·8lb. per square inch pressure upon its base, or any pipe there connected.—Fred. Walker.

FIG. 1.

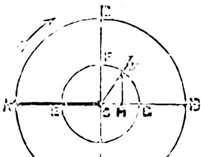


FIG. 2.

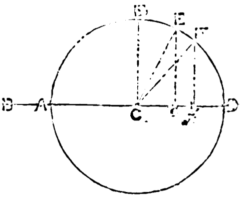


[47126.]—**Electrical.**—You can easily cover up the cells in winter, pour on the surface of liquid some paraffin, and then put some tow or wadding around the jars, or put the jars in a box filled with sawdust, or lined with felt all round lid as well. You will have no trouble with them then in the coldest winter.—W. J. Lancaster.

[47126.]—**Electrical.**—Frost does interfere with the working of Leclanché batteries to a serious extent. I once fitted some up in an exposed place, and they were ruined by the frost in winter; whereas some of the same cells placed in a bedroom have been working over two years, and at the present moment ring the bells sharp. It is of the utmost importance where amateurs place these batteries; and another matter worth their notice is: I make all my cell connections with solder (or else have the binding screws outside box), as a frequent source of failure is corroded connections; joining cells together, the sal-ammoniac quickly attacks the brass should any get spilled.—Electra.

[47138.]—**Tapering.**—I should advise "Experimenter" to get a large-size steel pencil-sharpener, and, if too small, use it as a model in having a larger one made. It consists of a simple piece of coned steel tube, with one edge sharpened, and the price is usually one penny at any stationer's.—John Hale.

[47142.]—**Marquetry.**—In answer to the latter part of "J. K.'s" query, he should write to Harger Bros., Settle, Yorks., for specimens and prices of marquetry veneers.—Collodion.

[47143].—**Aluminium.**—If Wm. John Grey knows a good and easy method of separating the aluminium alloy, and would divulge the same for a consideration, there is no reason why he should not be paid; but as to my demand being "rather a cool request," I cannot see where the difference lies between my query and a thousand others which are constantly asked and kindly and gratuitously answered by some of "ours," although "something for nothing" is not very often attainable. I quite believe with Mr. Grey, that when I can work my invention it will be very remunerative, especially as I believe there is a great future for aluminium in the manufacture of electrical apparatus, &c., its lightness, conductive power, and non-oxidisable qualities being far superior to the metals usually employed. Unfortunately for me, I am in no way connected with metallurgical skilled labour, and the difficulty of developing my discovery will, no doubt, consist in my not being able to meet with someone to work it for me. I know, but have not yet tried, the separation of Al and Zn by volatilising the Zn; then there is cupelling also—both, I think, expensive processes. I have obtained the metal nearly pure, owing to its melting point being higher than Zn. At the melting point of Zn the Al separates out if the heat is not increased: but it is rendered brittle, and I find it very difficult to keep the temperature even. Then, again, there are other metals, as I before stated (an impure alloy); these have to be separated, but I have no doubt the alloy as formed will prove valuable. It is much harder than zinc, does not oxidise, and will take a high polish.—Zelia Naien.

[47144.]—**Bending Wood.**—"W. P." should make a steam-chest of good, sound, red deal, about 1½in. thick, of convenient size, to hold what he has to steam—say, 3ft. 6in. by 9in. Put white-lead on the joints in nailing it together. Put some kind of simple safety-valve to it, and connect to large tea-kettle, with lid temporarily fastened down. Best kind of wood for bending, ash and elm. I should have said his steam-chest should be made with one end loose for putting stuff in which can be fastened with screws.—Collodion.

[47147.]—**Photographic.**—The size of any object produced on the screen is dependent on the length of focus of the lens employed, and the distance of the lens from such object. The size of the object may be increased either by lessening the distance from the object, or by using a lens of longer focus. A ½-plate lens being of longer focus than a ¼-plate one, will, of course, give the objects in the same view larger. The lengthening of the camera may be from the front. One of Messrs. Lancaster's lenses could no doubt be used with your camera. Write to them for particulars.—N. Mackie.

[47147.]—**Photographic.**—The size of the object on a photo. depends upon the focus of the lens, and the distance you are from the object. Thus, on a ¼-plate view, the distance is of course minute, whereas on a ½-plate the distance, though bearing exactly the same proportion to the foreground as in the ¼-plate, will seem to be much more distinct. You must, in photography, train your eye to pick out subjects that harmonise. Don't get just one object in the foreground and then an immense stretch of distance; the smallest object imaginable, thrown into the picture at the right spot, makes a bad picture into a good one. A dog even, or a horse, or, better, a human being, makes the view much more interesting. Look and study all first-class paintings, and you will find that the paintings have a harmony in all the details; some one part arresting the attention, and yet not at the cost of all other parts of painting. Try to select subjects well grouped, so that distance is broken. The instantograph lens can, of course, be used on any camera, but you cannot use a ½-plate lens on a quarter camera; better get rid of present camera, and get a ½-plate one; then you can take either ¼ or ½-plate views at will.—W. J. Lancaster.

[47148.]—**Fogging.**—You must look further for the cause of your plates fogging. The smell of size would not affect them, particularly in the short time they must have been exposed to it.—N. Mackie.

[47148.]—**Fogging.**—I should very much doubt two thicknesses of black twill being light-tight. You should have a thickness of ruby cloth. I have had light through three thicknesses of twill, &c., and one cannot be too careful in using the gelatine plates. Why don't you develop with pyro., bromide, and ammonia?—then you can restrain with the bromide, and may obtain a thin negative, from which you could obtain a transparency and then a stronger negative.—W. J. Lancaster.

[47149.]—**Changing Plates.**—As a very little cement at the corners of the plates would answer the purpose named, I should say that glue, gum, or anything almost, might be used without detriment to the films. But how do you intend to insure the plates being firmly and evenly pressed against the rabbet of the dark slide?—without which the image would be more or less out of focus. —W. Robinson, Jun.

[47149.]—**Changing Plates.**—You can fasten your plates very securely together with small well-gummed labels at the corners, and the slight amount of moisture required will not hurt the plates; but if you use double backs I don't see how you will be able to use plates thus cemented, unless you pick out plates of exactly the same thickness, the thickness together being equal to exactly the distance apart of the rabbets of the slide.—N. Mackie.

[47149.]—**Changing Plates.**—Probably a thin band of liquid glue would do all you want; but you would require a piece of black cardboard between each pair of plates; then, if the glue was brushed along one end of the cardboard, and this laid between the two plates, you would be able to remove it without damaging either of the plates. The French polish would not hold, I am afraid, sufficiently to keep the plates from moving their relative positions. Have the plate-box made to carry two plates in each division.—W. J. Lancaster.

[47150.]—**Steam-Engines.**—It is required to compare the values of two arrangements of engines, viz., a compound engine with cylinders 16in. and 28in., 50lb. of steam in boiler, 60 revs. per min., stroke 3ft., and a coupled engine with 2 cylinders, each 15in. dia., 22in. stroke, 120 revs. per min., both condensing engines. The greatest power in the compound engine will be when the high-pressure cylinder works with full steam; the areas of the cylinders are nearly in the proportion of 3 to 1. The stroke of each being the same, the expansions are therefore 3, the co-efficient of which is ·666, the average pressure will therefore be 50 + 15 × ·666 = 43·29lb., say, 43lb. The area of the large cylinder is 615·7in., then 615·7 × 43 × 360ft. per min. / 33,000 = 290 h.p. theoretically. In the coupled engine each cylinder would have to exert 145 h.p. each area of 15in. cylinders = 176·7in., the speed being 440ft. per min. Then 33,000 × 145 / 440 × 176·7 = 61·5lb. average pressure in each cylinder; then 61·5 / 65 = ·947, the co-efficient of expansion which represents ·7 of the stroke which the steam would be admitted in each cylinder. To compare the two engines, we must calculate the amount of steam required for each arrangement. In the compound engine we have the area of the high-pressure cylinder = 201in., then 201 × 36 × 2 × 60 revs. = 868,320 cubic inches of steam = 502·5 cubic foot per min. In the coupled engine we have the area of each cylinder = 176·7in. and 22in. stroke. Then 176·7 × 22 × 2 × 120 × ·7 = 653,083 cubic in. per min. = 377·9 cubic ft., and for each cylinder 377·9 × 2 = 755·8 cubic ft. Then—

755·8 cub. ft.	required per min. in coupled engine
502·5 cub. ft.	required per min. in compound engine
253·3 cub. ft.	balance in favour of compound engine

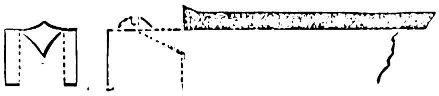
—J. H.

[47152.]—**Field-Glass.**—I am afraid you are mistaken about the object-lens of field-glass. If the spots are not air-bubbles, then they are on the surface of the flint, and are due to oxidation; these will have to be polished off, and are beyond your power. You had better ask some optician to tell you whether the marks are between the lenses or not before you attempt to alter it, as in all probability you will only injure the lenses instead of improving them. I shall be pleased to tell you how to remove the markings if you feel that you would like to attempt the job.—W. J. Lancaster.

[47164.]—**Microscopic.**—You can use a double-concave lens at the lower end of sliding tube, or if you have no sliding tube, mount it so that you can place it 3in. above the object-lens. A Barlow lens is better than a double-concave, but I have no doubt you will find the latter all you want. You might get several of them from any optician, say 6, 9, and 12in. focus, and each about 1in. diameter; then a simple cell could be made by yourself to carry the lenses, and you could occasionally use two together for increasing power more than the one lens alone.—W. J. Lancaster.

[47166.]—**Glazier's Diamond.**—You can have your diamond reset; send it to a good man, and I have no doubt you will be able to use it for years; only don't abuse it again.—W. J. Lancaster.

[47174.]—**Pedal Reeds.**—I believe that I can answer one of the questions here put—the last. My instrument (one of Cramer's) has underneath 2⅓ octaves of 16ft. notes to the pedals. These were slow in speaking, and more reedy than I liked. I conceived that the slowness might arise from the fact that the air enters on three sides, and thus blocks its own passage and delays the rarefaction underneath required for the first vibration of the tongue. I therefore took all the notes out, and pressing down the tongue of each, I, with a triangular file, held at about an angle of 60° from the top surface, filed so as to make a triangular cavity in the inner part of the end of the frame from side to side. I then adjusted the tongue so as to remain in a line with the top of the frame, so that the wind only entered at starting in one direction—namely, towards the free end of the tongue. I should say, however, that I also adjusted the frame closer to the tongues by means of chisel and hammer judiciously used not far from the edge. Anyone who is not in the habit of making adjustments of harmonium notes, nor had experience, had better be careful how he undertakes to make these alterations. The result of this I am quite satisfied with, as the notes are not at all slow in speaking, and the reediness is somewhat less, as might be expected, seeing that the triangular cavity does not cut off the wind so suddenly as the straight end did formerly. This, I think, would be an improvement throughout all scales, as I found by trial on an octave of Bourdon, the American twist did not improve the quickness of speech, but otherwise; and by no plan the same object is effected as to reediness. Anyone, however, adopting my plan had better try a note or two first to satisfy himself.—J. H. Huxley.



[47175.]—**Varnish.**—Shellac varnish, 1 part; alcohol, 2 to 4 parts. Or seedlac, 2oz.; sandarac, 1oz.; alcohol, 1 pint.—N. Mackie.

[47175.]—**Varnish.**—In reply to "[illegible]," I copy from an article in the *Bazaar* "On Argentic Gelatino-Bromide Dry-plates; their Manufacture, &c.," by Wm. Starkey Downes:—"Methylated spirit, 30oz.; place in a stone bottle; add 1oz. shellac; then place the bottle in hot water for 15 or 20 minutes, and well shake; next, add gum sandarac, 2½oz., well powdered; gum benzoin, 2oz. Shake well at different times, and let stand a day or two; then filter.—Collodion.

[47175.]—**Photo. Varnish.**—You cannot do better than as follows:—½ pint of white, hard, spirit-varnish, and 1 pint of methylated spirit. Mix cold, and when dissolved filter clear through the ordinary filtering paper. Now varnish a negative, and you will find the varnish [illegible] brittle. Add ¼oz. of castor-oil, and you will have a varnish that is hard and tough, and nearly colourless, one that I have used for the past 15 years. Photographers, note.—Old Photo.

[47190.]—**Fernery.**—There are so many details to be carefully attended to in keeping a nice fernery, that would take several pages to enunciate, and if you want to be successful, I would recommend you to get two books, "The Fern Garden," by Shirley Hibberd, and "The Window Gardener," by John R. Mollison. Both of them contain a mass of good information, and without it you will fail. Don't take everybody's advice about keeping the ferns healthy; everyone of your friends will advise you, and everyone different to the others. Fern-keeping is very similar to the story of the old man and the ass, who, you know, in trying to please everybody, lost his ass; and it is equally certain that if you continually change the regimes of your ferns you will lose them.—W. J. Lancaster.

[47196.]—**Gas v. Electricity.**—I beg to inform Mr. Grey that I don't keep tom cats—they are too gaseous. On the first page of our last number we see how gas is improved by incandescence, but this is not done without employing a motor to actuate the blowpipe, and which would add to the cost, as in the production of the electric light. It is the cost of the driving-power that stands in the way. So long as incandescence is produced, the purity of the gas is of no moment (vide Mr. Sprague's remarks), hence I infer that the gas that will produce the most heat is really the most efficient. Is not this the case with hydrogen gas? The copper and zinc battery evolves hydrogen, but if not in sufficient quantity to burn, could easily be made to do so by adding more zinc filings. After all the air has been driven out of the jar or bottle, it would burn through a suitable burner, and might be sufficient (this is the question) to produce incandescence when aided by the two poles of the electric jar. The wires could come through the top sides of jar, and carbon or platinum be the incandescent medium. I know the electricity would be small, but I do not know what effect would be made by burning the two elements in one combination. If anyone is going to try, let him wait twenty minutes after the gas is evolved and the jar closed, before he lights the burner (a tobacco-pipe through the cork will do); by that time the air will be driven out and no explosion will take place. You can buy a bottle with three necks at most chemists, arrange a stand for platinum or carbon, &c. But perhaps all this has been tried: if so, I only want to know the result so far as the incandescent light is concerned. —Fiddler.

[47201.]—**Instantaneous Photography.**—"Tyro" thanks "Ditton" for his reply, and will be glad of any help. The plates were the "Lancaster" extra rapid dry plates.

[47201.]—**Instantaneous Photography.**—There is little difficulty in obtaining instantaneous photographs of clouds. Your failure is probably owing to one of the three following causes:—Too slow plates, too small aperture in lens, or too weak developer.—W. Robinson, Jun.

[47206.]—**Dry-plate Developer.**—Citric acid would be useless, as it does not keep well itself. A little nitric or glacial acid would be better; but in strong solution, 25gr. or upwards pyro. keeps a long time without any addition. Methylated spirit in the proportion of one part, to two or three of water, materially assists in keeping solutions of gelatine good, and has no injurious action on prints.—W. Robinson, Jun.

[47210.]—**Pedometer.**—This instrument does not indicate speed, but distance only. It is regulated according to length of stride. I have one divided into spaces indicating 80 yards, and regulated it thus: Measured a distance of 10 yards, and walked over the space in my ordinary step. I found I took 12 steps = 96 steps in 80 yards. I then altered regulator till 96 beats of lever moved indicator one space (indicating 80 yards), turning screw to right, for slower, or *vice versâ*. Of course, the shorter the step the slower it must be set.—G. M. J. B.

[47210.]—**Pedometer.**—If yours is an ordinary pedometer, then the larger dial will give yards, and the smaller dial miles. You will have to regulate it so that when you have walked a measured mile then the fingers both indicate one mile—that is, the small finger points to 1, and the larger finger has gone once round and points to 0; if this finger is on either side of 0, then you must regulate the little screw at the back until the indications agree with the measured distances.—W. J. Lancaster.

[47216.]—**The Berliner Violin.**—We must wait a reply from the U.S. Perhaps the instructions given will make it an easy matter for all.—Fiddler.

[47216.]—**The Berliner Violin.**—I took off the finger-board of a violin, and made an affair somewhat similar in shape to a horse's collar, with a tang to it, which tang was glued on to the neck, and then the finger-board on top of that. This was made of mahogany, about ½in. square, and when strung up and bowed, it vibrated and interfered with the tone. But I believe that if it were made stronger in section, it might improve an inferior new fiddle; but, in the mean time, I am calmly waiting to see "any new violin that could compete with my old Klotz."—J. J. A., Liverpool.

[47217.]—**Induction Coil.**—Yes, connect the microphone with the primary coil, and the telephone with the secondary coil.—Albert Smith.

[47217.]—**Gaiffe's Medical Induction Coil.** Frank Smith can use this with his telephone. The primary, battery, and microphone form one circuit. The secondary is in circuit with telephones, line and return wire. You will require a switch to cut battery out when not in use.—George Tolman.

[47217.]—**Gaiffe's Medical Coil.**—You can use it in circuit from the microphone thus: Couple wires from microphone and battery to the larger binding screws of Gaiffe's coil; then connect line and earth, or the line telephone wires, if you don't use earth, to the binding screws, to which ordinary handles are attached.—W. J. Lancaster.

[47218.]—**Circulating Decimals.**—If Mr. A. J. Smith will write to me, I will send him a copy of a small pamphlet on this subject, which I had printed for my pupils, and which may give him the information he wants.—C. W. Bourne, The College, Inverness.

[47220.]—**To Mr. Lancaster.**—You can use the 3 layers of 16; you are not making an induction coil, and 5 or 6 layers of 16 would not matter; however, I would not now go beyond 3 layers of 16. You can increase the number of 30 and 34 with good effect. See that the connections at the end of each wire are clean and well soldered and insulated, or you will most probably fail.—W. J. Lancaster.

[47225.]—**Cup-and-Ball Microphone.**—Probably there is an accumulation of dust in the cup. A good shaking would perhaps dislodge the dust, and the rubbing of the ball against the surface of the carbon would bring it back again to its best form.—W. J. Lancaster.

[47225.]—**Cup-and-Ball Microphone.**—Is it quite clear that the fault is in the transmitter, and not in the receiver? Both receivers and transmitters sometimes fail, partially in consequence of the shrinkage of the wooden cases, when the diaphragms are unequally nipped, and a slight buckle in the diaphragm is the result. However, (1) shake the microphone well; if this does not effect a cure, (2) partly unscrew the microphone, so that the diaphragm may take its proper position, then screw up again tightly; if still unsatisfactory, (3) take off the diaphragm, remove the ball, and rub it round between two pieces of fine glass-paper; with a peg and some fine glass-paper, rub round the inside of the two cups; blow away all dust, and put together again. The cup-and-ball microphone clearly works by make and break, and as it consequently does not act as a tension regulator in a closed circuit, is not within Edison's patent; and the electro-magnet receiver is, by Bell's disclaimer, excepted from his patent. I may add that a microphone made with two conical pegs and a ring, which completes the circuit between the pegs, acts almost as well as the cup and ball microphone.—H. B. T. Strangways.

[47226.]—**Picture-Frame Making.**—A jack-plane is utterly unsuitable for fine work of any kind. You should use a trying-plane at least 2ft. long, and kept perfectly flat and sharp. I use an iron-soled and brass-boxed plane, with a single iron turned upside down and set at a very much less angle than ordinary plane irons are, and this, if kept sharp, is simply delicious on the frail, foreign, plaster-bottomed mouldings.—J. J. A., Liverpool.

[47226.]—**Picture-Frame Making.**—I don't know who your correspondent is, but my case is exactly the same. I am a practical man, and have a thorough knowledge of cabinet-making, tools, &c. I have, for amusement, just started picture-frame making for the decoration of our walls of school-room, dormitories, &c. Instead of making mitre-block and shooting-board, &c., I purchased same from Savory, Caxton House, Cirencester, buying the best. I have been at it two weeks, but cannot produce a true mitre. I am very anxious to have your opinion, because I have a lot of first-class pictures, &c., and want to make some really good frames. I find, by testing with a new 9in. square, that the angle pieces on the shooting-board are not fixed square. I should also like to know the best method of putting frames together—viz., how to hold one side secure while you glue and brad the corner, so as to bring the mitre true and flush.—J. F. Newland.

[47227.]—**Size and Power of Boilers.**—In reply to "J. H. W.," ·693 is an error, and should be ·846, which will bring the result to about 101 h.p.; ·846 is found from the formula 1 + H / R. This will not affect the boiler calculation.—J. A.

[47228.]—**Telephone.**—You will require 1oz. of 36 silk-covered wire, bobbins 1½in. in diameter, ½in. wide.—Albert Smith.

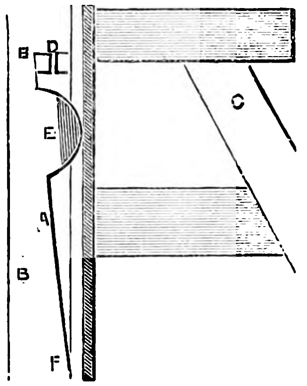
[47228.]—**Telephone.**—I have used 10 and 100 yards of 35 wire. You had better make your bobbins ⅝in. diameter by 5-16th. Fill with 35 wire winding it double; that is, *two* wires side by side.—George Tolman.

[47232.]—**The Merlin Patent Bicycle.**—A small drum, actuated by the levers and straps, runs loose on each side of the wheel. Each of the drums has a pawl, which engages a ratchet on the axle. The action is as follows:—When the lever is pressed down it draws the drum round forwards, the pawl engages the ratchet, and takes the wheel round too; but when the stroke is finished and spring in the drum brings it back to its former position, ready for another stroke, the clicking sound is prevented by means of a small piece of leather, which deadens all sound.—G. R. T.

[47234.]—**Weight of Girders.**—I do not think it would be profitable to make a box girder 12ft. long, which would break with a weight of only one ton. It would be a mere pipe, and impossible to put together with plates, angle iron, &c. A rolled joist would probably answer for so small a weight.—M.I.C.E.

[47236.]—**Object Mounting.**—If "A Constant Reader" will publish his address I will send him some of my mounting medium. I have mounted volvox and anatomical objects, and they are as fresh now as when they were first put up; the great thing is, the objects mounted in this medium do not require any preparation.—Albert Smith.

[47241.]—**Thief Detector.**—B is the pillar to which the gate C locks; A is a brass spring, fastened to the pillar at F; E is a half-ball of brass, soldered on to the spring A; H and D are two small squares of copper, D being screwed into the wood. Solder two pieces of wire to D and F. When the gate C is opened the half-ball E, with the spring A, flies forward, and makes contact at D. When the gate is shut, the spring is pushed back, and breaks the circuit. I hope this will suit.—B. Goren.



[47242.]—**How to Get Rid of Mites.**—Give a good coating of carbolic acid or a good coating of paint; gas-tar is a good thing.—Albert Smith.

[47243.]—**Dry-Plate Photography.**—In crown-glass, of which your lens is most likely made, I believe the chemical focus is usually about 39-40ths of the visual; but, as I said before, I think the exact distance can only be found by actual trial. Of course the ground-glass of the focussing-screen might be arranged as you propose, but it would be spoiled for use with an achromatic lens. Camera-making being quite out of my line, I regret that I cannot give you particulars for making dark slide, but I think you will find some information in recent back numbers.—W. Robinson, Jun.

[47245.]—**Electric Bells.**—Better look to your connections and contacts. Are they platinum-pointed contacts? Your batteries are evidently in good condition. See to earth or return wire.—George Tolman.

[47246.]—**Private Telegraph Wires.**—They are strained with a vice made for the purpose. Iron does not stretch. What do you mean by keeping tight? Do you mean copper? If so, it must be hard "drawn" wire. Insulators can be fixed close to wall, but must not touch.—George Tolman.

[47147.]—**Photographic.**—Any lens of longer focus than the one you have will proportionately increase the size of the image of distant objects; and if your camera has a movable front, it will be quite feasible to lengthen it in the way proposed; but scarcely so otherwise.—W. Robinson, Jun.

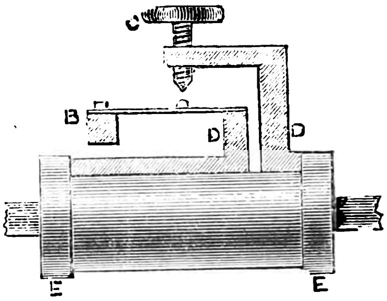
[47148.]—**Fogging.**—This is hardly likely to have been caused in the way you suggest, but is more probably owing to light having got to the plates in some way or other. What do you mean by "awaiting ferrous oxalate to redevelop"? If you have already developed and fogged the plates, better not waste any more time or chemicals on them.—W. Robinson, Jun.

[47249]—**Putting Steel Tongues in Concertinas.**—The cause of the tongues breaking is evidently because they are filed too thin near the rivet. The querist should have stated whether it is the treble or the bass notes that do break. Had he done this, and given his mode of fixing them in, I could have given him a definite reply. I do not approve of placing steel tongues in a concertina that has previously had brass ones. On the other hand, I do not think that it would be wise to put a brass tongue into an English concertina which has all the other notes of steel. I have repaired quantities of concertinas, but have never done such a thing. Try good spring brass, and hammer it well before cutting the vibrator out; then be careful in filing it, and, above all, take care not to file too much away from the rivet end. With these few hints you ought to succeed. The steel tongues only require careful filing, and some degree of knowledge in fixing.—G. Fryer.

[47250.]—**Galvanising Boat-Irons.**—I would suggest that the cause of your failure is that you didn't use pure zinc, as I have found that cuttings or scraps of ordinary sheet-zinc will not make good "soldering fluid," and I procured a lump of pure zinc from a galvanising establishment, which proved quite satisfactory. The sheet zinc is, I believe, alloyed in order to make it more tractable when rolling.—J. J. A., Liverpool.

[47254.]—**Electric Commutator for Intermittent Action.**—You will require a governor fixed on the axis of the ring armature, for which the design given below will answer as well as any. A, wooden cylinder on axis of armature; B, governor weight fixed on a spring, which flies out at the proper speed, and makes contact with the set screw C; D D, supports for the set screw C, and the spring and hammer B; E E, brass rings, connected one to each of the above; contact-springs from the frame of machine must press on the rings E E, and the springs are then to be put into circuit with the armature-brushes. You must use a magneto and not a dynamo machine if you want to succeed, and you will also find the Planté is more practical than Sutton's battery.—J. Sutcliffe.

[47254.]—**Electric Commutator for Intermittent Action.**—You can do this by having a pair of engine governors, so that when the speed slackens it will cut the storage cells out of circuit, and *vice versa*. If you require the current equal to, say, six Bunsens, then you must use twelve storage cells.—George Tolman.



[47257.]—**Bookbinding in Vellum.**—Parchment or vellum is quite unsuitable for books with limp covers and edges cut flush. Leather or cloth is more suitable for this kind of binding. No one, with any knowledge of the trade, would do such a thing. Vellum is often used for account-books of various sizes, but such books should have rather stout boards, and on no account be cut flush. By this, I mean that the vellum should be turned in, and squares allowed for the books if possible.—G. Fryer.

[47257.]—**Bookbinding in Vellum.**—The cause of the curling up mentioned is owing to the vellum not being lined; all parchment work, whether limp or boards, ought to have the vellum lined with white paper. Let "Argent Sable" paste a sheet of paper on his vellum, and allow to dry under a weight; then use the vellum in the usual way for limp work, and after the work is covered let it stand twelve hours under a light pressure, before cutting; he will then, I think, have no occasion to complain of the unruly behaviour of his covers.—Arthur E. Morris.

[47261.]—**Arsenic in Wall-Papers.**—Boil some specimen, and test the extract thus:—1. To a small portion of the solution add a drop of HCl of H_2SO_4 and H_2S: yellow precipitate. 2. Add $AgNO_3$: pale yellow precipitate. It is well to add also, drop by drop, a very dilute solution of $(HN_3)H_2O$. 3. Add $CuSO_4$, instead of $AgNO_3$: pale green precipitate.—R. Kanthack.

[47261.]—**Arsenic in Wall-Papers.**—The most simple method is Reinsch's test: boil some of the paper in a porcelain dish with some dilute hydrochloric acid and a strip of bright copper; the copper displaces the arsenic from the solution, and a dark grey compound of arsenic is deposited upon the copper: a blank experiment should be made first, because the acid sometimes contains arsenic.—Albert Smith.

[47261.]—**Arsenic in Wall-Papers.**—Immerse a piece of the paper in a strong solution of ammonia in a white plate or saucer; if the ammonia becomes blue, copper is present. Then drop a crystal of nitrate of silver into the blue liquid; if arsenic be present, the crystal will become coated with yellow arseniate of silver, which will disappear on stirring. This is an easy test, and may be performed by anyone.—F. S. Harrison, Alresford, Hants.

[47262.]—**Wheel-Grease.**—The following is a good recipe:—Mix one part of very fine blacklead, ground perfectly smooth, with four parts of lard. Camphor may be added, but is not absolutely necessary.—W. Henly Richmond.

[47264.]—**Lightning Conductors.**—See "Report of Lightning Rod Conference" (Spon), reviewed in English Mechanic, January 13th, 1882.—G.

[47264.]—**Lightning-Conductors.**—$\frac{3}{8}$ copper rope, stapled to building (without insulators); spread the ends out at the top, which should be attached to a copper tube or rod built in the building for stability. For earth, dig a hole 4ft. or 6ft. deep, 3ft. square, about 10ft. away from the bottom of structure; unravel the end of rope, place in the bottom of hole, and fill up with good hard foundry (not gas) coke.—George Tolman.

[47264.] — **Lightning - Conductors.** — The Lightning Rod Conference Report—the result of several years of patient research, by some of our most scientific men—recommends a wire-rope conductor of copper, $\frac{1}{2}$in. size, as the best form to use. A recent patent, referred to in the Report, is meeting with much favour, on account of its being easy to test after being erected. The conductor should be attached to the chimney by copper staples or strips, without insulators, and at the bottom connected to a 3ft. by 3ft. copper plate, imbedded in soil likely to be always damp, 6ft. or 8ft. below ground. It should make what is technically known as "good earth." At the top a copper rod of some 6ft. high, having a slightly-blunted point, and a circlet of finer ones a foot below is best. Fuller information given if letter addressed to 71, Albert-road, Dalston, London, E. —Yorkshire.

[47268.]—**Bellows for Brazing.**—I asked, a month or so ago, for information respecting the right kind of leather to use in making double bellows, and the reply I got was, "Ask for best strained sheep-skin." I have not begun my bellows yet, but the plan I thought of was to have the feeder on the top and the reservoir at bottom, the needful pressure being obtained by a strong chair-spring. This, I think, is neater, and more portable, and the pressure to the feeder can then be applied direct. My idea was to have a balanced brass valve and a brass seat, but I think yours is preferable as it is much simpler. Fletcher's little pamphlet "On the Use and Construction of the Blowpipe," is very useful.—Nemo.

[47268.]—**Bellows for Brazing.**—The leather for these should be calf, oil-dressed; the joint with the wood is made by getting the surface of the wood perfectly smooth, putting a layer of dubbin between the leather and wood, and nailing close with special broad-headed nails, the heads touching each other, or nearly so. To make tight bellows, to stand heavy pressures, is a matter of considerable difficulty, requiring experience. Brazing with blowpipe requires some practice, and if powdered spelter is used it should be mixed with wet powdered borax into a paste, gently heated until the borax is dry and fused, and then the full power of the blowpipe applied. If not treated this way, the spelter is burnt, or oxidised, and at once becomes useless. For small work it is better to use an alloy of equal parts of coin silver and copper, melted together and rolled into a thin sheet. This will make an edge to edge joint, which will stand bending, hammering, or rolling out.—Thos. Fletcher, Museum-street, Warrington.

[47269.]—**Electric Motor for Tricycle.**—It is not possible to store power by a dynamo-machine, in connection with the wheels of a tricycle, to any advantage. I have been informed that the French electric tricycle ran on a smooth level surface, and is not very suitable to go uphill. It was worked by a bichromate battery of large surface, and is only likely to be used as a curiosity. If you want a practical motor, I would advise a gas or air-engine. Both have the disadvantage of being rather warm; but a coiled spring would be better than any electric contrivance for a tricycle.—J. Sutcliffe.

[47273.]—**Lines of Force.**—You will find this described with two illustrations on page 152, No. 891, Vol. XXXV.—George Tolman.

[47174.]—**32ft. Pedal-Reeds.**—Let me know the size of your 32ft. reeds, and then I shall be able to furnish the desired information. Also let me know the number of reeds that you intend to add, and also a brief description of the instrument you wish to apply them to.—G. Fryer.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

Since our last "Ditton" has answered 46103, 46505, 46618; "Carino," 46470.

46652. To "Clerkenwell Clockmaker," p. 161.

QUERIES.

[47274.]—**Illuminating Clock.**—Can any correspondent tell me how to illuminate a 3ft. clock-dial, iron, outside in front of a bay window? Could a light be put inside of room and act on a reflector in front of clock, and so cause the light to show on the figures? The clock is 12in. from the window-glass. How large would the reflector be? Also, what kind of light?—Light.

[47275.]—**Oak Graining.**—Will some practical painter give me full particulars on oak-graining as to mixing the graining? I have tried brown umber mixed with oil, and I find it is too dark; and I am at a fix what to mix it with. I want to mix the umber with table beer (or turpentine, one painter told me). Will someone be kind enough to tell me what I am to lighten it with, and then I want to know how the over-grain is laid on?—An Amateur.

[47276.]—**Electrical Indicator.**—Will some of "our" friends please describe a water-level indicator? I wish to construct one for a reservoir one mile away from the pumping station, and 260ft. elevation. As the level is constantly changing, it should be capable of denoting the rise and fall respectively, as they occur, and to within, say, 3in. The reservoir is 9ft. 2in. deep from overflow to floor. A sketch would be a great help to me. Also, one of the receiving instruments.—Troubled.

[47277.]—**Engine.**—I have a cylinder 2$\frac{1}{4}$in. stroke, 1$\frac{3}{8}$in. dia., that I wish to fit up myself. Will any able reader instruct me a little the best way to make the slides, as the piston is cut off for a crosshead? Also, the weight of the flywheel, and would it work sewing-machine?—T. B.

[47278.]—**Patented or Not?**—If I put an iron tube round the bobbin of an electro-magnet, am I infringing on anyone's patent? I saw some at the Crystal Palace treated so, and they were marked patent. Is it not a very old idea?—Bobbin.

[47279.]—**Spoilt Glass Shelves.**—When making some alterations to my shop-window, I put some glass shelves away for future use, not having occasion for them at the time. Thinking the only thing I had to guard against was breakage, I stored them in a cellar, leaning against the wall, not in a particularly damp place. On examining them after several months, preparatory to using them again, I found them covered with cloudy spots and patches. I have tried every means I can think of to clean them, but without success. They look as if they were dirty, and it seems as if the polish has been eaten off the surface of the glass. Can any fellow-reader suggest the reason, and say what can be done with them?—J. E. A.

[47280.]—**Legal.**—To Mr. Wetherfield.—I have an iron-foundry of my own: I and my brother worked it as partners. We dissolved, and now he has built himself a foundry. Can he legally take the name of my foundry and call his foundry by the name by which the old foundry we jointly worked 16 years is known?—G. B.

[47281.]—**Tricycles.**—Can any of your correspondents say from his own experience what are the comparative merits for hill and level work of lever and chain driving tricycles? The Challenge tricycle No. 1 is an elegant machine, with one large wheel behind, and two small wheels in front. The large wheel is driven by two foot-levers, and being in the centre-line of the machine, this method seems to have some advantages. I observe, however, that the lever arrangement is very rare, nearly all tricycles being driven either by a chain or cog-wheels. All the other Challenge tricycles are so driven. If any of your correspondents can throw light on the subject, I shall be obliged.—B.

[47282.]—**A Foreground Query.**—I wrote a few months since to the Slade Professor at Oxford about the following subject; but the big man was, I suppose, too exalted to stoop to the consideration of a matter of such trifling interest, as he took not the smallest notice of my letter; I confess I regretted that Mr. Ruskin was not still the occupant of that chair of State:—Suppose I am sketching a scene, say a house or church with foliage at a distance of two fields, and do not wish to include more ground than half that distance, the building being more picturesque than when viewed more closely. In such a case the herbage, &c., of the distance—i.e., the field immediately in front of the building, is indistinct, with no visible leafage. If left thus in the picture, it seems to demand more detail; but if such detail is given, the result is, that the building, instead of appearing at a little distance, necessarily comes forward, because the detailed foreground immediately in front of it predicates the nearness, also, of such building, and the latter now demands to be treated as itself a foreground object—quod non erat desiderandum? In point of fact, no one sketching a scene sees the detailed leafage at his feet.—Then query? Ought it to be represented in detail, unless the scene is absolutely and solely a bit of foreground?—Country Sketcher.

[47283.]—**Launch Tubular Boiler.**—I want to know what is the specific gravity to which sea-water should be kept in a launch boiler (tubular). When should the water be changed, and in what manner is this done under steam?—J. F. E.

[46284.]—**Modelling in Plaster.**—I have taken and been a reader of your valuable journal for several years, yet I am not aware that the subject of modelling in plaster or any other material has been fully treated of. Now I should be glad if some one of your numerous correspondents well acquainted with the subject would give us a full account of it.—An Amateur.

[47285.]—**Gymnastic Apparatus.**—I inserted a query some weeks since asking for the manner in which ash bars up to 7ft. were bored for inserting steel rods. The answer "Jack of All Trades" kindly gave was hardly what I required, as he only informed me of the pattern of drill. What I require is the most approved machine for doing this work. If it is not possible to describe it in the answer to queries column, perhaps some obliging correspondent will inform me of the maker of the machine, or where I could have the bars drilled. I shall be very greatly obliged by this information.—Gymnastic.

[47286.]—**Chromograph.**—I have lately made one of these as follows:—10oz. glycerine, 2oz. gelatine, 1oz. kaolin, and a little salicylic acid with 8oz. water. I find after the first few copies they get very indistinct, and am afraid I have not quite sufficient of one of the articles: I should be glad to know which. The qualities of the materials used were the ordinary chemist's, not the "commercial." While on this subject, I may state I find a 10 per cent. solution of hydrochloric acid very useful to remove the old copy, just rubbed lightly over with a sponge.—Gymnastic.

[47287.]—**Magneto-electric Machine.**—Please give precise detailed instructions to wind wire on bobbins of above? Also, at what part of revolution should spring working on flats of spindle make and break contact? Having repaired a machine, cannot get it to work, and think fault exists where referred to. Ordinary upright machine for medical purposes.—A. Matthews.

[47288.]—**Drying-Racks for Dry Plates.**—Could any of our numerous readers kindly give me their experience in drying plates on their ends? I find the plates do not dry evenly if too close on the racks. I prefer them dried on their backs, but cannot dry half the quantity at a time.—J. R. Brown.

[47289.]—**Sulphur Casts.**—What is the proper mode of mixing colour (e.g., vermilion) with the sulphur, so as to avoid the patchy appearance on cooling? The results when fresh from the mould seem perfect: but on cooling and exposure, the polish disappears and the colour deadens.—J. P. H.

[47290.]—**Calculating Machine.**—Will anyone kindly oblige by directing me how to make a reckoning wheel such as is used in the railway clearing-house Euston-road, or any other easily-made calculator?—W. D.

[47291.]—**Boiler Ends.**—Kindly give me rule in plain figures for calculating the flat end of a boiler unstayed, the diam. of which is 5ft., thickness of plate $\frac{9}{16}$, single riveted to shell.—John.

[47292.]—**Bunsen's Battery Connections.**—Will any correspondent say how I could connect my carbons with copper wire or slip, otherwise than by using a clamp? If it can be done by depositing copper on the top and then soldering, kindly give instructions for soldering, as I have been told spirits of salts should not be used for battery connections.—Bond.

[47293.]—**Pump Query.**—Will some reader say what clearance the ram of a pump has to have from the bottom of the barrel, of the following descriptions:—Diam. of ram 12in., 2ft. stroke, and running at 38 revols. per minute; heat of water 120°. Is the speed too high?—No Name.

[47294.]—**New Combination of Altazimuth and Equatorial Mounting.**—Will Mr. Godfrey or "F.R.A.S." oblige us with a proper description, with figures, of the "Smeaton block"? I remember the latter correspondent making an illusion to it some months ago.—J. C. L.

[47295.]—**Decimal of the Year for Astronomical Observations.**—I should be glad to know how this is calculated. Mention is made in Vol. XX. that it belongs to the year with which it is associated, but nothing more.—J. C. L.

[47296.]—**Object-Glass Making and Correcting.**—Thanks to "O.V." for his kind reply to my query; his quotation for Chance's discs is quite correct for that size. May I now appeal to "Prismatique" whether he will go into the matter when he sends his promised letters on object-glass making? and if he would like to read the letters by Mr. Godfrey I alluded to in No. 899, I should be pleased to send him the numbers containing them.—J. C. L.

[47297.]—**Taking Cold.**—To Dr. Edmunds.—The last few months I have had an almost continued cold in the head, and now and then a slight cough. I am at the counter, and, of course, subject to the usual draughts of a shop. I am very thinly thatched, and perspire very much, and with very little exertion, and think that has something to do with the cause of colds. I wash my head in cold water every morning, and have just taken to my cold sponge bath for the summer. I don't wear a cap in the shop, and don't want to. Can you advise any remedy?—Is it debility, as I have felt a considerable languor for some time?—E. S.

[47298.]—**Examination of Malt.**—I want to examine malt chemically, but the filtration of the infusion, by means of the ordinary funnel and filter papers, occupies more time than I can spare. Will someone kindly inform me by what means I can effect this process with more rapidity?—Phœnix.

[47299.]—**Lantern Optics.**—Will any of the numerous optical correspondents of "ours" kindly answer the following?—When the source of light (lime-light) is placed within the principal focus of condenser, the enlarged disc of light on screen is well and sharply defined; but when placed in the principal focus, so as to give a parallel beam, the disc on the screen becomes dimmer and loses all sharpness of definition; in fact, is not a disc at all. Is this the usual experience? If not, where is the fault? If so, why should not the disc be equally well defined when a parallel beam is used as when a divergent one is used, as in the first case stated above?—M. A.

[47300.]—**Proportions of Cylinders.**—Would "Tubal-Kain" kindly answer the following questions? I wish to know the rule for finding out the proportion the high-pressure cylinder ought to have to the low-pressure cylinder in compound engines? Also, the advantage of working with dry steam, and the advantages of wet steam? Also, the rule for finding the temperature of any given pressure of steam? Please don't use algebra.—A Beginner.

[47301.]—**Vacuum Tubes and Coil.**—Will any of our correspondents kindly tell the probable cause of flashing or dancing in vacuum tubes? When everything is apparently in order, and the coil in great force, I am often troubled with a dancing or winking of the tubes, like gas light when there is water in the pipe. The cause of this, and how to avoid it, would much oblige—W. R. C.

[47302.]—**Contracted Tendons.**—Will any medical correspondent of the "E. M." kindly inform me what remedy I can apply for the following ailment?—The tendons of two of my fingers in the palm of one hand are so tightened as to contract the fingers so that they cannot be straightened, and on the tendons a hard lump or swelling has formed, and a similar hard lump has commenced forming at the foot of the thumb in each hand just below the joint in the palm of the hands.—Tropics.

[47303.]—**Rusty Water-pipes.**—I have some 1in. iron water-pipes which have been in use several years, and the water through which often comes away rusty, and is a source of great annoyance to me; in fact, causing spots of ironmould to appear on the goods which I immerse in the water. Can this be remedied in any way? I have adopted many means to try and clean the pipes, but with no satisfactory results as yet. A suggestion from any of ours will be thankfully received.—Puzzled.

[47304.]—**Division Plate.**—Will some correspondent oblige by answering the following?—I have a 5½in. centre lathe, to which I want to add a division plate. The pulley on the mandrel is mahogany, and is 7in. dia. I thought if I had a plate cast and screwed it on to the face of the wood pulley, it would answer. What would be the best metal to have, and how thick? What would be best numbers to have, and how am I to divide it? I have overhead motion and drill-spindle. What would be the best form of drill point to drill the plate with?—E. J. L.

[47305.]—**Photography.**—To Mr. Parkinson.—Would you kindly answer me the following, and oblige? I have taken several enlargements on bromo paper, but not one free from white spots. I thought they were caused by dust on the paper before exposure, and I was very careful afterwards; but still I had spots. Cause and remedy? What shall I use to spot out? Also, what should I use for spotting out silver prints? If there were dust on the lens, would it show on the paper or on taking a negative? On May 26, you stated you used Edwards' developer: Do you find it suits different makers' plates, and would the action be slower if the bromide of potash were increased, as one formula I have gives the bromide 200 grains?—F.

[47306.]—**Slide-Rests.**—As I have previously made some remarks on the plan of dividing the nut of the leading screw of a slide-rest, I should like to supplement them by asking Mr. Evans, apropos to his article on slide-rests, whether it is expedient to apply this means of correction to a new tool, however advantageous it may be for the repair of an old one. My objection is this: by dividing the nut into, say, two equal parts, all the work of the screw motion is thrown on one-half of the thread of the nut; and this, whether the parts are screwed up or not, and as a well-made screw and nut will work for a long time without any "back-lash," it seems a pity by dividing the nut to hasten the time when this will arrive. I should say it was better to wait until the nut is sufficiently worn to call for the remedy.—M. A.

[47307.]—**Mildew on Vines in Greenhouse.**—I have had the mildew in my greenhouse three years running, and lost the whole of the crop. The grapes are covered with a white film, and the leaves are spotted as if burnt. I have tried fumigation with sulphur and lime, and other supposed remedies, but to no purpose. I have now a splendid show of fruit, but the mildew has just made its appearance. Can any reader tell me how to stop it and save my grapes?—Amateur Gardener, Cheltenham.

[47308.]—**Inflamed Throat.**—To Dr. Edmunds.—About two months ago I had inflammation of the throat, which relapsed several times. At present I feel a constant desire to swallow or expectorate. Health fairly good.—North.

[47309.]—**Clarionet.**—I should be obliged if any of our readers would kindly tell me how to determine (theoretically) the dia. and length of bore, the distance between the holes, and the diam. of same. I wish to make a clarionet about a quarter-tone flatter than those in general use, and as I cannot get an instrument to take pattern from, I am forced to seek information where I can. I have looked through two works on acoustics but have found no such information. Should be glad to know if there are any books on the subject. I should also like to make my own reeds, and would like to know how to choose the cane, and how to proceed.—Old Blow-Hard.

[47310.]—**Naturalisation.**—Is a Frenchman by being "naturalised" as an Englishman thereby exonerated from military service in France? Could they imprison him if he went to France after failing to appear to serve when summoned? And has the French Government power to confiscate any property he may become possessed of in France?—Kanet.

[47311.]—**Cannon.**—Being about to cast a gunmetal cannon 2ft. long, and 1in. bore, I wish to know what thickness the metal ought to be at the breech end, so as to insure safety.—E. A. L.

[47312.]—**Dynamo-Machine**—To George Tolman.—Will you please give your opinion of arrangement of field-magnet? The core of F.M. is ½in. by 3in., bent to shape and screwed to soft iron pole-pieces 5in. long. My armature is of the Gramme form, and is 5½in. by 2¾in., and consists of 8 coils of 16 c.c. wire, 4 layers of 15 rows each, giving 30ft. on each coil. What amount and size of wire should I wind on field-magnet? Should it be arranged as shunt or circuit machine? Any suggestions as to better form of F.M. (to work with pole-pieces which I have by me) will be gladly received. Thanks for former answers.—In Want of Help.

[47313.]—**Tests for Bicarbonate of Soda and Tartaric Acid.**—Will some correspondent tell me how to test bicarbonate of soada and tartaric acid for commercial purity? I require them for mixing with flour, and find that some samples do not act as efficiently as others.—Novillo.

[47314.]—**Rotation of the Earth.**—How many times does the earth rotate in the 365 days forming the year, fractions corrected by leap year being disregarded? It appears to me if there are 365 alternations of day and night in the year, the earth must rotate either 364 or 366 times.—Cymro.

[47315.]—**Harmonium Pan.**—Will someone kindly give instructions for making a pan for harmonium to contain 2½ sets of reeds?—Gotha.

[47316.]—**North Pole of Electro-Magnet.**—Suppose I hold a bar of iron with its axis in a line with my sight, and commence to coil by winding in the direction of the motion of the hands of a watch, which end of the bar should I begin at—the distant or the near end—to make a true north and south polarity? State which end is north.—Pan Jack.

[47317.]—**Lewis' Incandescent Gas-Burner.**—To Mr. J. T. Sprague.—I have read your article on the new gas-burner with great interest. I am looking out for a good effective light for large shop and warehouses, either electric or some improved system of gas. The present gas-burners I consider very undesirable: in fact, unworthy of the age we live in. Can you confer a further favour by giving an idea of the cost and permanency of the "platinum wire cap," and the best means of supplying the compressed air? Can it be done by a small gas-engine, and what power would be required for, say, 50 burners of 50-candle power? Can the compressed air be economically stored, or would it have to be supplied as required?—D.

ANSWERS TO CORRESPONDENTS.

⁂ *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

⁂ Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, June 28, and unacknowledged elsewhere:—

H. Layton.—Hillman, Herbert, and Cooper.—Lurgan Mechanics' Institute.—Photo. Artists' Co-Operative Association.—J. K. Smythies.—E. B. Fenessy.—Serg.-Maj. Connors.—J. A. Maclean.—Arthur Hinde.—S. Norman.—Rogator.—H. B.—S. Taverner.—Ajax.—S. J.—Plumber.—Arthur Smith.—Air.—Dusty.—F. Rowe.—Cleaner (Salisbury).—Jack of All Trades.—Alfojoe.—F. H. H.—H. Field.—Student.—Ditton.—Crytax.—Nuda.—Veritas.—Seaweed.—Meteor.—Manchester.—Fred Walker.—T. H. Espin.—Enquirer.—E.—S. J.—Poor Scribe.—G. F. Finn.—R. T. B.—A. Stanley Williams.—C. Townley.

Frederick Petersen. (No, vulcanised paper is not celluloid. The manufacture of the latter has been frequently described.)—M. J. (Add water to the recipe given on p. 317. 2. Benzol, turpentine, Castile soap are among the many revivers used.)—Yelrum. (By means of blocks of lignum vitæ, which are grooved to fit into grooves on the shaft. The tremulant is scarcely suitable.)—Erin-go-Bragh. (They are all worked on the principle illustrated on pp. 87, 111. See also p. 224. The switch is an arrangement of brass rods connected to the different wires, so arranged that by the insertion of plugs any two wires can be connected together.)—Troubled One. (A number of recipes for eczema in last two volumes. Anointing with clarified beef-suet and powdering with oxide of zinc, repeating the coatings one over the other, is recommended; but you might try vaseline ointment.)—Troubled. (Several medical coils described recently. See p. 313. There are not so many ways of connecting up that you should be long puzzled.)—A Beginner. (Question cannot be answered. Make the hammer hit it hard; but perhaps it is a soft-sounding bell, and is as loud as it was intended to be. 2. As to making a telephone, you must look through recent indices, and choose for yourself.)—John C. Newbold. (No one can answer such a question without examining the motor, and your sketch does not give even an idea of its construction.)—Albt. Wyles. (The author will, doubtless, correct.)—G. H. H., Derby. (Such a recipe would be worth a trifle. Clean them up with the finest glass-paper, and polish with whiting and spirit. Then expose to sunlight behind glass. Some makers put whiting into the glue, others dry whitelead, using very pale glue.)—Salopian. (Of course, the two surviving sons share equally; the eldest son's claim is preposterous.)—Ch. Rabache. (You flatter us, we fear; but we must leave the establishment of a French counterpart of "ours" to some Frenchman. We fear our English subscribers would respond very slowly to your idea. We cannot spare space for the reproduction of reply 46051, and under the guise of a reply to 47053, we do not see our way to admit your dissertation on spectrum analysis.)—J. A. Jeffrey. (Should be glad to have the photograph.)—J. J. Rathbone. (Are you sure the bankrupt did not get his discharge? If so, you had better consult a respectable solicitor, and take action at once—that is, if the debtor is worth powder and shot.)—Senor Espanol. (We cannot insert queries as to prices, &c.; but why not write to Lancaster and Son? See their advertisement on back page.)—A. Illingsworth. (Not if it has been obtained honestly, as most probably it has; still, just now, people should be careful.)—Ferro-Carril. (Why should we occupy valuable space with reproductions of illustrations which can be obtained elsewhere, or of well-known objects in museums, which can be seen at any time?)—Pater. (The confinement and long hours *would* injure her, and unless she worked hard she would not make a living.)—Cymro. (You have simply confused yourself by rotating it once in a revolution. The question in its simple form is inserted.)—George. (A foot diameter has a circumference of 3·141ft.)—John Hale. (1. Bunsen; 2. A matter for experiment; 3. Depends on how the zinc and acid is bought; 4. Would have to be cleaned daily; 5. See 3; 6. As large as convenient, not smaller than No. 16; 7. About 4s. 6d. a cell, plus the cost of charging.)—Pan Jack. (Has any one said that it is not?)—W. Ebrington-Knight. (See p. 20, last volume, and the indices.) S. T. Smith. (You have not followed the instructions, and expect impossibilities. See p. 308, and recent back numbers. Must have a coil if you want shocks.)—Tinker. (If your query was received, it was inserted or answered here. As it appears to be only about solder, it is probable you were referred to back numbers. Look in the index to Vol. XXXIII., and you will discover references to a number of papers on solder and soldering.)—A Down Mechanic. (Fuchsin is a hydrochlorate of rosaniline; Hofman's methyl violet is prepared from rosaniline, iodide of methyl, alcohol, and potash. Both are be had of any dealer in dye-stuffs.)—Experiments. (You run great risks of having your questions dropped into the w. b. You might, at least, write plainly. We cannot discover whether you want to make or analyse extract of safflower. Probably you will find the questions answered in Slater's "Manual of Colours and Dye-Wares," just published by Lockwood and Co., Stationers' Hall-court, E.C.)—Mariner (See p. 308. You will have all the materials ready to hand. The zinc will be useful for certain purposes—cutting up into rods, for instance—or you can melt and cast to shape required. Thompson's "Electricity and Magnetism," Macmillan, and our back-numbers for practical hints.)—Tent Maker. (They use preparations of cochineal, combined with starch, and salts of tin. You could print on the material with ink, or use stencils. The methods used by calico-printers would be expensive and troublesome without proper plant. A good vermilion red is made with 5lb. vermilion to 1 gallon of thickening, the latter being a mixture of gum dragon and egg-albumen. The colour is faster the more albumen is used, 4lb. of albumen and ¾lb. of gum dragon to the gallon of colour being the best. After printing, the fabric is dried and steamed for an hour.) Paulatim. (You should consult the back volumes, and procure the catalogues of the makers who advertise in our columns. Nothing less than a 3in. back-geared lathe would be of much use.)—Electrician. (The weight and gauge vary to a certain extent with the size of coil. In No. 797, p. 410, there is a table of dimensions, &c., of coils described in this paper; on pp. 15, 16 of this volume, and on p. 313 dimensions, &c., of different coils are given.)—Junius. The rule is to make the layers as thick as the core, and twice its diameter for length. Perhaps you have not wound the wire correctly, and perhaps you have not battery power. Suppose the iron rod is ⅜in., then make the limbs 2in. long and fill bobbins 1in. in diameter and ¾in. long—that is, the groove in the bobbin should be ⅜in. by ¾in.)—Catarrah. (See Dr. Edmunds' paper on p. 441, No. 851.)—Harry A. Dix. (Varnish paints; but none will last very long.)—Sandblast. (See p. 235, No. 400, for an illustration of the sandblast. You can soften leather by soaking in water.)—One in a Fix. (We presume you really mean nickel, not nickel silver. Nickel is readily dissolved by nitric acid and by aqua regia, also by sulphuric and hydrochloric acid. Either your acids have not been strong enough, or your metal has been in too large pieces. 2. It ceases to work when the circuit is broken, but local action goes on.)—O. (The answer would be, Certainly, for if it gives any current at all it would work it. 2. Shellac varnish carefully applied is all that is required.)—A Constant Reader, Manchester. (The question has been answered many times in nearly every volume. See p. 110, No. 785; p. 313, No. 793, and more recently p. 240, No. 868, and p. 253, No. 869.)—Manchester. (Vitremanie is properly burnt-in glasswork, but you mean, we presume, the method of sticking coloured pictures on windows. That is done by varnishing the print with Canada balsam, or some other crystal oil varnish until transparent. The tools required are very few. See p. 100, No. 498. Materials of artist's colourmen generally.)—An Amateur Tinker. (We answered you on p. 341. For japanning tin, see No. 868; for cold brazing, see p. 81 of this volume.)—A New Subscriber, Longton. (Sprague's "Electricity: its Theory, Sources, and Application," E. and F. N. Spon, Charing-cross, 8s., but we believe it is out of print, and a new edition is being prepared. The present volume commenced with No. 885.)—E. M. (The addition of strong soapsuds to boiler feed may help to prevent the plates corroding; but it will also help to burn them by forming a layer of non-conducting slime between them and the water. Keep the plates clean by purifying the feed-water, and by frequent washing out.)—THOS. M. (As the object is to impregnate the leather, the slowest drying would be the best, provided it is not one of those qualities that never dry properly.)—AN AMATEUR. (See p. 496, No. 853.)—J. E. (A cheap and simple metronome was described and illustrated on p. 216, No. 841.)—PISCES. (Nos. 851 and 852 contain several recipes for aquarium cement. Both can be had.)—PRAGMATICAL. (For Holtz machine, see p. 179, No. 840; for the Voss machine, p. 335, No. 846.)—THOS. M. (1. Such a will would be perfectly valid. Two witnesses are required who must not be legatees. 2. Not necessary. 3. Trustees are not necessary. 4. The will can be revoked at any time by simply making another. It would cost you very little to get a respectable solicitor to make the will, and would be safer every way.)—W. H. P. (The Act can be procured from the Queen's printers, Spottiswoode and Co. We do not know the title, and do not think it applies to the cases mentioned.)—DESPONDENCY. (Try bathing them daily with water, in which Tidman's sea salt has been dissolved; very probably the weakness will pass off in a couple of years or so.)—J. J. ALLINGHAM. (No; half a crown.)—DUTCH SUBSCRIBER. (If you can answer Mr. Lancaster's questions, he will probably give the information asked for; but we cannot go to the expense of illustrations which would fill half a column that he may see what the camera is like.)—ELECT. APPRENTICE. (Mr. Tolman will, doubtless, supply parts, &c. He advertises in the "Sale Column." You had better ask the other questions privately. We cannot repeat matter already published.)—CELER ET AUDAX (Any of the makers who advertise in these pages would supply you. Such tires as you suggest would interfere very materially with the speed.)—J. H. HUXLEY. (You had better re-write the letter and make a fresh drawing—if you think it worth while. On the whole, we hardly think it is.)—S. CALTON, BEETLE CRUSHERS. (In type.)

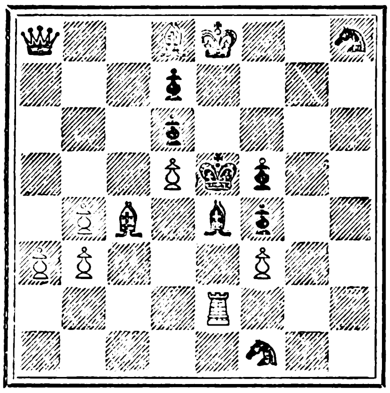
F. H. H.—B. B.—Nunquam non Paratus.—Tony B.—J. R. E.—Arthur E. Morris —M. Jonson have replied to queries already similarly or adequately answered.

CHESS.

ALL Communications for this department must be addressed to the Chess Editor, at the office of the ENGLISH MECHANIC, 31, Tavistock-street, Covent-garden, W.C.

PROBLEM DCCLIX.—By J. PIERCE.

Black.



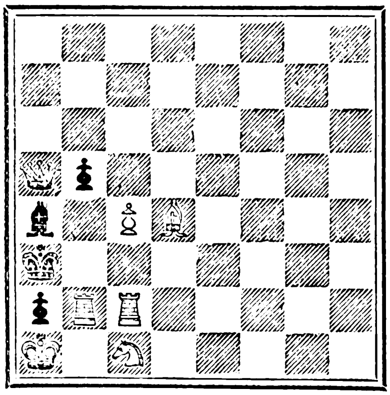
White.

White to play and mate in three moves.

PROBLEM DCCLX.—By "J. N. B."

From Brentano's *Chess Monthly*.

Black.



White.

White to play and sui-mate in three moves.

SOLUTION TO 755.

White.	*Black.*
1. Kt K R 6	1. Anything
2. Kt Q B 4	2. Anything
3. Mates accordingly.	

In this problem the K should be at Q B sq. and P at Q 3 to make it sound.

SOLUTION TO 756.

White.	*Black.*
1. Q to Q R 7	1. Anything
2. Mates	

NOTICES TO CORRESPONDENTS.

D. A.—Your solution to 756 is correct, as also those to 755. It is unfortunate the latter problem is so marred.

GAME recently played by correspondence between two amateurs (Steinitz Gambit):—

White.	*Black.*
1. P to K 4	1. P to K 4
2. Kt to Q B 3	2. Kt to Q B 3
3. P to B 4	3. P takes P
4. P to Q 4	4. Q to R 5 (ch)
5. K to K 2	5. P to Q 4
6. Kt takes P	6. B to Kt 5 (ch)
7. Kt to K B 3	7. Castles
8. K to Q 3	8. P to K B 4
9. Kt takes Q	9. P takes P (ch)
10. K takes P	10. B takes Q
11. P to Q B 4	11. Kt to K B 3 (ch)
12. K takes P	12. Kt takes Kt (ch)

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post-free to any part of the United Kingdom. For the United States, 13s., or 3 dols. 25c. gold; to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 3d. each to cover extra postage.

Messrs. JAMES W. QUEEN and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post-free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. XXIV., XXVI., XXVII., XXVIII., XXIX., XXX., XXXI., XXXII., and XXXIII., bound in cloth, 7s. each.

[Vol. XXXIV. Now ready.]

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in March and September, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d each, through any bookseller or newsagent, or 2½d. each, post-free from the office (except index numbers, which are 3d. each, or post-free, 3½d.)

Indexes for each half-yearly volume up to Vol. X. (except Vols. II., III., IV., V., and X.) inclusive, 2d. each. Post free 2½d. each. Indexes to subsequent vols., 3d. each, or post-free, 3½d. Cases for binding, 1s. 6d. each.

*** Subscribers are requested to order Cases and Vols. through their booksellers, and not to send direct. The regulations of the post-office prevent their transmission through the Post.

CHARGES FOR ADVERTISING.

	s.	d.
Thirty Words	2	6
Every additional eight words	0	6

Front Page Advertisements Five Shillings for the first 40 words afterwards 9d. per line. Paragraph Advertisements One Shilling per line. No front page or paragraph advertisement inserted for less than Five Shillings. Reduced terms for series of more than 6 insertions may be ascertained on application to the Publisher.

ADVERTISEMENTS in EXCHANGE COLUMN—for

	s.	d
Twenty-four words	0	3
For every succeeding Eight words	0	3

ADVERTISEMENTS in the SIXPENNY SALE COLUMN:

	s.	d.
Sixteen Words	0	6
For every succeeding Eight Words	0	6

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions; and in cases where the amount sent exceeds One Shilling the publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement and charged for.

Advertisements *must* reach the office by 3 p.m on Wednesday to insure insertion in the following Friday's number.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a Pink Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

Holloway's Pills and Ointment.—During summer, intestinal irritation is rife, so unless the liver acts aright, constitutional disturbance will ensue. The humblest can procure these health-preserving remedies, which quickly remove the vitiated bile, cool the overheated blood, and restore the jaded energies, better than vaunted tonics.

Every Workman connected with the Building Trades requiring a situation should advertise in "THE BUILDING NEWS," published every FRIDAY, price Fourpence, at 31, Tavistock-street, Covent-garden London, W.C.

"THE BUILDING NEWS" is the Principal Journal, representing Architects and Builders, and has the largest circulation of any Professional Journal in the kingdom.

Every Workman should insist on seeing "THE BUILDING NEWS" every week at his Club or Coffee House. He will find more "Lists of Tenders" for new work in it every week than in any similar paper, and can thus judge where work is likely to be had. He is also specially invited to make use of "Intercommunication" if he wants to know anything about his trade; to write to the Editor if he has any suggestions to make and to advertise in the paper when he wants work.

The charge for Advertisements for Situations is One Shilling or Twenty Words, and Sixpence for every Eight Words after.

OUR EXCHANGE COLUMN.

The charge for Exchange Notices is 3d. for the first 24 words, and 3d. for every succeeding 8 words.

Oil and Limelight **Dissolving View Apparatus** for Screw-cutting Lathe, Twist Drills.—D. W. N., Ernest Cottage, Peyton-place, Royal Hill, Greenwich.

Wanted, good 3in. to 4in. second-hand back-geared lathe, compound slide-rest, saw, chucks, drills, cheap. Full specification, cheap.—FIRE BRIGADE, Pontypool.

Agents Wanted.—Morgan's celebrated Improved Scale-Preventing Compound. Nothing better or cheaper.—W. H. MORGAN, Engineer, Gloucester.

Wanted, a good second-hand Lathe, about 3ft. 6in. centre to centre.—SHADLERS and COLEMAN, Ironmongers, Southhampton.

Wanted, Reid's work on "Clocks."—J. C. LEE, 26, Sheaf-street, Heeley, near Sheffield.

Agents Wanted to introduce our Oil Paintings, Copying, etc.; one stamp.—P. MITCHELL and Co., Artists, Sydenham.

Wanted, Wholesale Price-list of all kinds Woodworking machinery.—ELLIOTT and Co., Marlow, Bucks.

Wanted, Wholesale Price-lists of Soda Water Machinery.—ELLIOTT and Co., Marlow, Bucks.

Wanted, Proctor's "Other Worlds than Ours," cheap and in good condition.—X., 19, Long-street, Devizes.

Wanted, 2ft Locomotive Inside Cylinders in damaged condition. Will give Six Guineas.—ARTHUR HAUGHTON, 26, Park-road, Liverpool.

Addresses.

"Grateful's" address for "Tom B.'s" kindness is X. Y., High-street, Romford, Essex.

Wanted, addresses of all that have had dealings with "Sunlight."—Coton Lodge, Gnosall, near Stafford.

"Sunlight's" present address urgently wanted, as he has left Bath.—Coton Lodge, Gnosall, near Stafford.

Wanted, the address of Makers of Machines for stamping leather edging for book-case shelf fronts and leather-covered buttons.—J. H. P.

"Joiner"—Address to W. RATCLIFFE, 16, Barbara-street, Barnsbury, will oblige.

AMUSEMENT FOR WINTER.

MAKE YOUR OWN BICYCLES & TRICYCLES.

All the Parts and Materials, with full instructions, are furnished in the AMATEUR BICYCLE AND TRICYCLE CABINETS.

Prices, 4 guineas and 5 guineas.

NATIONAL BICYCLE COMPANY,
National Works, Coventry.
The Original Makers (Infringers Prosecuted).

Illustrated Lists Free on application.

RUBBER STAMP MAKING.—The "EXCELSIOR" APPARATUS (Registered) is cheap and effective. With this Machine *any* person can make stamps at once without previous experience. Send for particulars, press opinions, and testimonials, and see what others say.—GEO. W. SMITH and CO., 44, Springfield-place, Leeds. Beware of worthless apparatus.

WANTED, A GOOD GENERAL MECHANIC, one used to Portable Engine and Thrashing-machine work preferred.—Apply to J. BALDWIN, Wadhurst.

AN ENGINEER desires a PARTNERSHIP in small works. Riverside preferred. Good connection in launch engines, also several specialities introduced. Good opportunity for a firm to enter this new and lucrative trade.—H. R., 62, Harcombe-road, Stoke Newington, London.

The English Mechanic

AND

WORLD OF SCIENCE AND ART.

FRIDAY, JULY 7, 1882.

FIRE RISKS OF ELECTRIC LIGHTING.

IN our last volume we gave one or two papers on the precautions to be taken to avoid risks from fire in connection with electric lighting; and the suggestions of Prof. H. Morton have now been supplemented by an authoritative—so far as anything of the kind can be authoritative—opinion of the Council of the Society of Telegraph Engineers and of Electricians. The engineer of one of the fire insurance companies has already issued a pamphlet on the subject, in which the risks are clearly pointed out, as well as a method of avoiding them; but, naturally, the engineer has erred on the safe side, and the rules and regulations drawn up by a committee of the society above-named will probably be regarded by the public, and perhaps ultimately by the insurance companies, as a better working guide than the rather narrow rules suggested by an official of one of the companies. Those who are familiar with electrical phenomena do not need to be told that there are fire risks in connection with electric lighting, but they are not inclined to admit that the risks are any greater than they are in the case of gas lighting; and, certainly, the electricians, remembering the cost of copper rods, will object to being compelled to use them 50 per cent. heavier than they need be. The principal fire risk in connection with an installation of the electric light is an accidental heating of the "leads;" for although there is some little danger in the case of sparks falling from the carbons in the arc lamps, the experience gained during the exhibition at the Crystal Palace shows that simple precautions will effectually avoid any serious risk of fire from that source. The rules and regulations recommended by the Council of the Society of Telegraph Engineers and Electricians are based on a report made to them by a committee numbering amongst its members Profs. W. G. Adams, G. C. Foster, D. E. Hughes, and Sir Wm. Thomson; Dr. Hopkinson and Dr. De la Rue; and such well-known practical men as Sir C. Bright, W. H. Preece, C. E. Spagnoletti, A. Stroh, and E. Graves. The recommendations of such a body can be received with confidence; and, if proper attention is paid to them, there will not be many accidents either from fire or from the effects of the current upon the human body. The chief dangers, the council point out, arise mainly from ignorance and inexperience on the part of those who supply and fit up the requisite plant; and we may add that, until a trained staff of workmen can be raised, it is necessary for the electrician to critically examine every part of the circuit. The defects against which the electrical engineer has to guard are leakage, undue resistance in the conducting wires, and bad joints; they are, so to speak, internal and invisible, and even the sense of smell does not avail us as a detective as it does in the case of gas. Nevertheless, by careful testing the condition of an electric circuit can be ascertained with certainty and with great delicacy, and it is not surprising that these rules should strongly advise the frequent testing of the wires, especially as the skill needed is easily acquired with a little practice. The committee's report was evidently dead against the use of "earth" in any part of an electric lighting circuit, for the "rules" state that the chief enemies to be guarded against are the presence of moisture and the use of "earth," for moisture leads to loss of current and to the destruction of the conductor by electrolytic corrosion, and the "injudicious" use of "earth" as a part of the circuit tends to magnify every other source of difficulty and danger. From the use of the term injudicious it would appear that under some conditions the council consider it allowable to use "earth"; but those who are fitting up an electric lighting installation for themselves would do well to employ complete metallic circuits—in other words, lead and return wires, for the employment of gas and water-pipes ought not be allowed in any circumstances. The amateur electrician in fitting up his electric lighting circuit would no doubt use insulated wire throughout, as cheaper in the long run; but where considerable distances have to be covered, bare wires are permissible with certain precautions. In the first place bare wires should always be placed so that they can be seen at once, since, if other conducting bodies happen to fall on them, there is a liability to short circuit; but where possible it will, we think, always be advisable, when bare wires are used, to arrange the circuit so that the return is a considerable distance from the lead—so far, in fact, that no one can touch both wires at once. Bare wires are suitable only for out-of-door work, and where they are attached to insulating supports they should themselves be coated with insulating material for at least 2ft. on each side of the support. Joints must be mechanically and electrically perfect, which is readily accomplished by laying the two ends side by side, and binding smaller wire round, filling up all over with solder. As to the size of wires, the gauge should be proportioned to the currents to be conveyed, but wherever there is a change of circuit from a larger to a smaller wire, the latter should be protected by a safety-fuse melting at a temperature of 150° Fahr. The Council do not recommend the expenditure of 50 per cent. more than is necessary for wires, but prefer to rely upon fuses, which, it should be borne in mind, must always be inclosed in incombustible cases. They point out, however, that if wires become perceptibly warmed by the ordinary current, they are too small for the work, and ought to be replaced by larger leads. Besides the fuses on the branch circuits, there must always be one on the main circuit, of easily fusible metal, so that if the current attains any undue magnitude, the circuit will be broken. Every switch for turning current on or off must be so constructed that, when it is moved and left, there shall be no permanent arc, and no heating, while the base or stand on which it is fitted should be of slate, stoneware, or some other incombustible substance. All wires concealed from view should have their positions indicated, and where they pass through holes, or are liable in any way to abrasion, they should be protected with some suitable material. The dynamo should be fixed in a dry place, preferably on an insulating bed. To avoid accident to the person, the council recommend that the conductors and fittings should be so arranged that no one can be exposed to the shocks of alternating currents exceeding 60 volts, and there should never be a greater difference of potential than 200 volts between any two points in the same room. If such a difference does exist between two points within a house, then, whether the source of electricity be external or internal, a switch should be provided outside, by means of which the current can be cut off. By careful attention to these rules amateur electricians may safely light up their houses—that is, as safely as they can with gas, for there is always a risk of fire with every system of artificial illumination.

REVIEWS.

Handbook of the Polariscope and its Practical Applications. From the German of H. LANDOLT, by D. C. ROBB, B.A., and V. H. VELEY, B.A. London: Macmillan and Co.

FROM what can be gathered in the translator's preface, we are indebted to Mr. Frank Faulkner, of St. Helen's, for the appearance of Landolt's work on the Polariscope in an English dress, just as we were indebted to him for an English translation of Pasteur's "Studies on Fermentation." The present work in its roughly finished manuscript was placed in the hands of Mr. D. C. Robb, who unfortunately died before he could complete the duty of editing it, and it was finished by Mr. V. H. Veley. The translation follows as closely as possible the original, a few notes being added where Mr. Robb thought they might be useful. Prof. Landolt wrote his "handbook" at the request of friends who had read a paper of his on the mode of determining specific rotation, published in *Liebig's Annalen.* Accordingly, he has endeavoured to include an account of all the recent instruments and practical applications, and the notes appended by the editor render the work in its present dress a valuable textbook for the use of those who appreciate the value of the polariscope, or, in other words, the advantage of definite knowledge over rules of thumb in certain processes of manufacture. The optical activity of organic substances affords much assistance in determining the constitutional formula to be assigned to them, and an investigation of the connection between chemical constitution and optical power is a promising field for students. For this purpose, however, it is essential that determinations of specific rotation should be made with the most rigid accuracy, and special attention has been devoted to that branch of the subject by the author. After a few pages of introduction, in which the action of the polariser and analyser is explained briefly, the section on general aspects of optical activity commences the technical portion of the work, about one-fourth of the whole book consisting of descriptions of practical applications of rotatory power, which consequently render it of considerable value to many who would not care to go beyond the requirements of their own businesses. Camphor, cane-sugar, and glucose are the only solids the direct specific rotations of which have been accurately determined up to the present time; for although numerous investigations have been published as to many other substances, the observers have, as a rule, employed solutions containing only small percentages of active substance, so that only a few points have been determined, and those not of the greatest importance. Further, the concentration of the solutions only is mentioned, i.e., the number of grammes in 100 cubic centimetres, whereas, according to Landolt, the percentage composition by weight and the density of the solutions should be noted; for, to take an example, the specific rotation of tartaric acid is given in many texts-books briefly thus $[\alpha] = + 9{\cdot}6^{\circ}$, whereas the specific rotation in solutions containing 10 to 90 per cent. varies for the yellow ray D from $3{\cdot}25^{\circ}$ to $13{\cdot}68^{\circ}$; for the green ray b, from $1{\cdot}08^{\circ}$ to $16{\cdot}40^{\circ}$; and for the blue ray e, as much as from $- 6{\cdot}51^{\circ}$ to $+ 18{\cdot}64^{\circ}$. Similarly the specific rotation of cane-sugar is given as $[\alpha] = + 73^{\circ}$ to 74°, without note that that value is for the

VOL. XXXV.—NO. 902.

transition tint, although for the neighbouring ray D the value for solutions holding 25 per cent. of sugar is only $[\alpha]_D = 66{\cdot}44°$. Landolt goes on to say that the specific rotation of an active substance in a solution of given composition is constant, and, therefore, can be employed as a distinguishing characteristic of the substance; but he says, in order that it should possess this value, it is indispensably necessary that along with the value of $[\alpha]$ should be stated: (1) The ray with which the observations were made; (2) the description of the solvents; (3) the proportion of active substance present; (4) the temperature of the solution when the angle of rotation was observed; and (5) the direction of rotation. It will thus be seen that the author treats his subject in a thorough manner; and as it is freely illustrated, and contains descriptions of the different instruments, together with determinations and rotation-constants of many substances, the book will be of great value to the chemist who takes up this branch of the study, and a guide to those who frequently have occasion to use the polariscope in laboratories attached to factories. An appendix by Mr. I. Steiner, assistant to Mr. Faulkner, contains a valuable paper "On the Estimation of Maltose and Dextrin in Malt-Worts and Beers," a subject of special interest to technical chemists and brewers.

The Law of Kosmic Order. By Robert Brown, Jun., F.S.A. London: Longmans.

The author of this little work has already in two previous publications endeavoured to show the extent and character of the non-Aryan element in Hellenic mythology, to trace the career of the Semitic sun-god from the banks of the Euphrates to the Boiôtian plain, and onward to his pillars in the far west, and also to give the history of the Lunar power up to its final appearance as the sinister supporter of the Royal arms of Great Britain. The present work follows up the theme, but is from its nature of greater interest to the larger number of readers, for Mr. Brown notices the rise of the Year-concept with its sidereal band of the zodiacal signs, and he endeavours to show how those, to us, singular emblems attained their present position by a process so natural as to be almost inevitable, and consequently how hypotheses connecting the signs with religious, philosopical, and scientific ideas, are simply baseless. Briefly, but succinctly, the author shows how the three great divisions of time were probably made in the simplest manner; his first section, on the mental standpoint of archaic man, giving the keynote, as it were, to the evolutions of the concepts space, time, and number. In about 90 pages, however, it is impossible to deal with the subject in a style suited to popular reading, and this brochure is then, we may say, simply for students—a guide to a branch of archæology the most interesting of all. The sections in which the origin of the signs of the zodiac are described will, however, attract many readers, and cannot fail to instruct them, though the more intelligent amongst them will inevitably ask for more, which perhaps in one sense will meet the object of the author.

We have also received *The Great Giant Arithmos*, by Mary Steadman Aldis (Macmillan), a "most elementary arithmetic," a book intended to be read to children (very young children, we presume) by their mothers or nurses. The lessons delivered as if they were extemporised by the teacher would be admirable; but we are afraid that if any teacher attempts to read them to her pupils she will fail in teaching.)——*An Elementary Treatise on the Construction of Roofs of Wood and Iron*, by E. Wyndham Tarn (Crosby Lockwood and Co.) is an introduction to the first principles of roof construction for the use of architectural students.——*A Practical Treatise on the Joints Made and Used by Builders*, by Wyvill J. Christy (Crosby Lockwood) is a description of the various "joints" employed by artisans—is in fact a "dictionary of joints," which will be a useful work of reference to apprentices in the respective trades.——*Elementary Decoration*, by James William Facey (Crosby Lockwood), is a useful guide to the practical part of the work; but we hope the amateur will not copy the "designs" of the author. Speaking of black paint, Mr. Facey says that the "tendency of black to attract (!) heat is as great in proportion as that of white to repel it."——*The Manual of Colours and Dye Wares*, by J. W. Slater (Crosby Lockwood), is the second and much-enlarged edition of a very useful manual for all engaged in calico-printing and dyeing.——*The Boilermaker's Ready Reckoner*, by John Courtney, revised and edited by D. K. Clark (Crosby Lockwood), is chiefly valuable for its tables—the information on templating being very meagre. The dimensions in the tables are specially useful to the boilermaker who cannot work by decimals but must have his dimensions set out, as "1¼ 1-16."——*Experimental Physiology*, by Richard Owen, M.D., F.R.S. (Longmans), is really a defence of vivisection, and an attack on the anti-vivisectionists, with the full text of the "address" delivered when the author unveiled Harvey's statue at Folkestone last August.——From Messrs. Longmans we have also, as additions to the "Sunbeam" series, J. G. Wood's *Strange Dwellings*, Hartwig's *Arctic Regions* (extract from "The Polar World"), and Trench's *Realities of Irish Life*.

ARTIFICIAL FORMS OF SILICA RESEMBLING AGATE.

We have previously given tolerably full particulars of the methods by which attempts have been made to produce artificial diamonds, and in Vols. XXX. and XXXI. will be found several notes on the manufacture of imitation gems, the distinction between the terms "artificial" and "imitation" being obvious. If by any of the processes of the laboratory, and by the aid of any of its contents, the chemist can make a clear crystal of carbon, then he has produced an artificial diamond; if he merely mixes up sundry substances and produces an imitation diamond, that is interesting from the manufacturer's point of view, but is of no value from the scientific point of view. It will be remembered that artificial diamonds were produced by Mr. J. B. Hannay, and Messrs. Frémy and Feil had a similar success with rubies. We gather from a paper contributed to the Mineralogical Society by Messrs J. I'Anson and E. A. Pankhurst, that they have been practically as successful in the artificial production of agate, chalcedony, onyx, &c., and as the experiments which have led up to these results are simple and easily performed, they may be of more than usual interest to many of our readers. Chemical students who have had any experience with the silicates know that when a solution containing an alkaline silicate is acted upon by a reagent capable of separating the silica from the base, the silica is generally thrown down in the solid form. The chemist makes a note of the reaction; the mineralogist goes further, and studies the form in which the precipitate appears. The form varies with the conditions of the experiment, and by studying these Messrs. I'Anson and Pankhurst sought to elucidate experimentally the wondrous and beautiful varieties of structure seen in natural specimens of silica. The great group of banded agates presents an infinite variety of form, but is readily separated into two types—one in which the solidification appears to have taken place in successive layers from within outwards; another in which the layers seem to have grown from without inwards. These two types may therefore be named respectively the exogenous and endogenous. With the exogenous type of agate are grouped such stalactitic forms of silica as show in transverse section a series of concentric rings or bands. Such stalactitic forms may be obtained by taking a solution of silicate of soda or potash and dropping into it any of the strong acids; but, in order to produce the branching coral-like forms, Messrs. I'Anson and Pankhurst adopt the following procedure: "A strong solution of silicate is taken, containing a certain amount of alkaline carbonate, and a strong acid (sulphuric seems to give the best results) is introduced by means of a pipette to the bottom of the vessel in which the solution is contained. Bubbles of carbonic acid gas immediately arise, carrying with them a certain amount of the stronger acid. Round the stream of ascending bubbles, silica is deposited by the decomposition of the alkaline silicate, and in a very few minutes a tube is formed reaching from the bottom to the surface of the solution." The walls of the tube increase in thickness by the deposition of silica on the outer surface, so long as the flow of acid is kept up. The carbonic acid evolved at first is essential to the commencement of the tube; but that once formed, sulphuric or other acids can be forced through it, and by the application of pressure to the surface of the fluid in the pipette, the action can be kept up for a long time, stalactites ¼in. in diameter being formed without much difficulty. The same result can be produced by passing an acid gas or any other reagent capable of separating the silica—such, e.g., as the acid salts of various metals—in fact, the experiment can be varied in many ways, the specific gravity of the fluid as compared with that of the reagent and of the precipitated silica having much influence on the form assumed. Where the specific gravities are equal the tubes may take indifferently any direction with regard to gravity. The stalactitic productions thus made are considered the analogues of all the group of banded stalactitic growths where the growth appears to have proceeded from a central cavity which has been subsequently filled in with a core. If the action is carried so far that the fluid surrounding the tube becomes saturated with the acid reagent, the whole of the fluid gelatinises by the precipitation of amorphous gelatinous silica, so that if such stalactitic forms had been produced in nature in an inclosed rock cavity containing an alkaline silicate solution, by the infiltration of an acid solution, a like result would follow. Such natural forms constantly occur, and it is probable that Messrs. I'Anson and Pankhurst have discovered the mode of their formation. They account for the endogenous type, by supposing the rock in which is the cavity containing the alkaline silicate to be permeated by an acid solution or gas. The layers of silica would then be deposited on the walls of the cavity, and as the action continued, the layers would grow inwards until the central portion would set into an amorphous mass. These forms have been produced by modifications of the process above described. By the use of acid solutions containing vegetable and earthy salts, the colouring of many natural stones has been imitated, and it seems probable that jaspers, moss-agates, &c., have been coloured naturally by chemical precipitates. The most prevalent colouring matters, for instance, are the red and yellow ferric, and the green ferrous oxides. If ferric chloride be added to alkaline silicates, a more or less flocculent, red or yellow-coloured precipitate is produced, around which will grow a filmy white deposit of silica, frequently taking the banded form seen in jaspers and allied stones. The green, mossy markings of the moss-agate and the darker colour of the onyx can be perfectly produced. The precipitated silica, however, being deposited at no great pressure or temperature, the artificial stones fall short of the natural ones in hardness and stability, crumbling up when exposed to the air, though some forms, approximating closely to common opal in appearance, but of lower specific gravity, remain with little or no alteration after once being dried. It is conceivable that, with suitable conditions of temperature and pressure, perfect artificial agates could be produced; but the resemblances are so remarkable that there can be little doubt Messrs. I'Anson and Pankhurst have solved an interesting problem. So far we have only indicated some of the reagents and salts that may be used, and it is scarcely necessary to give a list which, however long, would probably not include all—the student of chemistry will find no difficulty on that head; but he may be advised to allow the stalactitic forms to come into contact with the sides of the containing vessel while the process of growth is going on, by which means their progress can be conveniently watched. A solution of commercial alkaline silicate, especially silicate of soda, is capable of dissolving considerable quantities of pure gelatinous silica as well as various silicates produced by precipitation with sulphates of copper, iron, &c. Thus, if solutions of ferric sulphate, or chloride, or cupric sulphate are poured into an alkaline silicate, coloured precipitates are produced, which, after washing, are dissolved in alkaline silicates yielding purplish red and green solutions, which can be used for colouring the preparations above described. Further investigations will probably lead to a method of making the artificial agates, jaspers, &c., as hard and durable as the natural specimens, for very hard preparations of silica are occasionally found by the manufacturers ot silicates in the course of their operations.

THE ACHROMATIC OBJECT-GLASS.—IV.

By W. BRADBURY.

(*Continued from page* 372.)

THE following table of Tulley's curves appeared in the correspondence columns of this journal some time ago. I have endeavoured to deduce from them the refractive indices, and also the dispersive ratios. It is not possible to do this accurately, but the numbers are sufficiently near the actual values to show the properties of the glass. One kind of crown appears to have been used throughout, most probably that known as "Ratcliffe Crown," and it evidently varied very little in its optical properties; the flint glass had a specific gravity ranging from 3,192 to 3,466.

A TABLE OF CURVES EMPLOYED BY THE OPTICIAN, TULLEY.

FLINT.—Sp. gr., 3,192. Refractive index, 1·574. Ratio of refraction, 1·52.
CROWN.—Sp. gr., 2,527. Refractive index, 1·53. Dispersive ratio, or value of δ = ·725.

Focus.	Crown	7·5	Flint	10·1
30	lens	11·5	lens	20·5
Focus.	Crown	8·0	Flint	7·4
27	lens	7·5	lens	24·5
Focus.	Crown	11·5	Flint	15·25
44	lens	16·8	lens	32·50
Focus.	Crown	18·4	Flint	24·4
72	lens	26·8	lens	52·0

FLINT.—Sp. gr., 3,334. Index, 1·588.
CROWN.—As before. Ratto of refraction, 1·642. Dispersive ratio, ·71.

Focus.	Crown	8·0	Flint	11
30	lens	12·5	lens	27

FLINT.—Sp. gr., 3,354. Index, 1·592.
CROWN.—As before. Ratio of refraction, 1·656. Dispersive ratio, ·68.

Focus.	Crown	8·0	Flint	12·11
30	lens	14·3	lens	28·5
Focus.	Crown	13·6	Flint	16·3
44	lens	17·2	lens	54·0

FLINT.—Sp. gr., 3,437. Index, 1·597.
CROWN.—As before. Ratio of refraction 1·726. Dispersive ratio, ·66.

Focus.	Crown	13·6	Flint	17
44	lens	18·8	lens	67
Focus.	Crown	8·0	Flint	13·15
30	lens	17·2	lens	32·60

FLINT.—Sp. gr., 3,466. Index, 1·6.
CROWN.—As before. Ratio of refraction, 1·74. Dispersive ratio, ·65.

Focus.	Crown	14·3	Flint	18
44	lens	19·4	lens	72

An examination of this series of numbers will show, that with one exception, the same system of arrangement is followed throughout. Commencing with the crown lens, it will be seen that in a rough way, the proportion of its radii may be taken as 2 to 3; while the flint lens, having a proportion of 1 to 2 in the lightest kind, gradually rises to 1 to 4 with the heaviest glass. This is in exact agreement with theoretical deductions.

The second pair seems to be a departure from the regular method: the crown lens is nearly equi-convex, with the flattest side anterior; and this, though only a slight alteration, increases the aberration so much as to need a higher ratio in the flint curves. No other similar instance is given, so that we may conclude it was an exception to the general practice, and more difficult to arrange satisfactorily.

If we compare the above radii with those which theory assigns to be due to the specified optical properties, it would seem that nearly all have the characteristic feature which led Dollond to devise the triple object-glass—viz., the convex lens appears too strong. Such combinations, if formed of spherical curves, would be affected with positive aberration or under-corrected. But we must remember, that there is a great deal more in the method of working than in the actual curves made use of. When the artist was master of his method, it was, without doubt, a great advantage to have a combination, which always left a slight margin for final correction, of one definite kind, rather than those which, being nearly in perfect balance; when correctly wrought, were apt to leave a final error of an uncertain character, owing to uncontrollable deviations in working. But, apart from any special practice, I believe it would have been found easier to introduce the final correction, if the flint curves had had a higher ratio.

The method of computing curvatures, which is described by the writer in Rees' "Cyclopædia" as being that used by Tulley, seems to have originated in the following way:—Soon after Dollond's discovery of the method of producing achromatism, Benjamin Martin published a work entitled "New Elements of Optics." Martin seems to have possessed very considerable mechanical skill, as well as theoretic knowledge; for he was enabled to test the truth of his deductions, by experiments on optical glass. His first work was to find the actual value of the refractive index of any species of glass.

Newton's experiments had given 30 / 21, or as near as possible 3 / 2, as the value of the index of refraction, and it does not appear to have been suspected to be variable. Such a value defined the radius of curvature, as the focal length of an equi-convex lens; and in case of unequal curvature, the same quantity was twice the product of the radii divided by their sum. These distances were found to be correct by experiment. But when Martin proceeded to test several lenses, ground to the same curves but of different species of glass, he found a great discrepancy between the actual and the calculated focus, especially with the denser or flint lenses. The focus calculated by the above rule was termed the *geometrical* focus, and that given by trial, the *refracted* focus. Martin found, by measuring these distances and dividing the former by the latter, that he obtained a number which was constant for the same species of glass. Hence, when he knew this number, he could find the true or refracted focus of any lens made of this glass: or, if he knew the radii and refracted focus, he could find out the number belonging to any kind of glass.

Martin thus obtained the true measure of the refractive power; for it will be evident that his value ($2a$) is really the double of the refractive power, or, of the refractive index diminished by unity. So that the real refractive index is ($1 + a$). Martin's rule gave $R / 2a$ as the refractive focus of an equi-convex; the ordinary rule is $R / 2 (\mu - 1)$, so that the identity of the two terms is apparent. He was thus enabled to tabulate the refractive powers of various kinds of glass.

The retention of the obsolete and useless term, "geometric focus," leads to much confusion. It is scarcely necessary to add that it does not represent a focus at all, but merely indicates an imaginary point, derived from the erroneous supposition, that the refractive index was an invariable quantity.

Martin, having found a definite measure of the refractive power, next turned his attention to the subject of dispersion. Taking two pieces of crown and flint glass, he proceeded to compare them in a manner similar to his previous experiments. As he had before ground equal convexities, and compared their refractions; he now made them into equal prisms, and compared their dispersions. By measuring, as well as he could, the distance to which the red and violet extremities were separated by each prism, he found that of the flint wider than that of the crown, in the proportion of 5 to 3. He then gradually reduced the flint prism until both separated the rays alike; and when they were arranged in opposition, dispersion was practically neutralised.

By applying analogous reasoning to the action of lenses, he deduced the general laws, which must govern the formation of an achromatic compound. "The radii of the lenses must have the same proportion as the differences of the sines of incidence and refraction in red and violet rays in prisms of equal refracting angles of white and crown glass. The radii or foci (geometric) of the lenses must have the same proportion as the angles of dissipation in refraction by such prisms, and, of course, the same proportion as the lengths of the coloured spectra produced thereby.

"In all cases of a compound lens for producing vision without colours, the ratio of the radii, r and R of the concave and convex lenses must be as 5 to 3, and then the ratio of their foci (refracted) for parallel rays will be as 3 to 2 nearly."

It will have been noticed, in the table of Tulley's curves, that a number is given termed, "Ratio of refraction." This does not mean the ratio of the refractive powers of the glasses, but the ratio of the differences of the red and violet indices for each glass; or, as it may be termed more correctly, the ratio of their dispersions. Martin's law simply states that the radii, and consequently the refracting angles of the lenses, must be directly proportionate to their dispersions. It is now usual to divide the dispersion by the refractive power. The number so obtained is the *dispersive* power; because while the quantity a in Martin's rule, or the refractive power, is the measure of the effect of a substance in changing the direction of the ray, the dispersive power shows what part of the whole angular deviation is occupied by the colorific interval. Expressed in terms of the foci, which is by far the most intelligible way, Martin's rule is: the focal lengths must be directly as the dispersive powers. As a means of indicating the character of the glasses in combination, Tulley used the term "ratio of refraction"; but "ratio of dispersive powers," or the value of δ in the table, is much more complete, as it takes into account the refraction also.

Having succeeded in obtaining a general relation between the curves, which would satisfy the conditions of achromatism, Martin next engaged the more delicate problem of finding a *particular* relation which should destroy the spherical aberration. He does not seem to have met with much success, partly because his mathematical analysis was not sufficiently complete, and partly because the opportunities of comparing theory with practice were not very extensive.

PRACTICAL NOTES ON PLUMBING.—XXXVIII.*

By P. J. DAVIES, H.M.A.S.P., &c.

(*Continued from page* 346.)

Tip-up Lavatory Basins.

THIS kind of lavatory basin is shown at Fig. 224. G is the container with its trunk shown bedded into the dip-pipe of the Ʊ-trap; L is the basin. This basin swings upon two pivots at P, suitable bearings being fixed on the sides of the container; the basin has suitable stops or buffers to prevent the too sudden closing; in this case the rubber buffer is shown fixed under the spout of the cock at O, and held there by the claw. The container should be fixed below the top slab, and the hole in the slab made of sufficient size to allow the basin to swing without touching. In fixing these basins take care that the pivots are properly fastened: otherwise when the basin is jammed or bumped against the buffers, the basin will become loose and probably get broken. For another method of fixing the pivots see P P, Fig. 225. This is for screwing up to the top or slab, or it may be fixed to the false bottom, the latter method usually being adopted.

Fig. 226 illustrates a skeleton of the round container tip-up basin, as fixed over the ordinary half Ʊ-trap. When such basins are fixed over these traps, take great care to well ventilate the outlet of the trap, *but not* as shown at R; for reasons, see *Building News*, page 753, December 9th, 1881.

FOURNIER'S ELECTRIC BATTERY.

AN electric battery possessing some novel features has been recently patented in this country by M. Geo. Fournier, of Paris. The principal novelty is the use of a paste, or compound of lead oxide and glycerine, which is moulded into any suitable form for use as a battery-plate, either in primary or secondary batteries. The patentee claims the use of any other metallic oxides capable of forming with glycerine a solid compound insoluble in water. In forming the plates, the lead oxide and glycerine are mixed in such proportions as to form a thick paste, sufficiently fluid to be run into moulds. In about twenty-four hours after being thus "cast," the mixture sets into a solid mass which is insoluble in water. This compound is exceedingly reducible, so much so that when immersed in dilute sulphuric acid together and in circuit with metallic zinc, it becomes reduced to the metallic state as fast as the zinc is attacked. It is, therefore, says the patentee, eminently suited for use in galvanic batteries, as it will prevent galvanic polarisation, and it may either wholly replace carbon or be applied in layers upon carbon or other conductor of electricity. Being an excellent depolarising agent, it enables one to obtain a constant single-fluid battery.

As above mentioned, the compound becomes completely reduced and, therefore, in the present example we have metallic lead as the product of the reduction, which, being in a complete state of division will be very readily reoxidised for use again as a depolarising agent, or even become peroxidised, and may therefore be employed with advantage in the construction of secondary batteries, which may be prepared by the direct peroxidation of plates composed of a compound of lead oxide and glycerine without the intermediate reduction of the lead to the metallic state.

The oxide of lead is the oxide best suited to form the plastic mass with glycerine, but other matters still better adapted to oppose polarisation of the electrode, such as the peroxides of lead, manganese, &c., may be added. These, although not capable alone of combining with glycerine, are nevertheless susceptible of being agglomerated (when mixed in suitable proportions) with lead oxide and glycerine, and form therewith a solid mass. The addition of peroxides confers greater depolarising properties, as the compound then contains, weight for weight, a higher proportion of oxygen; besides which the peroxides being better conductors of electricity than the oxides, the internal resistance of the battery is notably reduced and its power correspondingly increased. This quality of conductibility consequently enables the portions of the mixture not already peroxidised to be more easily peroxidised by the passage of the electric current, and permits of the production of plates of any desired thickness wholly composed of lead peroxide, and very suitable for use either in primary or secondary batteries.

Let us consider, first, the action of a primary battery, in which a plate composed of glycerine, lead oxide, and lead peroxide, agglomerated as above mentioned, and plunged in a dilute solution of sulphuric acid contained in a cell, forms the negative plate or element, and a copper plate, for example, of suitable thickness forms the positive plate or element. When the circuit is closed, the sulphuric acid attacks the copper plate forming sulphate of copper, and disengaging hydrogen which passes to the plate composed of glycerine, lead oxide, and peroxide; that plate would soon be covered and polarised were the hydrogen not in contact with a matter capable of very readily oxidising it. No polarisation will therefore take place, and the battery will act with uniform constancy so long as the acid acts on the copper plate, and there remains in the compound plate any oxygen to oxidise the hydrogen thereby disengaged.

A battery thus composed is, so to speak, of indefinite duration, as it may be readily reconstituted or reconverted into its primitive elements by the passage of an electric current. Suppose that the whole of the sulphuric acid has combined with the copper and formed sulphate of copper, and the hydrogen thereby disengaged has combined with the whole of the oxygen of the compound plate of lead oxide, lead peroxide, and glycerine, there will remain in the battery only the plate of copper partially attacked, sulphate of copper, and the plate of reduced lead. If now an electric current be passed through the battery in the proper way, the sulphate of copper will be decomposed, copper will be deposited on the copper plate, the oxygen of the decomposed sulphate of copper will combine with the reduced lead plate and reoxidise it, the sulphuric acid will be set free again, and the battery will then be reconstituted and ready for further action.

In the case of secondary batteries the compound plate of oxide, peroxide, and glycerine is immersed in a dilute sulphuric acid solution, in presence either of a sheet of lead, or, better still, a plate composed of lead oxide, metallic lead in powder, and glycerine. A current passed through this battery under proper conditions will decompose the water, the oxygen combining with the plate of oxide, peroxide, and glycerine, completely peroxidising it, the hydrogen passing to the other plate. Thus we have the elements of a Planté accumulator, with the difference that the substances employed are in a condition more favourable for oxidation and reduction than sheet lead.

ON THE ACTION OF THE MICROPHONE.*

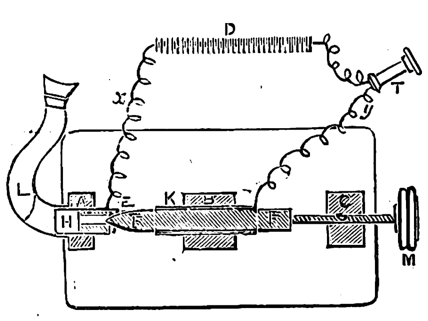
By Prof. James Blyth, M.A., F.R.S.E.

IN the microphone transmitter, as usually employed in circuit with a battery and a Bell telephone, we have essentially two pieces of carbon resting lightly against each other through which the current passes. That the instrument may work effectively, two things are requisite: first, that the carbons be always in contact or at least sufficiently near for the current to pass between them, and, secondly, that they may be not pressed together so tightly as to prevent any motion of the one relatively to the other. This state of things is sufficiently well described by the term "loose contact," first used, I believe, by Professor Stokes. To understand the action of the microphone we have to find out what effects are taking place at the loose contact when the instrument is acted upon by sonorous waves. These are twofold: first, the effect produced by the sound waves (that is, the variations of density due to the condensations and rarefactions of the air), which pass directly through the air when they arrive at the loose contact, and, secondly, the effect produced by tremors set up in the entire instrument, wooden supports and carbons together, by the sound waves which strike against it and are thereby stopped.

For distinction we may call the first of these the air effect and the second the tremor effect. In my experiments I have endeavoured to arrange the instrument so as to isolate these effects, and, as far as possible, examine each of them separately. To isolate the air effect it is obviously necessary either to fix the carbons rigidly in their supports so as to avoid any motion of the one relatively to the other, or to use a strong current and place them just clear of contact with each other.

The following experiment illustrates how this may be done.

A, B, and C are three blocks of brass firmly fixed to a heavy wooden soleplate. To the top of A is soldered a piece of brass tube, H, about 2in. long and $\frac{5}{8}$in. bore. To the top of B is soldered a piece of similar tube, K, about 4in. long. Through C passes a fine screw S worked by a milled head, M. A piece of carbon-rod, E, is fixed firmly into H and has a hole $\frac{1}{4}$in. in diameter drilled through its centre. A long piece of carbon, F, pointed at one end, passes tightly through the tube K and can be moved backwards and forwards by the screw S. A piece of indiarubber tube, L, is passed over the left end of the tube H, and to this is attached a mouthpiece, M. By means of the wires x and y soldered



---

* A paper read before the Royal Society of Edinburgh.

to the carbon rods, they are put in circuit with the battery (twenty Grove's cells) and the telephone T, which must either have a small resistance or be placed in a separate circuit from that containing the battery so as to be acted upon inductively.

When the carbon F is screwed tightly into the hollow of E the circuit is completely closed and no sound uttered into M is heard at T¹. But when F is drawn gradually back until small electric arcs are seen to pass between F and E, every sound uttered into M is loudly and distinctly reproduced in the telephone T. Here we have clearly only the air effect acting, and that solely upon the small electric arcs passing the carbons.

I have found it, as yet, somewhat difficult to get the sounds to last for any length of time, in consequence of the arc distance soon getting too great for the current to pass and requiring re-adjustment. When the arc begins and ends a sharp click is heard in the telephone; but in the interval during which the arc lasts the sounds are distinct.

As far as the tremor effect is concerned, it is obvious that the microphone action must depend, either (1) upon the variation of resistance due to variation of pressure, or (2) to variation in the extent of surface contact due to the elastic yielding of the carbons under pressure.

To test the first of these causes, I made about two years ago some experiments on the effect of pressure upon the specific resistance of carbon. for this purpose I took a short length of carbon rod, and soldered wires to it at a short distance from each end. By means of these wires the resistance of the carbon rod was balanced in the Wheatstone bridge. Pressure was then applied by means of a lever to the carbon in a longitudinal direction. No appreciable variation in the resistance was observed even under considerable pressure; and it only became manifest when the pressure was sufficient to bend or crush the carbon. I have recently repeated these experiments with the greatest care, and found the same results. I observed also that similar experiments, with the same result, have quite lately been made by Professor Silvanus Thompson. Hence we can hardly, I think, believe that variation of specific resistance due to pressure can have the slightest effect in producing the microphone action.

To test the second cause above mentioned, that is, the variation of resistance due to variation in the extent of surface contact due to elastic yielding under pressure, I experimented as follows: In the apparatus already described, I replaced the tubular carbon by a finely-pointed piece, so as to have two fine points exactly opposite each other. The resistance of the points was balanced in the bridge in the usual way. Pressure was then applied by a known number of turns or parts of a turn of the fine screw, and the change of resistance noted. The screw was then brought back to former position, and the pressure relieved so as to allow the elasticity of the carbon to act and restore the points to their first condition. It is obvious that if the change of resistance were due merely to elastic yielding it should now be the same as before. This I found not to be the case. From the gritty nature of the carbon the points of contact I found were perpetually changing, and hence the variation of resistance produced in this way obeyed no regular law. From this irregularity it is impossible, I think, to conclude that this cause could explain the transmission of musical sounds for less articulate speech.

As far as my experiments go, the following appears to be something like the true explanation of the microphone action. What I have termed the air and the tremor effects take place simultaneously. The tremor effect produces a jolting of the carbons sufficient to allow momentary minute electric arcs to take place between the points which are just clear of contact with each other. Simultaneously with this the air effect comes in, and, on account of the variations of density due to the condensations and rarefactions of the air, acts upon the minute electric arcs so as to vary their resistance. The tremor effect explains merely production of the musical pitch of the sounds heard in the telephone, whereas it is to the air effect that we must look for the transmission of the quality of the sounds uttered into the microphone transmitter. The microphone is thus so far a delicate make and break analogous to the old Reiss transmitter, with the important addition, however, of minute momentary gaps filled with a material which is sensitive to the minute harmonic variations of the atmospheric density which constitute sonorous vibrations.

THE SALTNESS OF THE SEA.

DURING a recent voyage to Campbell Island, in the South Pacific, M. Bouquet de la Grye, took occasion to make careful observations on the saltness of the sea. Referring to his paper in the *Annales de Chimie et de Physique*, for details of method, we propose to give here his principal results.

In the Mediterranean, an inclosed sea, with strong evaporation, the saltness reaches as high as 22 grammes of chlorine per litre of water. In the port of Marseilles the water of the surface has only 20·75gr., but in the open water one finds 21·71gr. There is also progressive increase from west to east.

Near the Coast of Egypt, the influence of the the Nile was observed before that of the land was recognised. The fall was sudden, about 0·80gr., while the densimeter and thermometer showed no variation. Before arriving at Port Said, the chlorination went down to 19·45gr., a certain proof of currents bearing the Nile water eastward.

The analysis of water of the Suez Canal, at 23 different points, led to the following conclusions: The fresh water of the Nile has an influence on the saltness of surface-water, which is felt beyond Lake Timsah. The recovery of chlorine begins about the second station; there is a very slow increase at first, as far as the entrance of El Kantara, then a rapid increase as the Bitter Lakes are approached. At the latter, one finds 37·20gr., and 37·47gr.

Continuing the examination, it appears that the Red Sea diminishes in saltness from North to South; at first the saltness is slightly over that of the Mediterranean; but it soon falls below it. This is explained by the influence of the Southwest monsoon, which is accompanied with torrential rains.

When the voyagers were entering the Indian Archipelago, all the rivers were overflowing—the water was troubled by the mud flowing down—and the chlorination, always under 20gr., descended to 17·42gr., opposite Batavia. This was the smallest figure reached during the voyage.

The waters of Java and of New Guinea also gave low figures as far as the Torres Straits. There a complete change was encountered. The rainy season was five months distant; the coast was sandy and dry, and the water-courses were low; thus, notwithstanding nearness of land, which was skirted twelve days, the author found only one chlorination under 20gr.; this was off Keppel Bay, where the river Fitzroy enters the sea.

From Sydney to Campbell Island the same saltness: the wind was then blowing from the north, the weather was mild, but the spring was little advanced, and the ice of the Polar circle had not commenced to melt. Four months later, at the time of quitting Campbell Island, there was already a change; the water was less salt, and in some places off the New Zealand coast, figures under 20gr. were met with.

In traversing the Pacific Ocean, an extra saline zone is found under the southern tropic; then a zone of comparatively fresh water, the equatorial zone. To the north there is, again, an extra elevation of chlorine under the northern tropic, and beyond a strong diminution; this arises from the polar current descending along the Coast of America.

Coming to the last part of the voyage across the Atlantic, the tables show that the neighbourhood of the American coast gave waters very fresh and icy, which are suddenly replaced by hot and very salt waters, when the Gulf Stream is entered; then as the route of steam-packets goes along the great bank of Newfoundland, one passes from the current to find anew the fresh and cold waters; these being succeeded by the average water, in which navigation continues to European seas.

"*En résumé*, we have found in the Pacific the law indicated by Gay-Lussac and by Humboldt, and verified by MM. Roux and Savy in the Atlantic. It may be enunciated thus: *Under the two tropics the saltness is greater than under the equator, and beyond the tropics.*

"In indicating," the author proceeds, "that the saltness usually diminishes as coasts are approached, a fact is stated which is the consequence of the rivers bringing to the sea a large tribute of fresh water, and in some circumstances great advantage might be derived from this knowledge, especially in navigating along the coast of Africa or America. How far out would not the waters of the Amazon be revealed by the sole test of chlorination, where the thermometer and the densimeter indicated nothing? The approach of icebergs in cold seas would likewise be indicated by change in the saltness.

"As regards navigation, then, chlorometry may yield very useful direct results; but, better still, the investigation of currents cannot, it seems to me, be properly carried on without it.

"Maps giving every three months the chlorination of the sea would lead to a more exact notion of currents, and would make known new currents. But the question may further be looked at with reference to the slope producing currents. One may investigate the form taken by the surface of the ocean according to the saltness and temperature of all its component parts. Approaching one side of this new question, should we continue to denote as the mean level in a port the level obtained as the mean of a certain number of heights taken at all seasons? Evidently not, because there is neither equilibrium of height nor comparison possible between waters estimated differently, and having densities variable according to this saltness and their temperature. We may not bring into the same average the fresh waters which in spring spread over our coasts, and the salt waters of other seasons. In summer, a tidal wave whose force is represented by a weight, and not by a height, will lead to figures different from those of winter. And let it not be thought that the corrections belonging to different chlorinations are insignificant. When a new level is now sought in surveying operations, its value might be given to nearly a millimetre; when the stability of a coast is to be measured, it is still this approximation that is had in view. Indeed, for a difference of 15°, we have, with mean saltness, 0·004m. difference per metre in height If the tide be 5m., the correction due to temperature gives differences of 0·02m.; this is the entire value of one of the latter waves considered.

"As to the correction due to difference of saltness, it is much greater. At Honfleur, at Havre, and especially at Saint Nazaire, the chlorination of the sea may make the density pass from 1·028 to 1·012; for 5m. of tide the correction is 0·08m. It is these differences that render so little comparable the means of heights of the tide obtained for long periods. At Brest, where the maregraph acts at the mouth of the Penfeld, the annual means are discordant.

"We add, that when we have to do with the level of equilibrium, it is necessary to further make a correction which is as the low water, for this latter level remains the same for a great stretch of sea, while the border of the coast, through local circumstances, narrow passages hindering the play of tides, &c., presents various surelevations; but this correction does not apply either to seas without tides, nor to points projecting into the ocean.

"Where the level of equilibrium, then, has to be investigated, one must take account of the density at low-water mark of the place, and there is occasion henceforth to complete the indications of maregraphs, by adding for each day the temperature of the sea and the weight of the chlorine."

As regards the general question of levelling of seas, it is pointed out that the sea is not everywhere a level surface in the geometrical sense. In all seas there is equilibrium of weight, and there are merely tendencies to equilibrium of level.

M. Bouquet de la Grye has sought to apply these principles to the level of the Atlantic, and taking as zero the plane which passes through the Cape Verde Islands, we find, under the tropic of Cancer a depression of two metres, and near the United States a considerable surelevation, in some cases exceeding four metres. Thus, we have a difference of level of six metres between two points of the same ocean.

THE RELATION OF APERTURE AND POWER IN THE MICROSCOPE.[*]

By Professor E. Abbe, Hon. F.R.M.S.

I.—General Considerations as to Wide and Narrow Apertures.

(*Continued from p. 375.*)

WHENEVER the depth of the object under observation is not very restricted, and it is essential that the depth dimension shall be within the reach of direct observation, low and moderate powers cannot be overstepped, and no greater aperture should therefore be used than is required for the effectiveness of these powers—an excess in such a case is a real damage. High powers and correspondingly wide apertures are restricted to those observations which do not require any perceptible depth of vision, i.e. to two different cases (1) when the objects are quite flat or exceedingly thin; (2) when preparations of greater depth are sufficiently transparent to admit of an *indirect* recognition of their solid structure by means of successive optical sections through *successive* focussing of different planes. For the latter method of observation the loss of penetration with increasing power and aperture is no drawback, but rather an advantage, because it enhances the distinct separation of the sectional images at successive foci. A disregard of these natural restrictions in the use of wide apertures is obviously the origin of the opinion that aperture *per se* is antagonistic to good definition. It is quite true that there are many even very delicate objects which are much better seen under a given amplification with a system of very moderate than with one of very wide aperture, the former giving a clear view of the whole structure, the latter showing perhaps some distinct points, but as a whole veiled in haze. Provided, of course, that we have well-corrected objectives, the fault here is not on the part of the lens, but on the side of the object, which requires for proper recognition a greater range of depth than is reconcilable with a wide aperture. The theoretical suggestion which has been brought forward in support of the notion that different parts of the clear area of an objective produce *dissimilar* images, and that *therefore* the resultant image must show increasing confusion with increasing aperture, cannot apply to the delineation of a plane object. In a well-corrected objective the partial pictures received through the various parts of the aperture-area are always strictly similar so far as one plane of the object is concerned. The confusion suggested is nothing else but confusion of the images of *different depths*—lack of penetration, but not lack of "definition" in any reasonable sense of that term. Provided the objectives are properly corrected and the objects are fit for the delineation of an image, undisturbed by interfering confused images from other planes, the "defining power" of an objective is always greater with greater aperture for every kind of objects, inasmuch as under all circumstances the wider aperture admits of the utilisation of higher amplifications than can be obtained without perceptible loss of sharpness (with the same objects) by lower apertures.

---

[*] From the *Journal* of the Royal Microscopical [illegible]

There is therefore no drawback in principle to the use of a large aperture when the objects are suitable. But the considerations above lead to the conclusion:—

> *Wide apertures (together with high powers) for those preparations only which do not require perceptible depth of vision—i.e., for exceedingly flat or thin objects, and for transparent objects which can be studied by optical sections. Moderate and low apertures when a wide range of penetration cannot be dispensed with.*

4. There is still another point of view, and one of special practical importance, which shows the positive damage connected with the use of *unnecessarily* wide apertures. The increase of aperture is prejudicial to the ease and convenience of microscopical work in two essential respects.

1stly, It necessitates a progressive reduction of the working distance of the objective. Owing to the rapid increase of the anterior aberration with increasing obliquity of the marginal rays (particularly in the case of dry lenses), perfect correction of a system cannot be obtained unless the layer of low refraction between the object and the front lens (i.e., the working distance) is reduced to a certain fraction of the focal length of the system, which fraction is necessarily diminished in a rapid proportion as the aperture becomes greater and greater. Whilst there is no objection to retaining as working distance 7-10ths of the focal length for an aperture of 30°, if the aperture is 60° not more than 3-10ths can be allowed, and with an aperture of 116° really good correction is not reconcilable with a working distance exceeding 1-10th of the focal length. It is, therefore, an obvious disadvantage to use aperture angles of 60° and 110°, when the power which is required or available can be obtained with 30° and 60° respectively.

2ndly, Increase of aperture is inseparable from a rapid increase of sensibility of the objectives for slight deviations from the conditions of perfect correction. The state of correction of an objective depends on the thickness of the refracting film between the radiant and the front lens, represented by the cover-glass and that portion of the preparation which is above the actual focus. This is a variable element independent of the objective itself. In order to avoid large aberrations which must result from the change of that element, its variations must either be confined to narrow limits or must be compensated for by a corresponding change in the objective. Now there is a great difference in regard to this requirement between the objectives of low and of wide aperture, in particular with the dry system. An objective of a few degrees is almost insensible, it may be focussed to the bottom of a trough of water without any loss of performance. With 30° differences in the cover-glasses within the usual limits are still inappreciable, and an object may be seen at the depth of a drop hanging on the under surface of a cover-glass. With 60° a deviation of the cover-glass from its standard thickness by not more than 0·1mm., or a corresponding increase of the depth of the preparation above the actual focus, will introduce perceptible aberrations and a visible loss of definition if not compensated for. With an aperture exceeding 100° in a dry lens, the same result will arise from a change of thickness of 0·02mm. only. To preserve always the best correction in such a system would necessitate a change of the correction-collar for almost every change of focus in the inspection of successive layers, unless the preparation is exceedingly thin.

The reduction of this sensibility in somewhat large apertures is one of the great practical advantages of the immersion-method. The extreme increase of that sensibility which is met with when the aperture of *dry* lenses approaches the maximal value of *a* for air (1 N.A.), is in my opinion a strong objection to the construction of such lenses with greater apertures than 0·80-0·85. Not only in this case must the working distance be reduced to an intolerably small amount in order to obtain proper correction, but the preservation of that correction in the practical use of the systems is almost impossible, notwithstanding the correction-collar, whilst at all events the very slight benefit of optical performance is not worth speaking of in comparison to the large increase obtained with the immersion-method under so much more favourable conditions. I need scarcely point out here that the claim of a *special* insensibility of certain lenses in regard to differences of the cover-glass (as has been sometimes made) is, to say the least, either great thoughtlessness or simple self-delusion, just as are similar claims of *special* penetration in favour of certain objectives. The aberrations in question, as well as the dissipation-circles from difference of focus, originate *outside* the microscope. The particular construction of the objective cannot possibly therefore influence their amount in a cone of rays of given aperture, and the degree in which both become *visible* in the ultimate image of the microscope must be strictly determined by the same elements which determine the visibility of any real object of given dimensions at the same plane of focus. There is no room left, therefore, for special properties of different constructions. It is, however, true that an *apparent* insensibility, as well as an apparent depth of focus, is sometimes found—viz., in *badly* corrected objectives. When a system has no distinct focus at all, it is quite evident that the dissipation-circles arising from different thicknesses of the cover-glass, and from the difference of focus of different levels, may become much greater before the deterioration of the indistinct image becomes visible. Well-corrected objectives *must* be sensitive in both respects in strict accordance with their aperture so far as one and the same system of construction (dry or immersion) is in question.

So far as the necessity of obtaining a certain amount of amplification in an efficacious manner *requires* a certain aperture, the above-mentioned restrictions and difficulties in the proper managemen of the objective cannot be avoided. But all restrictions in regard to the objects, and all the trouble taken in the adjustment of the objectives, is quite for nothing when the same result can be obtained with a lower aperture. If for the sake of convenience the precautions required in the use of wide-angled lenses should be disregarded in working with the lower powers of wide apertures, the performance of such lenses is always *worse* than that of much narrower apertures under the same amplification. The best wide-angled system, if not carefully adjusted when in use, is not better than a *bad* low-angled lens, for the tolerably sharp image, which could be still obtained through the central part of the aperture alone (even under the imperfect state of correction) is disturbed by the coarse dissipation of light from the ineffective marginal parts of the aperture.

The amateur who likes the microscope for his amusement may not much object to some extra trouble connected with the use of wide-angled low-power lenses, which he admires as brilliant specimens of optical art. For those, however, who *work* with the microscope, the econmy of labour to which they are obliged will be expressed by the rule:—

> *Never use wider apertures than are necessary for the effectiveness of the power, because excess of aperture is always waste of time and labour.*

5. A few remarks about another point of practical interest. By those who plead in favour of large apertures *in all cases*, it has been sometimes suggested as a rational plan for reconciling opposite demands, to have all objectives constructed with relatively wide angles, and to reduce them by stops or diaphragms when smaller angles are desired. The greater penetration and insensibility of the low apertures may of course be attained thereby; but nevertheless this device is only a makeshift, and the result is inferior to that obtained by objectives *originally* arranged for a lower aperture. It is not merely that the stops cannot increase the working distance (which will always remain at the point corresponding to the full aperture of the lens), but that the low-angled lens which is made out of a *good* wide-angled one by means of a stop, is in optical respects a relatively *bad* objective—not nearly as well corrected as the same power would be if carefully adjusted for the lower angle. The reason will be readily understood from the following consideration.

The best correction of an objective of given aperture depends on the proper *distribution* of a certain amount of residuary aberration, which cannot be eliminated with our present means. The greater the aperture the more aberration must be intentionally left *at the central part of the system* in order to prevent an obnoxious accumulation in the marginal zone. It is obvious, therefore, that with an aperture-angle of say 90° the inmost cone of 45° cannot be so well corrected as it might be if the marginal zone could be left out of account. The effect is by no means inconsiderable, particularly in regard to the colour corrections. Owing to the chromatic differences of the spherical aberration the central portion of a somewhat wide aperture must always, even in a well-arranged objective, be perceptibly under-corrected chromatically, and in using this central part alone (the compensating influence of the over-corrected marginal zone being done away with), we have the performance of an inferior lens. In point of fact, no intelligent optician would ever make an objective of 30° aperture on the same formula as one of 60°, or one of 60° on the same formula as another of 100°, though this could be done by merely reducing the clear diameter of the lenses.

There cannot, therefore, be a reconciliation between the pleasure of exhibiting mere optical accomplishment and the interests of the working microscopist. Bad lenses will certainly not meet the demand for low and medium powers affording the utmost possible economy of time and labour in scientific work. This can be done only by systems in which all advantages attendant upon the lower aperture are fully realised by constructions specially aiming at the *best* which can be obtained under the actual conditions of the case.

The *progressive increase of aperture in the higher powers*, formerly within the capabilities of the dry system, and at a later period by the development of the immersion method, is without any reasonable doubt, the most important feature of the *modern advance of microscopical optics*. It has rendered possible the successful extention of microscopical research to minuter and minuter objects, which otherwise would have been impossible by the ineffectiveness of all increase of amplification beyond certain low figures. The appreciation of that progress and the recognition of its true basis has led to a tendency to increase more and more the aperture of *every* kind of objectives. The fact has been disregarded that it is an entirely different thing whether the object is to promote the performance of the Microscope *in the whole* at the limits of its power, or to promote its performance for aims beyond these limits. The opinion has thus arisen that what is a benefit for one kind of lenses must also be a benefit for every other kind. Objectives of low and medium powers (1-inch to ¼-inch) of 15° to 60° are proclaimed at this time by many microscopists as old-fashioned and worthless thing; 45° to 100°, or even 60° to 140°, are wanted for the same powers. Now as from a purely technical point of view, it *is* an accomplishment when the delineating power of an objective cannot be exhauxted even with the deepest eyepieces, opticians (notwithstanding the total bootlessness of such a super-abundance) of coure take pleasure in making such "superior" lenses, and the natural consequence is that the lower apertures required for useful scientific research are likely to be esteemed as second-rate work, no longer worthy of high technical art.

This opinion is a fatal mistake, and its practical effect, if not counteracted, will be a decided retrogradation of microscopical optics. Nobody, of course, can have the least objection to the construction of lenses of any description whatever for the personal pleasure of this or that microscopist. Strong opposition should, however, be made against all tendencies of captivating microscopical optics in favour of such predilections, at the cost of the general usefulness of the instrument.

Scientific work with the microscope will always require not only high-power objectives of the widest attainable apertures, but also carefully finished lower powers of small and very moderate apertures.

ON PLANT-DRYING AND SOME PHENOMENA OF VEGETABLE DEATH.*

By Leo. H. Grindon.

We are now in the heart of the season when it is useful to give a little time to the preservation of plants for the Herbarium. Collections of dried specimens of course are not to be regarded as anything more than means to an end. It is not accumulating a vast quantity of vegetable mummies that makes a botanist, however elaborately they may be arranged, however pretty their epitaphs. Botany is the study of plants as they live and grow, their manner and customs, their curious ways and changes, noting these carefully, and then, in order that the memory may be assisted at times when living examples are unfavourable, drying one or two good examples in the best possible manner, sorting and labelling them, so that the whole constitute a kind of dictionary. This is the true and essential idea of an Herbarium or Hortus Siccus, the only one that is to be approved, the only one that carries with it the ideas of common sense and of really practical results for good to the collector. When the work of our hands can be supplemented with gifts from friends, and particularly from friends residing in foreign countries, so much the better. But it must never be forgotten that no can ever claim exact knowledge of a plant who has merely seen it dead.

---

* From the *Field Naturalist*.

The very ancient adage, that if a thing be worth doing at all it is worth doing well, applies to the preservation of plants for the Herbarium as much as to any great and important work or business. Specimens that are no better than fragments of brown stick, or that seem effigies of plants cut out of thin brown-paper, the flowers shrivelled and shrunk so as to be no longer intelligible, the leaves crumpled and doubled up, everything confused and mashed together, such as one may see sometimes in collections, are altogether undeserving of the name. Nothing that is not dried in the best manner possible, — its colours and configuration preserved as perfectly as the nature of the plant will admit—ought ever to be allowed a permanent place in the Herbarium. The bad may be tolerated awhile, in default of better, but the further a specimen is from vivid and pleasing resemblance to the living thing, the speedier should be the endeavour to supersede it. Specimens from abroad that cannot be superseded of course we do not speak of. It is of plants within reach that none but admirable representatives of their best features while alive should be considered worthy of a place. Plants dry very variously. Some require not a moment's trouble, others demand patience. Now and then the case is hopeless, and we are constrained to fall back upon the pencil, and prefer drawings, coloured ones if possible. Grasses and their allies, most kind of ferns, plants that resemble heather, "everlastings," the mature leaves of shrubs and trees, call for only the minimum. Those which try the patience, and can be managed only after considerable experience with easy ones, are such as may be illustrated by citation of the hyacinth. To secure the best results, obtain first half a dozen pieces of stout millboard, cut to about eighteen inches by twelve. Then gather together a hundred old newspapers, and fold them neat and square to about the dimensions of the millboards. Four or five yards of common white cotton wadding, a score of sheets of tissue paper, and as many of blotting paper, all cut to the same size, complete the apparatus. One of the boards serve for the foundation; on this lay a newspaper, then a piece of wadding, and upon this place the specimen intended to be dried. The cotton being soft and retentive, every portion can be laid in a a proper and natural way, including the petals of the flowers. A newspaper above, two or three if the specimens have thick stems, and so on, till all shall be deposited in the way of the first. If the specimens are sticky, or hairy, or of a kind that the wadding seems likely to adhere to, then, before depositing them on it, introduce a half sheet of the tissue-paper. A heavy weight must be put on the top of all, sufficient to embed the specimens in the wadding; then leave the whole to rest for twenty-four hours. All the papers must then be changed, dry ones being put in their place; and if the plant seems to throw off a very considerable amount of moisture, such as will render the wadding quite damp, change the wadding also. A second and even a third change is desirable, at the end of two or three days or a week, and when this is made introduce the blotting paper, pressing again till everything is perfectly flat, and the specimens are absolutely dry.

Such is the simple process by which the writer of these lines has succeeded in the art of preserving the colours and forms, not only of robust and tractable plants, but of the most delicate, and very many of the obdurate. Every petal, every leaflet, retains the form it had in life, and nine specimens out of ten keep their colours excellently. To ensure the keeping of *colour*, it is well, if time can be spared, to change the blotting paper many times, and to dry it thoroughly before the fire, but this need not be done till after the third day from the beginning.

Most curious are the phenomena now to be witnessed. If those pertaining to the history of life are full of interest, those which accompany death almost equally arrest attention. The grand conspicuous phenomena of autumn we do not here so much refer to as to those observable during the preparation of Herbarium specimens. In autumn, as well known, the leaves fall in consequence of the development of a peculiar layer of cellular tissue at the point of junction of the petiole to the stem of the plant; while the colours come of the leaf being "super-oxygenated." But no one has yet uttered so much as a hint as to why some super-oxygenate into yellow, others into crimson, others into brown; one here and there, the ash, for example, declining to super-oxygenate at all, and simply dropping to the ground. Leaves and leaflets when drying between papers, are often cast off, probably in consequence of derangement in the onward flow of the sap. This happens very markedly in fir-trees, ericas, the wistaria, and various species of cissus and ampelopsis. Peduncles and petals also leave go, as in berberies, flax, the Boussingaultia and many solanums. The entire inflorescence on that beautiful grass, the Zizania aquatica, falls to bits so completely that a skeleton only remains. Crimson flowers very often change to a fine violet-purple, as in the case of the erica cinerea, the Lagerstrœmia, cyclamens, and the hairy willow herb. The cowslip, on the other hand, changes from yellow to green; and the vanda from white, variously and exquisitely mottled, to irrepressible black. Not unfrequently the entire plant changes to black, and will not be hindered, as happens with the aucuba, the lathræa, and the monotropa, in the two last of which, being parasites, we might perhaps expect it; but the aucuba — well, why here? Many plants, while drying, after death give out an agreeable perfume. New-made hay supplies a familiar illustration. We have other examples in sweet melilot and the woodruff. Sometimes the petals shrivel and contract in a very singular manner, quite different from the usual, as seen in agrimony and the Bauera; or they go into glassy films, as in the eucharis. Anemones, poplars, droseras, hellebores, stain the paper, the dye often not coming out for many months, and even years. Mercury is content to assume a beautiful indigo blue colour, which, it if said, can be extracted.

These are but a few of the curious changes that could be mentioned. They are given with a view to showing the beginner that he must never be astonished at what may occur. In the case of change of one pleasant colour to another, there is nothing really to regret. The only thing to lament over when one's specimens are of colours they need not be, is that we have ourselves been unskilful or neglectful.

SCIENTIFIC SOCIETIES.

ROYAL MICROSCOPICAL SOCIETY.

THE last meeting of the session of the above Society was held on the 14th ult., at King's College, Strand, the President (Prof. P. Martin Duncan, F.R.S.) in the chair.

The President called attention to the donation of a complete set of the *Geological Magazine*, and Mr. Stewart to the "Studies in Microscopical Science," edited by Mr. A. C. Cole, the illustrations of which he considered were very good, and the letterpress appeared to be equally so. The novel feature was that a microscopical preparation accompanied each part.

Mr. Crisp exhibited a ¼in. objective by Tolles, with a very tapering front, and stated that it was claimed on Mr. Tolles' behalf that he was the first to make such fronts about ten years ago.

Mr. Ingpen said that he had one of Andrew Ross's ½in. objectives with a triplet front dated 1848, which was similarly tapered.

Mr. Beck said that he had made them in the same way for the last fifteen years.

The President, referring to J. L. de Lanessan's "Traité de Zoologie-Protozaires" 8vo., Paris, 1882, pp. vii. and 336, and 281 figs.), said that it treated of *Amœbæ* on a somewhat grand scale, particularly as regarded the larger kinds, and he would suggest to some of the Fellows that they should search for these species as being of great interest. He obtained one from the Hampstead ponds which he found full of minute refractile points.

Mr. Stewart said he had examined some large *Amœbæ*, a short time ago, which came from Mr. Ingpen's aquarium, and were crowded with refractile points. They were distinctly crystalline in character, and had a vesicular nucleus.

Mr. Hartog said that he used to find the nuclei in the large *Amœbæ* with a very distinct network, although one which he found had a hollow nucleus.

The President inquired if Mr. Hartog had ever been able to iodise or get any colour out of *Amœbæ*?

Mr. Hartog said he had stained them with picro-carmine, but had not done so with iodine.

Dr. Ralph, the President of the Victoria (Australia) Microscopical Society, responding to a welcome from the President and the meeting, said he should like to take that opportunity of bringing before the Fellows of the Society the examination of the leaves of various kinds of plants by means of the action of prussic acid and ammonia. The process was a very simple one, it being only necessary to place the section under the microscope, and then introduce the compound. He had only had time as yet to examine a few kinds of leaves in this way, but the vine had hitherto given the most marked instances of the chemical action to which he referred. A longitudinal section as thin as possible being made of the leaf and placed under the microscope, the fluid should be added, and would be found to penetrate the structure, chiefly acting on the ducts, which were within reach of the bark. In a few moments, the most extraordinary colours made their appearance, such as claret, amber, port-wine colour, and others having all the appearance of a coloured injection of the tissue, only that in about a quarter of an hour it all disappeared. Other leaves which he had tried behaved much in the same way, though they did not all respond to the reagent in an equal degree. It was only in the brittle, sappy stems that it was possible to get the least results. He had lately tried what he believed was the panix, but he found the results were uncertain. Sometimes it failed, and sometimes it did not. The question of interest, however, was whether they could extend their observations to other plants. In consequence of these observations, he had been able to treat sections of the human subject with prussic acid with marked effects. Whenever he got in the plasma amorphous particles distinctly blue in colour, he also found the formation of amyloid bodies in the blood. These bodies were very well defined, and under favourable circumstances in polarised light, the black cross could be seen. The production of amyloid forms by chemical means, not only under the action of hydrocyanic acid, but by chloral, formic acid, or solution of copper in ammonia, was a point of considerable interest. If a portion of either of these reagents were added to fresh blood, and examined carefully under the microscope, they would, in all probability, find these starch-like bodies developed in the field. It was not easy to show the process in a room to a number of persons; but if any one present was interested in these subjects, he should be very glad to demonstrate what he had been describing.

Mr. H. Stewart inquired whether these bodies were supposed to be formed by the reagent, or were they supposed to be really present before, but only to be made visible by the reaction?

Dr. Ralph said that under favourable circumstances they might see a globule which they would be disposed to say was oil; when the reagent was added it would increase in size from about the 1-3000in. to about the 1-1000in.; later it would suddenly become opaque, and then it would colour in such a way that any one looking at it would say at once that it was starch. So far as he had carried out the observations, it seemed as if these starch-grains really did develop, and he thought it might be an instance of the commencement of the process of amyloid deposit.

Dr. Morris, of Sydney, was introduced to the meeting by the President, and detailed some experiments which he had made in mounting diatoms in phosphorus in such a way as not to be inflammable. As he had only just arrived from Sydney, he had not had time to write anything on the subject. He had seen some of the specimens which had been mounted in England, and was under the impression that the solution was too strong. He proposed, therefore, to reduce it to such a strength that if a piece of white blotting-paper was put into it, it would not blaze up. By such a solution, all difficulty as to using the medium was done away with, the only necessary precaution being to have a basin of water near at hand to dip the fingers into.

Mr. Stephenson said that if they used a weak solution, they would get a proportionately lower refractive index, whereas the principal object in mounting in phosphorus was to get as great a difference as possible between the refractive index of the medium and that of the object, for on this difference alone did the increase of visibility depend.

Mr. Crisp said that if phosphorus was used diluted to a refractive index of 1·8, the visibility of the diatom would be proportionately reduced, and as there was no virtue in phosphorus, except for its high refractive index, it would be better not to use it at all in such a condition, but to take some non-inflammable substance which had the lower refractive index.

Dr. Morris said he had tried some *Navicula*, and that with an oil-immersion lens the object mounted in phosphorus was resolved in the most perfect manner—far superior to anything that could be seen with balsam.

Mr. Crisp said that it must be borne in mind that the danger incidental to the use of phosphorus was not confined to the process of mounting. A case recently occurred, in which an object-glass, brought down too hard broke the cover-glass, and the observer, having wiped off the exuding phosphorus with his handkerchief, put it into his pocket and set himself on fire.

Mr. Ingpen said he had brought for trial some of Steinheil's eyepieces, which he thought would be of interest, on account of the speciality of their construction, and of much value for microscopical purposes when it was necessary, or, at any rate desired, to use deep eyepieces for increasing magnifying power. It was well-known that with higher objectives than 1in. the deeper Huyghenian eyepieces failed to give good definition; but these gave a remarkably sharp image. It might, of course, be a matter of opinion as to the value of increase of power by means of eyepieces; but there could be no doubt as to the superiority of this combination over the ordinary form. The field of view was rather small, not exceeding 40°. The combination consisted of three lenses cemented together, the two outer ones being of flint-glass and the middle one of crown-glass, the stops being grooves ground in the edges and filled in with black after the manner of a Coddington lens.

Mr. Crisp explained the new method devised by Dr. Ehrlich, the assistant of Dr. Koch, for preparing the bacteria of tuberculosis, which constituted a considerable improvement upon the original process. It produces a more intense colour in the bacteria, so that they appear larger, and can be recognised with a lower power, even, it is said, of 250 diameters. The substance he makes use of, instead of methyl-blue and caustic potash, is *phenylamine*.

Prof. Abbe's process of increasing the consistency of pure cedar oil, so as to render it less fluid and therefore more convenient for use as a homogeneous-immersion fluid, was explained by Mr. Crisp. The oil is spread out in thin layers, and exposed to the action of the air and light for a long time, until it becomes of the consistency of castor-oil.

Mr. W. F. Petterd's letter was read accompanying a collection of diatoms from Tasmania.

M. A. Cates' letter, reiterating his claim to the discovery of a method of staining the nucleus of *living* infusoria, was read by Mr. Crisp, who said that the author of the interpolation by which such a claim was described as "erroneous," now agreed that he was mistaken in the view he had expressed, not having in fact sufficiently noticed that the claim related essentially to the nucleus of the *living* animals.

Mr. Crisp called attention to a process devised by E. Korschelt, of Freiburg, for preserving infusoria and *Amœbæ* by the use principally of osmic acid and chromic acid, no method having hitherto been found for the latter organisms. Dr. A. Gruber had also succeeded in preserving Heliozoa by the method, in excellent condition.

Mr. R. Miller's description of his caoutchouc cement for making and sealing cells was read, in which he stated that he did not claim to have discovered any new material, but to have accidentally hit upon a new method of combination.. The material so obtained was singularly easy to work, and reliable in its results. It was used not only for making the cells but for sealing them afterwards.

Dr. Van Heurck's letter was read describing favourably his further experiences with the Swan lamps and Faure-Reynier accumulators.

Prof. Abbe's note was read with reference to the description of his camera lucida, inserted in the *Journal*, that the benefit of the arrangement consisted simply in the ease with which it may be used. In other respects it did not possess any advantage over those forms which fulfil the condition that the image is seen without reflection or other loss of light.

Mr. Ahrens exhibited and explained the construction of his new erecting binocular microscope. In general outline it presented much the same form as that of Mr. Stephenson's, the tubes being inclined, whilst the stage was horizontal. The erection of the image was, however, obtained by introducing a Nachet-erector prism over the objective, another prism similar to the Wenham being used above to divide the pencils.

Dr. Millar said that whilst he could speak with great praise of the advantages of the erecting binocular as an instrument to work with, leaving nothing to be desired for comfort and convenience, he thought the one now before them did not appear to give an entirely satisfactory stereoscopic effect.

Mr. Michael said there was no doubt that a binocular microscope, with a flat stage and an erecting arrangement, was an immense help to those who worked at living objects. In drawing from living insects he had found it of the greatest practical service.

Prof. Liversidge's communication on the "silver-fish" of Sydney was read, in which he defended the accuracy of the observations of Hooke recorded in his "Micrographia" (1665) as against the strictures of Mr. W. Blades in his "Enemies of Books" (3rd ed., 1881). Specimens of the insects were sent, and labels and sheets of paper destroyed by them exhibited.

Mr. Hartog said there was no doubt as to the animal being *Lepisma Saccharina*, the same that was often found in this country. It was mentioned by Emerson Tennant as being thought by some to prey upon books, but the author thought that it rather preyed upon the insects which were found in the books, a view which he (Mr. Hartog) thought was an error.

Mr. Thoms' letter on "Saccharomyces" was read, in which he mentioned that he had devoted all his spare time for ten years in tracking these organisms, and now made all his bread without any yeast, so called.

Mr. Bennett, to whom the letter was addressed, made some remarks upon the subject.

Prof. Abbe's paper "On the Relation of Aperture to Power," Part II., was laid before the meeting by Mr. Crisp, who said that as it was a very long communication, he had prepared a résumé of it, which presented the leading points in a condensed form suitable for being read to the meeting. This he was proceeding to do, when

Mr. Beck, interposing, said he thought that as the paper was an important one, and required a good deal of consideration, a résumé of it would be of very little use to them. He would suggest, therefore, that the paper should be printed, and that when it had been before them *in extenso*, an evening should be specially devoted to its consideration and discussion.

The Chairman (Mr. Glaisher, in the absence of the President), on the contrary, thought that it would be very useful to have an abstract of the paper read.

Mr. J. Mayall, jun., also thought it very desirable that the Society should be in possession of Professor Abbe's views, without having to wait until the next issue of the *Journal*. The meeting having indorsed this view, Mr. Crisp read a *résumé* of the paper.

The Chairman said that the paper was obviously one of very considerable importance, and he had great pleasure in proposing that the warm thanks of the Society should be presented to Professor Abbe for it.

Mr. Stephenson seconded the suggestion, and said that, having had the advantage of reading the paper in M.S., he believed it would be found to contain a most exhaustive discussion of the subject.

Mr. Crisp said that it was the first attempt that had been made to establish a definite relation between aperture and power, and it could not fail to prevent the perpetration in future of such absurdities as had been issued in the way of low-power objectives, with very large aperture.

The Chairman said that the report of the Committee appointed to consider the question of standard gauges for eyepieces and substages had been adopted by the council. The gauges recommended for eyepieces were 1·35in. and 0·92in., and for substages 1·5in.

Mr. Crisp said that it should be mentioned that there had been some difference of opinion, both on the part of the Committee and Council, as to whether there should not be a third intermediate gauge; also, that in selecting the sizes mentioned by the Chairman, regard had been had to the sizes which were at present in most frequent use, so as not to disturb existing arrangements more than could be helped.

The following papers were taken as read: "Plant Crystals," by Dr. Aser Poli, of Rome, "Note on the Rev. G. L. Mills' Paper on Diatoms in Peruvian Guano," by Mr. F. Kitton.

The meeting then adjourned for the vacation, until October 11th.

USEFUL AND SCIENTIFIC NOTES.

A Blind Man's Vision.—M. J. Plateau, who for the last forty years has been totally blind, has just published a little paper on the sensations which he experiences in his eyes. He states that he has constantly in his eyes the sensations of light; his field of vision is divided into spaces, of which some are very clear, and others sombre or almost black. These spaces are not precisely limited, but run into each other at their borders; but what is remarkable is that their general tint alternates between gray and reddish. For example, if it be grey M. Plateau perceives now, in a few hours it will be red; then a few hours later, the grey again, and so on. The reddish tint is that obtained by mixing pale rose-colour, or rather flesh-colour, with a certain quantity of black. The relative arrangement of these different spaces is always the same, but the intensity of their tints varies. The central space shows itself sometimes very clear, sometimes very sombre; above and below, as far as the limits of the visual field, there is sometimes clearness, sometimes obscurity. It is the same with the space to the left: there is generally a vertical, almost black band, and the space to the right of that, as far as its limit, is almost always clear and ruddy. These appearances seem to M. Plateau to fill the whole extent of his ordinary visual field. He believes the distance at which they are is small. These same appearance follow all the movements of the eyes, as if they resulted from a modification of the retinas. It appears to M. Plateau that the two eyes do not participate in the same manner in the tints in question; but he is absolutely incapable of distinguishing what belongs to the one from what belongs to the other. He has not been able to establish any coincidence between the changes of the general tint and the work of digestion.

VALUE of exports per head of the population in the Australian Colonies:—New South Wales, £21 11s. 2½d.; Victoria, £18 15s. 3d.; South Australia, £21 1s. 7½d.; Queensland, £15 10s. 8¼d.; Tasmania, £13 6s. 1¾d.; Western Australia, £17 4s. 0½d.; New Zealand, £13 7s. 10½d. General average, £18 5s. 6¼d.

SCIENTIFIC NEWS.

THE Dun Echt Circular, No. 53, contains a *Science Observer* telegram, announcing that Mr. S. C. Chandler, jun., finds the period of the variable star D. M. + 1° 3408 to be only 0·83 day. A minimum occurred on July 1, 12h. 57·6m. G.M.T. On reference to p. 324, XXXIV., a note from Dun Echt Circular, No. 41, will be found, in which the period is given as 5·24 days.

Prof. Schmidt saw comet Wells at Athens on June 10. He gives the position as 3h. 59·7m. Athens M.T., R.A. 5h. 0m. 40s., N. Dec. 23° 19 4′. The distance of the comet from the nearest limb of the sun was 2·8°.

The comet seen during the eclipse observations has not been again observed. It was carefully looked for in Egypt during the week after the eclipse, both before and after sunset, but was not detected.

The flint disc for the great telescope of the Lick Observatory proved to be, like the crown, a most successful casting. The trustees of the Observatory have ordered a meridian circle with 6in. aperture from Messrs. Repsold, of Hamburg There will be two divided circles, each having four reading microscopes; the axis of revolution will be a telescope with collimators east and west. The object-glasses for the instrument, and the collimators will be made by Alvan Clark and Sons.

It is stated that the Crystal Palace Company are endeavouring to organise an exhibition, during the autumn and winter, of gas and electric-lighting appliances. The direct competition of the rivals would be very attractive, especially if the relative costs of the systems were given by a jury of experts.

Prof. Houston, of Philadelphia, thinks that underground wires for electric lighting are perfectly feasible, and much safer than overhead wires. The municipal authorities of Chicago have determined that the wires shall be placed underground.

The report of the Streets Committee of the City of London on the tenders for the electric lighting of certain districts has been issued with a map. The figures given in the tenders are remarkable; but it is scarcely fair to take the cost of the plant, putting it down, and removing it into account, when comparing the estimates with the present gas-bills. To take No. 1 district, the gas-bill is about £551; the cost of the electric light for twelve months (that is, the charge for the actual working) varies from £498 to £1,620; but the total cost varies from £2,190 to £5,750. Adding 10 per cent. of the actual outlay for plant to the lowest working figures the bill would be £837 as against £551 for gas. In view of these and other facts, the Streets Committee think it unadvisable to proceed further at present.

The Smithsonian Report for 1880 contains a "Synopsis of the Writings of Sir W. Herschel," prepared by E. S. Holden and C. S. Hastings. The "general appendix" in this volume has very few of the usual scientific papers, but there is a "record" of recent scientific progress, in which the subjects are each treated by well-known students: *e.g.*, Prof. Holden writes the record of astronomy. It is intended to make this record a special feature of the report, but it will not exclude the monographs which have heretofore formed so valuable a part of the annual volumes.

Mr. Stretton's little book on "Railway Accidents" is evidently a success. A second issue of the third edition is announced, with additional pages and diagrams. We trust the author's object of tracing and preventing avoidable accidents may be in some measure secured, and that he may reap the reward of his long and persistent efforts on behalf of railway employés and the travelling public.

The expeditions intended to make a series of observations in the Arctic regions—the circumpolar expeditions, as they are called—are nearly all en route, and by August 1 will commence their work, which will be continued for thirteen months. The results will be discussed at an international conference.

A project by Prof. Wellner, of Brünn, for utilising the motions of the sea, was recently noticed in our columns; part of it consisted in letting the compressed air enter the lower divisions of an immersed wheel, of water-wheel-shape. Prof. Wellner has patented (in Austria) steam-wheels working in the same way —a new type of steam-engine. The mechanical work depends on the lifting power of the specifically lighter steam in the heavier liquid. The steam may be generated immediately below or brought from elsewhere. The escape-pipe at the upper part of the case may either let the steam into the open air or into a condenser. These machines may be connected with ordinary ones, and then afford a means of utilising the waste steam.

Magic photographs, in which the image is developed by tobacco-smoke, have been lately supplied in various tobacco-shops on the Continent. A cigarette mouthpiece is provided, and with it are some white photographic papers about the size of a postage-stamp. One of the latter is placed over a lateral orifice in the mouthpiece, and a sliding piece drawn over it. After smoking, one finds the image on the paper. *La Nature* explains the process. A small photograph, prepared on chloride of silver paper, as usual, but without intensifying, is put in a solution of bichloride of mercury, where it pales and disappears. The bichloride of mercury changes the photograph partly into white chloride of silver, and partly into protochloride of mercury, also white, making the image invisible. The image may be brought back by action of hypochlorite of soda, or of ammoniacal vapours. Tobacco-smoke, as containing the latter, does very well. The principle of magic photographs was indicated by Herschel in 1840.

It was announced that an exhibition of electricity was to be held at Vienna this year, and another at Munich. Considering the disadvantage of these being at the same time, the Vienna Committee have resolved to delay till August—October, 1883. In Bavaria, the railway authorities have offered the Exhibition Committee trains for trial of systems of lighting, and the telegraph authorities lines for trial of long-distance telephoning; the longest of the latter is Munich to Dresden, 550 kilometres (say 343 miles.) Telephonic experiments have been lately made with success, by day, on the line between Paris and Dijon, a distance of 314 kilometres (196 miles). It is curious to read that three telegraphic stations have been recently opened in Palestine, at Nazareth, Tiberias, and Safiè. In Arabia, the material is getting ready for construction of the system of telegraph-lines of Hedjaz. Part is destined for the first lines from Djedda to Mecca, and from Mecca to Yambo and to Medina; the rest for connection of the lines projected for Hedjaz with the existing lines in Yemen.

New experiments have been made by M. Richet with a view to ascertaining the *minimum fatal dose* of the principal alkaline chlorides (of lithium, sodium, potassium, rubidium, and cæsium) on animals. The animals selected were small guineapigs, and the substances were injected under the skin. M. Richet finds no relation between the atomic weight of the alkali metals and their physiological activity.

Glove-leather is usually coloured by manual labour with brushes. This process, besides being slow, has the disadvantage that ugly edges are produced on the flesh side, and the colouring, in spite of great care, is never quite uniformly distributed. Herr Kristen, of Brünn, has sought to remedy this by a (patented) process, in which uniform colouring is effected with the aid of centrifugal force, the skin being fixed on a horizontal disc, the colouring poured on it at the middle and the disc rotated. Thus an equal distribution of the matter is obtained. The liquid in excess flies over the edge, and is caught in a funnel, which guides it to a reservoir, whence a pump bringsit again to the disc. In about 10 to 15 minutes a skin is finished. Only one man is required for five of the machines, which are placed near one another, and driven by the same shaft. In twelve hours 150 skins can easily be coloured by this method, and in a very satisfactory way.

In Berlin an exhibition of machines and raw products of soap, perfumery, wax and candle manufacture was opened on 4th June.

A method of lighting miners' lamps by electricity formed the subject of a recent paper by M. Hubert, to a scientific society in Hainaut. The body of the lamp is traversed by two tin tubes, holding two other concentric wooden tubes, which serve to insulate copper wires passing through (tightly) to a small piece of platinum wire near the wick. The explosive gas cannot enter along with the current. On applying the two series to the electrodes of a battery, the platinum glows and the wick is lit. The battery is a bichromate; two zinc plates and four carbon plates being immersed in a mixture of bichromate of potash and water, acidulated one-tenth of its weight with sulphuric acid. To avoid sparks, two plates of carbon and of zinc are held out of the acid by two springs. After applying the lamp to the electrode to light it, the springs, on being released from pressure, raise the plates from the liquid, and, on removing the lamp, no spark can pass, since the circuit is ruptured within the battery.

The idea, expressed a short time ago, that red-beet was destined to rival the vine in production of wine, appeared open to serious doubt. M. Lefort, a member of the French Academy of Medicine, has recently furnished technical reasons for rejecting it. The spirit produced in the vinification of the must of beet contains, in addition to vinic alcohol, some aldehyde, which is the chief cause of the depreciation of beet-spirits; also propylic, butylic, and amylic alcohol, substances that are poisonous even in small doses, as the experiments of MM. Dujardin-Beaumetz and Audigé have proved. There is further to be cited an alkaloid called *betaïne*, which is always met with in the beet, in a proportion of 1 to 5 per cent., according to the roots, and whose physiological properties are unknown. In fine, the pretended beet-wine is simply a pale red liquid, containing 4 to 5 per cent. of alcohol, easy to keep, but of a very disagreeable flavour by reason of the odorant principle of the beet. This manufacture, M. Lefort holds, cannot have a great future.

The manufacture of alcohol from potatoes by means of hydrochloric acid is carried on entirely in Germany (according to *Le Genie Civil*) as follows: The potatoes are introduced into apparatus in which they are treated with steam at high pressure; then saccharification is effected with hydrochloric acid, and the excess of acid is neutralised with carbonate of soda. The cooled mass is submitted to fermentation in vats, then distilled. When saturation has been reached, the residues may, without inconvenience, be employed as food for cattle.

One day recently, the Hotel de Ville at Arras was struck by lightning and set on fire, though the belfry has a lightning conductor over 12 metres long, which was repaired last year by a local electrician. The part struck (above the mayor's rooms) appears to have been within the cone of protection according to received ideas. A specialist, M. Jarriant, has suggested three possible causes of the phenomenon: (1) Solution of continuity in the metallic circuit; (2) insufficient section of the conductor; (3) a bad condition of earth-connection. On May 31st, lightning struck the earth covering the powder-magazine of the Fort Werder, near Strasbourg. The ground-sill of the magazine, a stone more than a yard thick, was shivered to pieces. It is remarkable that none of the new forts raised by the Germans about Strasbourg have been furnished with lightning-rods—an inexcusable imprudence (says *L'Electricité*), because many examples prove that lightning has a real affinity for powder.

The first electric railway in Holland has been opened. It runs along the North Sea, from the sea-baths of Zandvoort (a place connected by rail with Harlem) to the park of Kostverloren, the length being two kilometres (1¼ miles). The line is constructed by Siemens and Halske, of Berlin.

An interesting report on the results of experiments in Russia, with moving targets for artillery fire, appears in the *Revue d'Artillerie* for June. Such targets give good results, it is stated, when they have the form of a drum or a two-wheeled vehicle, with two long cables attached (the length of cable being not over 2,500 metres, and the traction being by horses). The targets are moved either across or along the line of fire. Temporary supports, with guide-rollers for the cables, are planted on the ground.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made Payable to J. PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original." —*Montaigne's Essays.*

ζ HERCULIS.—ξ BOÖTIS.

[20235.]—IN letter 20212 (Vol. XXXV., No. 901, p. 377), "F.R.A.S." refers to the distance separating the components of ζ Herculis at the present time. I again carefully measured this star on the evening of Friday, June 30th, with the following results:—P = 106·2°; D = 1·2″; Ep. 1882·49. This is the mean result of 4 measures, and I believe may be relied on, say, within 3° of the position angle, and about 0·1″ of the distance.

I shall be happy to measure the second companion of ξ Boötis for Mr. H. Sadler (letter 20179, Vol. XXXV., No. 900, p. 349) on the first opportunity.

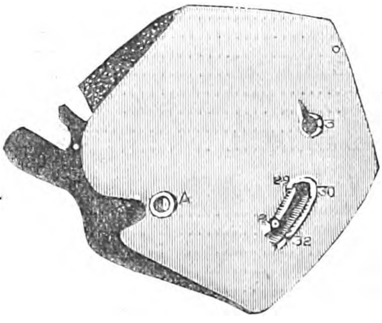
PTOLEMÆUS.

[20236.]—IN Tab. LXXII., Fig. 51, Schröter has delineated four deep pits, two of them being nearly as large as the crater, Ptolemæus A. From "Celestial Objects," and also from Neison's "Moon," it appears that these curious objects have not been seen since Schröter's time, though Mädler observed the floor for four years, and saw 11 small craterlets upon it. In the *Astronomical Register* for February, p. 45, however, I gave a brief account of some observations of one of these large pits, the northern one (η of Schröter); and last night I was favoured wish a few short, but very interesting, glimpses through gaps in the clouds, with the following result:—

1882, June 23, 9h. 20m. to 9h. 30m., 2·75in. achrom., p. 102. Moon's age, 8·1 days. Definition fair, but a little fluttery. The two principal pits appeared very conspicuous, and nearly as large as the crater A. They were nearly, but not quite, filled with shadow, the eastern side being bright, with perhaps a trace of a very low wall. The southern one had a short extension of the shadow south, and on its east side was a bright spot, No. 3, which last, sometimes appearing as a crater, has been seen to vary considerably in brightness. The northern pit was still more interesting. On its east and west edges were two minute spots, Nos. 29 and 30, both of which are really small crater cones. From spot 29 a ridge ran N.W. to the pretty large craterlet 2, which, under a higher illumination, appears as a bright streak *t*. This ridge was pretty lofty, and quite conspicuous. Another ridge ran from spot 30 to 32, forming a light streak *v*, at full moon; this was also very plain. The space included by these two ridges, which are perhaps shown too far apart in the sketch, was nearly filled with shadow, and very dark elsewhere. There was only just time to draw the outline, and insert these features in the accompanying sketch, before clouds completely obscured the moon; but much other small detail was visible on the floor.



It is remarkable that such very large and prominent features as these should have escaped attention for so long, and should not always be visible soon after sunrise. Thus, on May 27, 1882, at 8h. 30m., moon's age 8·4 days, not a trace of either of these great depressions, or of the ridges, could be seen, though the floor was carefully examined with a 5¼in. Calver, and power of 275. Nor has the slightest vestige ever been observed at sunset.

I am anxious to obtain every possible information with regard to these wonderful objects during the next few months, and should, therefore, be very glad of any assistance. The inclosed sketch will serve to point out roughly the positions, &c., of these objects; but if anyone who thinks of looking them up will write me a line, I shall be happy to give the positions of certain measured and other spots and objects in the neighbourhood, which will serve to fix their positions exactly, and other information which might be of use.

A. Stanley Williams.

CATALOGUE OF SUSPECTED VARIABLE STARS.—I.

Andromeda, Aquarius, Aquila, Argo.

[20237.]—We have collected from various sources a catalogue of all the stars suspected of variation, the number of which has now reached to between four and five hundred. The variation of so many of them may be watched with an opera-glass, that we think, perhaps, by publication of them, some of your readers may be induced to undertake observations of them. We shall give them in order of the constellations, arranged alphabetically. The places are only given roughly, but will be sufficient to identify the star on the star-map. We are aware that the catalogue is very incomplete, but trust that such as it is it may be acceptable to your readers:—

CARBON CONNECTIONS.

[20238.]—The plan suggested by "Beetle Crusher" of drilling a vertical hole in the carbon and filling it with lead, I used to find defective, until I improved upon it as follows: Place a small piece of platinum foil, tinned on the upper surface into the drilled hole, and pour in the solder or lead around some removable object; then, when cool, fill the hole.

I found the surface of the lead soon oxidised otherwise, and filling by degrees prevented shrinkage.

D. H.

SECONDARY BATTERIES—SUGGESTED IMPROVEMENTS.

[20239.]—These batteries are likely to become so important in the future, for the purpose of storage of power, that any suggestions which may be productive of improvement, are, I think, worthy of consideration and experiment.

In the first place, it is advisable to consider what are the principles which give rise to the action of this battery, and also to show in what manner it differs from the ordinary sort. In this we employ the same metal on each side, and thus we are enabled to use one conducting fluid instead of two, which is free from some inconveniences which arise from the use of two fluids. Next, we must choose a metal which is capable of three degrees of oxidation, and further, this metal and its oxides should be able, or nearly so, to resist combining with the fluid which we are using. Now, in the oxides of lead, and in dilute sulphuric acid, we have the necessary conditions. Let us now observe what takes place when in use. Having the plates on both sides covered with the *intermediate* oxide of lead; upon applying the "dynamo," the plates are polarised, causing one to have a greater affinity for oxygen, and the other a less. By this means the intermediate oxide on one plate takes another molecule of oxygen, which the other plate loses. Upon disconnecting our dynamo, there is energy in the side having the lower oxide, to drag (as it were) the superfluous oxygen from the other plate; but this cannot take place until a passage is made for the electricity—as it were, a back door to find its way to the opposite side, and in by another back door; for, the immediate space being occupied, no room is left for the passage of the electricity till another way is afforded; and thus, by completing the circuit, we can intermediately employ the electricity for work, or any purpose we require.

But it is a mistake, I think, to use so large a quantity of metal to conduct the electricity provided by only a thin coating of oxide. As the possible store of energy must depend upon the quantity of oxide present, it is evident that there is a great disproportion between the large quantity of metal employed for conducting, and the small quantity of oxide furnishing the electricity.

To improve upon this, I propose that a number of flat, porous jars be provided, fitting into a suitable case. Into the middle of each of these should be put a thin plate of lead, and filled up with the oxide of lead; and then that the acid liquid be poured over all so as to fill every vacancy. Now, notwithstanding the extra space occupied by the porous jars, it is plain that by this method a much larger quantity of oxide is stored in the same space, and the construction of the battery is rendered much more simple.

Every alternate plate is to be connected to one conducting wire, and the other alternate plates with the other conducting wire, and by this method we may get a large *surface* of plate connected with a large *quantity* of the oxide; and hence a much larger storing capacity.

But we are not confined to lead as our metallic conductor, nor to its oxide as our oxygen carrier, for there are a variety of substances which will be found suitable to fulfil the required conditions.

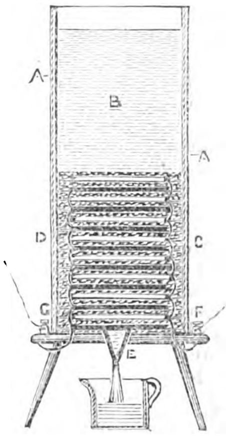
And it is a fortunate circumstance for our first cost of battery, that in iron—the cheapest of metals—we have, as I think, the most suitable metal which could be found to answer the purpose, for we have the three oxides—namely, the protoxide, the intermediate black oxide commonly called the magnetic oxide, and the sesquioxide, and it so happens that this intermediate oxide is a combination of the other two. But, moreover, all these oxides are insoluble in phosphoric acid, or nearly so; and hence we have a successful method of forming a cheap secondary battery by employing the oxides of iron and dilute phosphoric acid; and possibly the cheap salt phosphate of soda might be found to answer in the place of phosphoric acid. Now, adopting the plan of porous cells described, and using thin iron plates, all the cells may be packed with the magnetic oxide and the liquid supplied; and then all would be ready for the application of the dynamo to store up energy. Or, instead of this oxide, we might supply every alternate cell with the protoxide of iron, and the other alternate cells with the sesquioxide of iron, and then the liquid being added, the battery would at once be ready for doing work. But in the latter method the weight of each of the oxides should be proportioned, so as to form the magnetic oxide, and nothing over, making all capable of being effective. By this plan of battery it will be evident that every surface of the cells will have opposite to it another surface, having opposite polarity; the extreme ends of course excepted.

I hope some of our readers, who may have handy all the materials and accessories required, will try the experiment, and report the result to the English Mechanic, or point out any inconsistency in the chemical and electrical reasonings which I have put forward, and thus help us on the road to success, which, as we know, is often the results of our mistakes.

J. H. Huxley.

IMPROVED BICHROMATE BATTERY.

[20240.]—The following is the description of an improved bichromate battery which I have designed, with a view to producing constancy, compactness, and cheapness. It consists, as is shown in the annexed sketch, of a containing vessel of a construction which I will now describe. Take about 15in. of glazed earthenware drain-pipe, say, 5in. outside diameter, and fit one end of it with a water-tight stopper, having a 1½in. hole in the centre. This may be of wood, turned to fit, and afterwards made water-tight by pouring some melted pitch round the edge. The 1½in. hole should have a small conical nozzle fixed in, as shown, with a very small orifice at the base, capable of letting



out about one pint per minute of any liquid that is placed in the vessel. The plates of the battery are carbon and amalgamated zinc. To fill the battery, first place a small piece of round wire gauze over the conical nozzle inside the battery, then lightly lay a thin layer of pine sawdust about ¼in. thick; this being done, place a plate of carbon on it, having a guttapercha covered wire attached to it, then cover with another thin layer of sawdust. On this lay a plate of zinc, also having a guttapercha wire attached to it. Then another layer of sawdust, and so on, until the requisite number of plates are deposited in the battery jar. The wires should all be brought up to the top of the vessel over the mouth to two binding-screws; the carbon wires to one, and the zinc wires to the other. In the sketch this arrangement is shown differently, thus making the meaning clearer to the readers of this article. The vessel should be placed on a stool, having a round tube in the centre, through which place the nozzle, and any suitable vessel should be placed under it, in order to catch any liquid flowing from the battery. To charge the battery, saturate bichromate of potash to the proportion of 2oz. to one pint of water, and fill the jar with it to about 1in. of the top; then add 1oz. of concentrated sulphuric acid to every pint of the solution, and add more acid as the work of the battery is being carried on.

The action of the battery is as follows:—The solution filters down to the bottom through the sawdust, and out of the nozzle into the vessel beneath; that being full it is quickly removed and another substituted, the contents of the first being poured back into the battery-jar. To stop the action of the battery, let all the liquid run out without replacing it. The object of this battery is to produce a circulation of the solution, thus preventing gas congregating round the different poles and stopping its action. The shape of the battery plates is immaterial so long as they are of good stuff. The wires from them should be carefully examined, to see there is no inlet to the acid, and all holes or parts exposed should be painted over with sealing-wax varnish. The explanation of the sketch is as follows:—A, is the containing vessel; B, the battery solution; C, the wires on this side are connected to the zinc plates, shown white; D, the wires on this side are connected to the carbon plates, shown black; E, is the nozzle; F and G are the binding-screws placed on the stool for the sake of compactness.

Beetle Crushers.

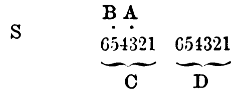
TO "ORDERIC VITAL," MR. BELL, AND MR. BRASHEAR.

[20211.]—IN answer to "Orderic Vital" (20138), I have purposely tried again a round hole of about the same area as the triangular hole—*i.e.*, giving about the same amount of light, and I can perceive no difference in the shadings from the same speculum. "O. V." will easily perceive that since a round hole is not a point, the shutter must touch some part of it first, and this is but true of a triangular hole. When we have only small holes to deal with, and not mathematical points, it is little matter what shape the hole is, so that it has some pretension to arranging its light symmetrically round its centre. "Prismatique," who, like myself, looks at the subject from a practical point of view, is correct when he says (20188) "my judgment leads me to suppose the shape of the point is not so important in zone testing as it is in testing from the centre of curvature with an eyepiece. The extreme smallness of the hole, I should say, is what is required in the shadow test, as there is no magnification of the objective itself in the usual sense." I use a round hole in my experiments upon flexure; but, in the measurement of the foci of the zones, it is the point where the rays from opposite sides of the zones cross we want to ascertain, and if the hole, whatever its shape (in reason), is practically a point to the unaided eye, this is all we want; beyond this our unaided vision cannot go. It is different where we magnify the hole with an eyepiece. In answer to "O. V.'s" last paragraph, I am happy to say that Mr. Calver has very generously lent me a beautiful short focus, 12in. speculum, as being, on account of its short focus, a very good test for the rule. I can safely say it is one of the very best I ever saw, most regular in its curve, and good up to the very edge; its curve he considered exactly right, as proved by actual observation. I most carefully tested it over and over again, and it answered most admirably to the rule of dividing the square of the semi-diameter of the middle of the zones by double the focus for parallel rays. This, with the results of "O. V.'s" trouble and labour, has quite confirmed me in the belief that the rule is correct as far as we want it, and it is pleasing to thus see theory and practice agreeing: this should always be the case, and of course will be where they are both right. I should like further to say that Mr. Calver's kindness has led him to offer me the use of some other specula if I require them.

In answer to Mr. Brashear (10156, p. 328), I can say that I am glad that our American cousins are taking an interest in our subject; by the way, I have some real American cousins, a county over there being, I am told, named after one of them, "Wassell County," so I hope a friendly feeling will ever exist between us, and that our columns may ever be the medium of a national exchange of thought, and that if our American cousins improve (as they generally do) on us, they will let us have the benefit of their improvements through our columns at an early date. No doubt the measuring of the zone's foci, as a test for the parabola, has occurred to many; but no one seems to have reduced it to practice with anything like success or certainty, and then made it known. This is what I have aimed at, and so far have succeeded; and the more I examine the subject in the light of all the correspondence that is now going on, the more I am convinced of its importance and thoroughly practical and reliable character. Now, as to the diffraction-rings Mr. Brashear refers to, I find no practical inconvenience from them; they do not extend one-tenth over the area of the zone, so we have nine-tenths of the area of the zone to judge from, and this is enough; in fact, I cannot understand how any difficulty in the testing can have arisen from this cause, except Mr. B. attempted to use too narrow zones: but I have before been careful to explain that every speculum ought to be divided into six zones, thus I divide a 12in. into 1in. wide zones, a 6in. into ½in. wide zones, and so on for all sizes; with these zones the diffraction-rings do not interfere with the shadings. The suggestion of "O. V." and Mr. Brashear to take the "exact focus of the central zone and the outside zone, then if the amount of longitudinal aberration is correct, and the curve is regular from centre to edge, no diaphragms need be used." Now, the practical objection to this plan is the difficulty of taking the exact focus of the very centre rays on account of their small angle; and then here is the advantage of taking all the foci of the zones: we extend our measurements over a large area and a large number of measurements, and we can see if the proportion is regular. Thus, if we find Nos. 1, 2, 3, and 4 zones shorting regularly, and then find No. 5 zone not so short as it should be, as compared with No. 1 and the others, then we may suspect that we have made some mistake, or that there is a mound about where No. 5 zone comes; we examine the whole aperture without stops, and do not see a mound; we shall re-measure, and find out how we have made the mistake. Thus, the outer zones become a check on any mistake of our measurement of the centre zones; but such a mistake could only occur to an amateur of little or no experience, or by an accidental shifting of the measuring apparatus. Now, by testing 2-100ths on each side of the supposed centre zone focus (as I have explained before), and, seeing if the shadings are alike, we can get even the centre zone focus to the 1-200th inch, and this is near enough for anything. But, as I have already explained, whatever mistake we make in the measurement of the zones, the actual error on a celestial object is only ¼ of this mistake. This is very fortunate.

A correspondent of mine has worked out the formula given in letter 20183, and he says, "I have worked it out for your supposed 6in. mirror. Your value (*i.e.*, by the rule I use) is ·063, and by it (the formula) ·0621, which looks as if you were somewhere about the mark." In other words, the rule seems to be an approximation to the 1000th inch, which is near enough.

Now, as to Dr. Hastings' letter, which "O. V." and Mr. Brashear have kindly got for us (see 20184, p. 357). First, he says, "Thus we see that the mathematical optician is right" (2nd col., 20 lines from bottom). From this I understand that the rule "O. V.," from mathematical reasoning, and I from practical experiments, believe to be correct, is correct in Dr. H.'s opinion; therefore a speculum that does not conform to it is not perfect as to its correction for aberration. But now follows the difficulty in Dr. H.'s mind as to the practical carrying out of this form of testing. He says, "But it should not be overlooked that by no purely experimental method can one find the point C." My answer is: We do not depend on finding the point C exactly, or at all, for, practically, whether we test from the point C or a little before or a little behind it, there is no perceptible difference in the ratio of the zones' foci as given by the rule, so that we need not trouble ourselves about the point C to an inch or two, and surely any amateur can put the edge of the shutter opposite the hole in the chimney to an inch or two; for the shutter being an inch from the point C makes no difference in the ratio. I am quite sure, for I have tested hundreds (perhaps thousands) of times without ever being careful to an inch in having the shutter-edge opposite the hole, and I have never detected any difference in the ratio of the zones' foci, whenever I have put the shutter-edge within these limits, and I am sure I should have detected any difference had there been any perceptible. Therefore, as we do not depend on finding the point C to commence measuring from, the deduction of "O. V." has no application to this mode of testing. He says, "Unless the place of the radiant point can be unerringly decided upon, this method of paraboisation is totally useless, for a very slight change in position may give either double or quadruple aberration" (3rd column, 17th line from top). Now I will go down the cellar (literally), and put all this to the test of fact on a 12in. speculum, and let all our amateurs know the result when I come back.—Well, I have come up from the cellar, and can now reassure our amateur friends that they need not be afraid that this beautifully simple way of testing by the zones' foci has suffered under the most severe testing, which I will now describe by the aid of a diagram, which will help to show our kind mathematical friends what is the question we have asked them to help us to decide. Let S be the speculum and A the radiant point, i.e., the hole in the chimney; now let 1, 2, 3, 4, 5, 6 C represent the respective foci of the zones No. 1, 2, 3, 4, 5, 6, into which our speculum is divided; now the foci 1, 2, 3, 4, 5 C, have each a certain distance from 6 C, which the rule gives us. I find the most convenient way of measuring this is to set the index to the distance obtained by the rule for the focus of the zone No. 1; we then, by the adjusting-screw set the edge of the shutter to the focus of zone No. 1; therefore, O on the scale ought to be the focus of the centre of the speculum for the radiant point, if the speculum is parabolical.



Now, this is the way we find the point where the focus of the centre of the speculum is, and where we have to start from for our measurements; We have now only to find the foci of No. 2, 3, 4, and 5 zones by the measuring screw, and we see at once if they correspond with the calculated distances, and, consequently, have the proper ratio among themselves. If they have, then our speculum is perfect as to the correction for aberration. Now, if by moving A to B, so as to throw the zones' foci to D, the ratio between the foci of the zones is perceptibly altered; then we must be very careful to have the shutter exactly opposite the hole—i.e., at the same distance from the speculum. Now, "O. V." and Dr. Hastings seem to think that a very minute deviation from equality in distance from the speculum between the radiant point A and the shutter, will make all the difference between the rule where double the focus is the divisor, and the rule where four times the focus is the divisor. If this be so, then this test is almost useless and unreliable. Well, now I will tell them the facts of the case, as I have just proved down the cellar. I took a 12in. speculum whose figure and ratio of zones' foci I was well acquainted with. I set the testing apparatus so that the shutter should be exactly the same distance from the speculum as the hole. I carefully measured the zones' foci, and found them to be exactly the same as when I had many times before measured them, with the shutter at a more convenient distance from the speculum—i.e., about opposite the middle of the chimney, say about 1in. from the hole further from the speculum (for I have never been particular to ½in., and I shall be less particular in the future, for an inch or two makes no perceptible difference). I have no doubt a slight difference is made in the ratio, by thus moving the shutter and radiant point an inch or so; but it is, perhaps, only 1,000,000in., which I do not think we need attempt to measure. But I thought I would put the test to a severer test, as to its utility, and reliability, and certainty, so I put the shutter 3in. from the hole further back. I measured the foci of the zones, and found no perceptible difference in their ratio, and this is the point in dispute as affecting the reliability of the test. This experiment made me rejoice for the amateur's sake, for I could now tell him if he only put the shutter within 3in. of the hole, he could use the rule with confidence, as being practically perfect, and need not spend twelve months of his time in studying the mere shadow test, and then be only able to guess somewhere near the parabola. But to make certainty doubly certain, I thought I would put the shutter double 3in. away, so I put it by guess, as I felt confidence in the rule holding good at that distance. I measured the zones' foci, and found no perceptible difference in their ratio. I measured the distance between the shutter and hole, and found it to be 7in. So, now all I can say to the amateur is that, if he cannot adjust his shutter to within a few inches of the radiant point (the hole), he has no business to attempt speculum making; it will not suit his capacity. What I should advise every amateur is to put the shutter about opposite to the middle of the chimney, or a little further away for convenience sake, and he need not fear the results being practically altered from the exact truth. I thus have, at the earnest request of "O. V.," looked into this subject, and feel that he and Dr. Hastings have not exactly comprehended what we practical amateurs asked of them to decide for us by mathematics; they have been to a great deal of trouble to oblige us, and I am thankful to have their help; they have proved the rule to hold good when the shutter is exactly at the same distance from the speculum as the radiant point. I have proved experimentally that the rule holds good to all practical ends when the shutter, for convenience sake, is a few inches further from the speculum than the radiant point; therefore, we need not be anxious where we place the shutter within reason. I will try to show this in another way: suppose we have a 12in. parabolical speculum of very short focus—i.e., where the aberration is a great deal, say, ·195, which was the case with one speculum I had to test. Now it is evident that to obliterate this aberration, which it has at double its focus (i.e., the so-called centre of curvature), we must remove the radiant point to such a distance that the rays will be practically parallel, which will, according to our supposition of having a parabolical speculum, cause the rays from all the zones to meet in a point; say this distance is 5,000 yards. Now, it takes the moving of the radiant point 5,000 yards to obliterate ·195 of aberration. How little, then, must the movement of the radiant point or shutter a few inches alter the aberration if 5,000 yards are required to obliterate the aberration of about 2-10in. The same reasoning applies whether we move the shutter or the radiant point, for they are related to one another.

I am much obliged to "O. V.," Mr. Brashear, and Dr. Hastings, and all others who have, I think, with much trouble, proved the rule. The thanks of all amateurs are due to them for their contributions. To Mr. Calver, also, our thanks are due by lending me so perfect a speculum to test the rule by. I may add that every speculum of his I have examined has its edge good. He has certainly mastered this difficulty, and need not make his specula ½in. larger than ordered, with the understanding that the edge is bad, and must be stopped off.

Again, it does not do to depend on the "rolling back" of the edge to make up for the under-correction of the other part of the speculum, and thus work to a rule that undercorrects; a "rolling back" edge is worse than useless with a high power and a small object (a star); it is confusing to the image. A speculum to be good must be good to the edge and regular in its curve from edge to centre. A speculum to be perfect must have all this, and its zones' foci corresponding to the ratio given by the rule—divide the square of the semi-diameter by double the focal length of the speculum for parallel rays. **H. A. Wassell.**

Addenbrook Villa, Love-lane, Stourbridge.

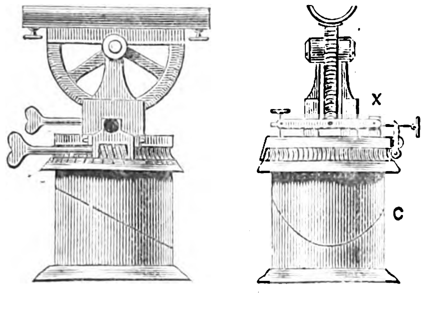
ABERRATION OF A MIRROR—COMBINATION ALTAZIMUTH AND EQUATOREAL — CROWN GLASS ACHROMATISM — TRANSIT OF VENUS: A SUGGESTION.

[20242.]—THE formula for computing specular aberration, obtained by "W. H. G.," is in agreement with my result. I do not see the necessity for using a large and small p in the equation. Is it a misprint? The final result is better expressed in the form of two fractions than by one. We then have.—

$$m = \frac{y^2}{p} + \frac{y^4}{2p^3} = \frac{y^2}{2f} + \frac{y^4}{16f^3}.$$

The first quantity is the same formula as used by Mr. Wassell—viz., the square of the semi-aperture divided by twice the focus, and, consequently four times the focal error. The second term is the square of the first divided by $4f$, and is therefore too small to be of any practical use. Hence the central parabolic aberration is shown quite near enough by the first term.

Mr. Grubb's mounting, described by "More Light," is identical in principle with "Smeaton's Block"; but we should not be justified in concluding that because he has made a stand of this kind he claims to be the inventor of the principle. When looking over "Rees' Cyclopædia," I was struck with the usefulness and simplicity of "Smeaton's Block," and made a rough sketch of it. I send a reproduction, so that in case Mr. Godfrey has not also done the same, it may be used. The stand is certainly superior in stability and compactness to the one figured by "More Light." Scarcely any description is needed. The short cylindrical block C is split in the manner of "More Light's" diagram; and the upper half may be swung round on the lower till the vertical axis is brought into the position of the polar axis. This upper half carried the divided circle and tangent-wheel, upon which rests the foundation-plate of the vertical circle standards. The horizontal tangent-screw is clamped by a set-screw pressing against the block X. This block also forms the fulcrum of a frame carrying the vertical tangent-screw. This screw is clamped by a set-screw pressing on the foundation-plate.



Smeaton's principle may be applied to the ordinary altazimuth-stand at very little cost; and, considering the usefulness of the combination, it is a wonder that it is not more commonly used.

As one of those who has read, with considerable interest, Mr. Penny's original theories, I regret to see the sentence with which he concludes his second paper. I presume the "other plan mentioned in No. 1," refers to his method of uniting coloured rays by two lenses of the same material. An *object-glass* producing achromatism (so called) by parallelism of the coloured rays is, I think, almost useless in comparison with the ordinary form. The perfection of an o.g. depends on the precision with which all the rays are united. If Mr. Penny thinks the action of crown and flint can be successfully imitated by *one* kind of glass only, why does he not give a combination by which the truth of the theory may be tested?

May I be allowed to offer a suggestion, which, at this period, may not be considered inappropriate? As months roll on, the time for the transit of Venus will arrive; and in the beginning of next year we hope to read full details from those who dwell where it will be well seen. Would "our" able and courteous "F.R.A.S." object to write one or two articles describing the different methods of obtaining the solar parallax, what parts of the area of visibility are specially adapted for each, and any other matters incidental to the coming Transit. Such information, in the lucid style inseparable from "F.R.A.S.," would enable anyone to read published accounts intelligently.

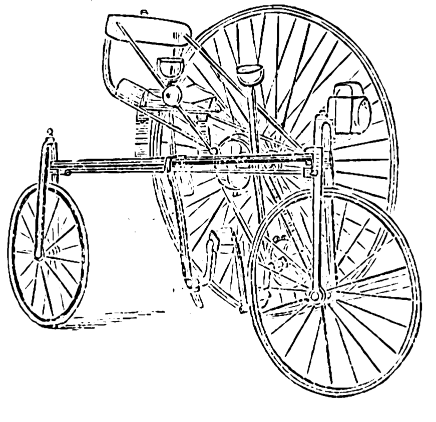
EDGING FLATS.

[20243.]—As the subject of edging flats has frequently been started in our journal, perhaps I may be allowed to describe my own method which, though perhaps not new, is original so far as I am concerned. I first turn in the lathe a piece of wood, 6in. or 8in. long, and 1¼in., or whatever the minor axis is desired; cut this at an angle of 45°; about the middle, fix a suitable piece of glass with pitch or other cement between the two parts of wood, then grind glass down to wood all round; this gives the outline of glass accurately, also angles at ends as well as preserving edge from nippling. I grind on an ordinary grindstone.

Cotswold.

COVENTRY TRICYCLE, WITH WESTROPP SEAT.

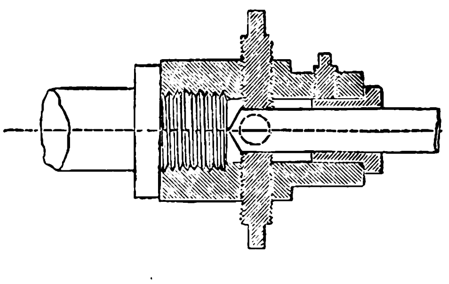
[20244.]—I INCLOSE photo. of Coventry rotary, with seat "*à la* Westropp." It will explain itself; but one thing must be borne in mind—viz., that it is *essential* to keep the webbing strained, so that *full* power may be obtained over the treadles; therefore, I have a ratchet on the right-hand side of the seat to tighten it up when stretched.



Cheltenham, June 30th. **M. Jeffrey.**

SIMPLE DRILL CHUCK.

[20245.]—I FORWARD drawing of a simple drill-chuck in which drills can be regulated to a nicety by the four set-screws at the back. The drawing shows the shank of drill and thimble parallel; but it is better to taper the shank, or cone the inside of thimble to allow freedom of action. Where the drills are the same diameter, the thimble may be dispensed with. Perhaps one or more of your correspondents would help me, through your columns, to true the rim of a tricycle, which is every way (not the circle) through an upset, bent sideways.

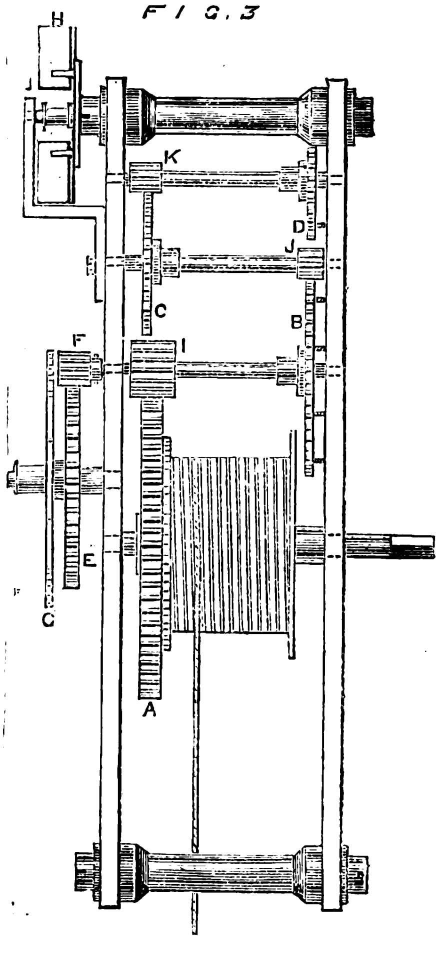


C. Townley.

CHIME-CLOCK MAKING.—III.

[20246.]—THE barrels being finished, the main wheels may now be fitted on. They should fit the arbor well, but not too tight to prevent them turning freely. They are secured in their place by a key; the way shown in Fig. 3 is the usual one. A square-bottomed groove, the thickness of the key, is turned in the arbor, one side of it being flush with the main wheel. The key Fig. 4 is then fitted to it, and secured by a screw tapped into the wheel. The second plan is to fit a brass collet over the arbor, press it close up to the wheel and drill a pin-hole right through collet and arbor, and fit a pin in tightly. The clicks and springs for winding must now be made, and fitted to the wheels. Having completed this, the barrels are ready to be placed in the frames. Drill out the barrel holes a trifle smaller than the pivots, and carefully broach them out to fit. In broaching out pivot-holes, it is necessary to insure a good bearing hole that the two holes should be parallel with one another. The broach should therefore be tested by placing a square on the clock frame, when it will be seen whether it is square or not, and a little side-pressure applied while turning the broach in the hole will bring it right. In all good work the pivots are fitted tightly by the

FIG. 3



cutting broach, and afterwards freed by a round broach, which burnishes the hole, and insures it being perfectly round. The round broach should be kept well polished, and a little oil used with it. I have omitted to mention that the going-barrel must have the going or maintaining power ratchet fitted between the barrel ratchet and the main wheel. It should have about 160 or 180 teeth, and the teeth must be turned the opposite way to those in the barrel ratchet. See Fig. 1.

Fig. 3 will show the arrangement of the hour-striking train, and I will, in my future papers, give drawings of the going and chiming train; but for this week we will confine ourselves to Fig. 3. The barrel and its wheel have already been described. The pinion 1 has twelve leaves, and is driven by the main wheel A of 144. Its back pivot projects through the frame to carry the brass pinion F, which drives the locking-plate E. The pin wheel B of 80 is attached to the arbor by a brass collet soldered on, to which the wheel is riveted. Eight pins are put round the web of the wheel at equal distances from each other to lift the hour-hammer. The pin wheel drives the pinion J with 10 leaves, upon whose arbor the pallet locking-wheel C of 72 teeth is fixed. It will thus be seen that the wheel C makes one revolution for every blow of the hammer. The pinion K, with 8 leaves, is driven by C, and the warning-wheel D is attached to its arbor. The warning-wheel, in its turn, drives the fly pinion, the front pivot of which runs in the frame as usual; but the back pivot is run in the cock L to allow of a longer fly being used than could be got in any other way.

Having thus briefly explained this train, we come to the pinions. These are made out of ordinary pinion wire. They are sized from the wheels by the sector. Having obtained the wire the correct size, we will commence with the first pinion of twelve; cut off a piece of wire long enough to make the pinion; turn or file off the leaves, except just where the head of pinion is wanted; set the pinion perfectly true, and turn the arbor true; the pivots should also be turned down a little larger than they will be when finished. Face up the sides of the pinion perfectly flat, and smooth them up with a fine file. The leaves of the pinion next require smoothing up with a rounding-off file, and the bottoms of the spaces squared out. You need do no more than just clean the drawplate marks out. Next smear the pinion head over with common soap, to prevent scaling; heat it in a clear fire to a bright red, and plunge it in clear water that has just had the chill taken off it; harden head arbor and pivots; do not make it too hot and get head arbor and pivots evenly heated before you harden; temper by flaring over a gas-flame. The correct temper is known by the oil on the pinion taking fire, and remaining alight after being withdrawn from the flame. Blow the oil flame out, and allow the pinion to cool: a smooth file should now just cut it. The pinion will now probably be considerably out of truth. To set it true, mark the high side with a piece of chalk; lay it on a smooth stake, and pene the side opposite to the chalk-mark with a light peneing hammer; use the hammer gently, giving the pinion a few light blows, and then trying it in the lathe again. If still out of truth, continue the peneing until the pinion runs true. To polish the head, cut a piece of soft wood to fit the spaces, and use flour-emery mixed into a paste with oil to polish with.

W. Baldwin.

110, Richmond-road, Dalston.

THE TURKISH OR HOT-AIR AND VAPOUR BATH, AND THE SCIENTIFIC PRINCIPLES ON WHICH IT SHOULD BE CONSTRUCTED.

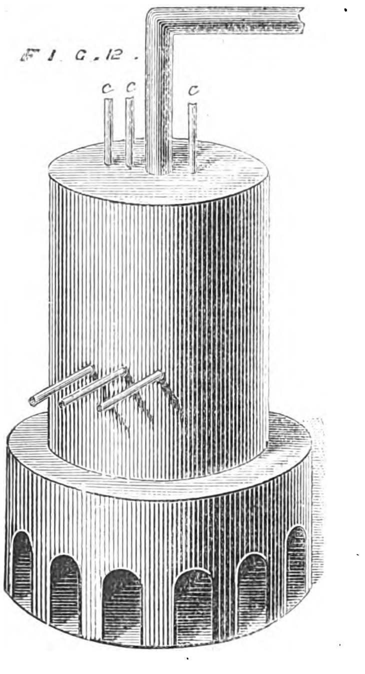
(*Continued from p.* 379.)

[20247.]—HAVING now satisfied myself that I had mastered the principles of the hot-air bath, I decided on converting a recess at the side of the chimney, and the portion of the room adjoining, into a chamber for either hot air or vapour.

I extended it into the room by a wooden partition, which had a small window fitted to its door to give light (a reference to Fig. 3 will make this plain). My bathroom was thus 7ft. 3in. long, 4ft. 6in. across, and 10ft. high. The furnace was at the corner near the door, marked F; in the opposite corner was a shower-bath S, and there was room to place a sitz-bath when wanted. There was a small table, with basin and other conveniences for washing, and a comfortable cane-chair that I brought home with me from Bombay; it pulled out, and made into a comfortable couch, and it was a luxury to sit in it. I used this chamber as my daily washing-room; but it was of an evening always ready to receive a bather; and the children soon got to enjoy and look for their vapour-bath. I had an iron gas-pipe passed across the table, with two T-pieces and nipples, so that by an indiarubber tube I could have a light if I used it after dark; or light a small gas-stove, and get warm water readily for shower or sitz-bath; a tap, leading from the large cistern of water on the roof, supplying cold water ad libitum, as a pipe from it led into the dressing-room in that corner.

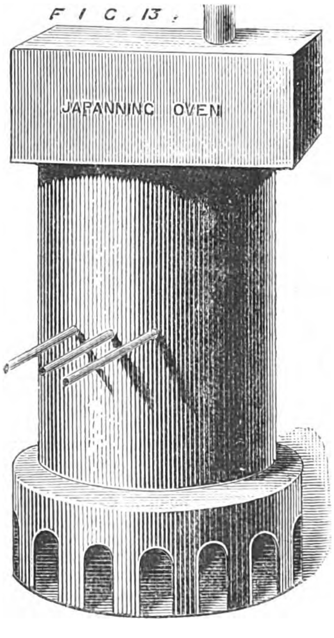
To show the arrangement complete, I give an elevation of it in Fig. 12. I found it to answer well, and used it while I remained in England. The alteration I made in the burners of the gas-stove obliged me to raise the chambers, and add another one on which the two upper ones stood, and inside which was placed the gas-stove. This cylinder was about 9in. high, and at its base it was cut into a number of arches, through which the air in the apartment was drawn into the outer chamber and thence discharged through the stove-pipe into the chimney. By this arrangement the lowest, and consequently the coolest, stratum of air was constantly removed, and thus the temperature could be made equable, and as high or low as the bather chose. By use of a damper in the stove-pipe, which was of considerable length, as it first passed up to the ceiling, and by an elbow along the upper corner of the wall, through the wall, which was the side of the recess into the chimney, the draught could be regulated, its great length gave it great power. It might very well be called the foul-air extractor.

FIG. 12.



I utilised this for many purposes besides bathing. A very slight flame gave me a dry air for drying chemical precipitates; by placing a large tin canister with a hole in its cover, and its bottom to fit the stove-pipe, I made a drying-closet, which answered fairly for chemical purposes. It was also admirable for drying any small article varnished. It was a japanning closet, as illustrated in Fig. 13.

FIG. 13.



The bath-room and apparatus I have described answered well; and as the stove was easily moved from under the arched cylinder, I could give a vapour-bath by simply placing a saucepan over a three-legged support, under which was placed the gas-stove. The air from its combustion mixed with the steam, and soon added to the heat of the bath-room.

To create a ventilating current, I placed a simple single flame Bunsen burner in the hot-air apparatus, and it caused sufficient draught through the outer chamber and the stove-pipe to thoroughly ventilate it. Cold air to any extent came in through the inner chamber, according as the connection with the air outside was open or closed.

For most purposes the apparatus was very effective. After a while, it caused the seams of the wooden partition to open. I fell back on my floor-cloth. An old one, which was becoming shabby, was used to line the whole of the woodwork. As, after a vapour-bath, it remained moist, I prohibited vapour-baths till the lining was as dry as a bone. I then gave it a coating of linseed oil, prepared in the same way as sailors do to make oilskin coats for themselves, and with this I painted it over very carefully, laying it on evenly, and allowing no drip. Three coats of this were followed by a coat of white zinc paint, which, when thoroughly dried, received a final coating of coachmaker's varnish—which, after a vapour-bath, could be rubbed over by a sponge, and the condensed moisture removed.

The whole arrangement did not cost £5, and was quite as good and efficient as the expensive contrivances which a professed gas engineer or a builder would have charged from £30 to almost any amount, according to details and finish.

I will now briefly recapitulate the essentials.

1. You must have a perfectly air-tight apartment of moderate size, not a small box not much bigger than a coffin.

2. You must have an efficient heating apparatus under your own control, so arranged that the heated air comes from outside, and is, therefore, pure.

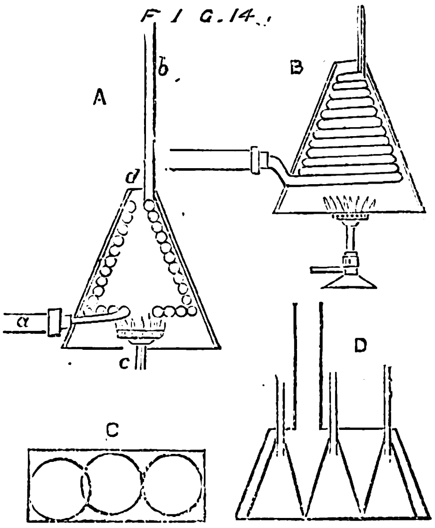
3. You must have an escape for the impure air and products of combustion; and not merely an escape; you must have it in your power to create a draught to carry it off.

4. You must have the means of lowering the temperature, so that you need not leave your bath in a sweat. If you do so you will catch cold

5. The room adjoining your bath proper should be comfortably furnished, and free from draughts, and you should be able to regulate its temperature.

Circumstances obliged me to go abroad to a place where gas was not procurable, so I left my apparatus at home with a relation who was good enough to give it house room. My landlord made me take out the tubes from the walls and remove all the things I had added, and place the room in the state it was in when I entered the house. A bricklayer and plasterer soon did this, and I myself repaired the paper and paint. A year or eighteen months after this my friend got into bad health, and wrote to ask what he was to do with the apparatus. I desired him to do what he liked with it, as it was not worth paying rent for, and if left in damp might deteriorate. He had visiting him a friend, the captain of a large ship trading to America, who had a look at the apparatus and took in its use at once, and said, "If you will give it to me I'll take it to my brother in America. I think it will just suit him; he is just the fellow to appreciate a dodge like that. So to America it went about the year 1870, and was found useful.

FIG. 14.



My friend, his friend, and brother have gone the way of all flesh, but what has become of my apparatus I know not. It was a rough and ready adaptation of odds and ends, picked up chiefly at an old iron store for a scientific purpose. Its actual cost was but little, but it involved a good deal of labour, but that no enthusiastic amateur mechanic grudges.

If its resuscitation proves of use to the fair Isabelle Stuart I shall be pleased.

Should I make another vapour-bath, I would do it as follows:—I would get some ½in. wrought-iron gas-pipe made into a cone, 6in. at base, and 8in. high, as shown in Fig. 14; A, section; B, elevation. This cone I would inclose in a conical iron box, with a hole top and bottom; three of these cones I would arrange as in 14 C; each should be connected with an inch gas-pipe, leading to the outside of the house. The lower four coils, as may be seen by the sectional drawing, are placed on the same level. These I propose heating with a rose gas-burner of Griffin's pattern; the fresh air goes in at *a*, the heated pure air passes out at *b*; the impure air passes through the flame at *c*, and escapes with the products of combustion at *d*. In this instance I would make the outer chamber an angular box, to contain the three coils, and would use one, two, or three as I found advisable; each hole for the gas-burner should have a sliding cover, to be slipped on when its burner was not in use. Of course, a simple arrangement of this sort might be made—in which case no rectangular case would be required—the pipe *b* would have to be led out on one side, and the cone should terminate in a small stove-pipe. The reason for inclosing the three in a case is to make one stove-pipe sufficient. It strikes me that this would be a very simple form of hot-air bath. Of course, the other arrangements as to the room would remain the same.

Although this is specially a paper of the vapour and hot-air bath put together as a reply to "Delta," 46899, and Isabelle Stuart, 47050, I have had the matter on my mind for some time, and on looking through some old papers, I came on my sketches and memoranda of my early attempts. At times it has run through my mind that I might add to my limited income by developing these ideas into an apparatus which I might patent; but I abandoned that idea, as I felt that the forms of apparatus which could be constructed were countless, and that *scientific principles could not be patented*—that they were the property of all educated minds that could understand and appreciate them; and, moreover, any attempt to do so by the amateur would be a failure, as if there were a demand for such apparatus the practical mechanic could soon devise modifications which might be better or cheaper, or of more elegant form, and drive the amateur patentee out of the market. Patents, when they guarantee to a real inventor a reward for his ingenuity and payment for his labours, are an incitement to invention and an aid to progress; but when they are prostituted to lock up the application of scientific principles, which I hold are the property of all that can apply them, they are a pest and a bar to progress. I, therefore, offer my ideas on these points to the public through your columns, and shall be pleased if they prove useful to any. **Gereb Adml.**

INDICATIVE SYMBOLS.

[20248.]—THERE is a great want of a short mode of expressing certain words or phrases containing a compounded meaning, which are constantly-recurring when writing on many subjects. Chemical science has already, since the time of Berzelius, adopted symbols, such as H, O, C, N, &c., to represent hydrogen, oxygen, carbon, nitrogen, &c.; but the science of mechanics, even now, is almost unprovided with such a short way of expressing ideas. We are constantly writing of yards, feet, inches, pounds, tons, or, just as often, of metres, litres, kilogrammes, grammes, which are French measures. Again, we write of square yards, or feet, or inches, of cubic yards, &c., foot-pounds, foot-tons, square metres, cubic metres, metre-kilogrammes, &c. What I propose to establish is, by common consent and usage, to employ a Roman capital (and small), the initial letter of the measure or idea signified, whenever it may have to be written.

Thus let Y always mean yard, F foot, I inch, P pound, T ton; also let Y^2 represent square yards, Y^3 cubic yards, F^2 square feet, F^3 cubic feet. In like manner, let M, L, G be always written to express metres, litres, and grammes respectively. To the English measures there are subordinates in common use, the ounce and grain, which would be represented by o and g. In the French system there are several commonly used, multiples and sub-multiples of the M, L, G. These would be represented by m, c, x, signifying 1000. 100, 10 times M, L or G respectively, and by $\bar{m}$, $\bar{c}$, $\bar{x}$, signifying 1-1,000, 1-100, 1-10 parts of M, L, or G respectively. Thus m M is 1,000 metres (kilometre), c L 100 litres (hectolitres), x G 10 grammes (decagrammes), $\bar{c}$ M is 1-100 metre (centimetre) $\bar{x}$ L 1-10 litre (decilitre), &c.; the bar above the letter indicating the fractional character. Also Fp Ft would be written for foot-pounds, foot-tons, and Mk for metre kilogrammes, &c. As the French often use kilometre, kilolitre, and kilogramme, it may be useful to write Km, Kl, Kg, which are equivalent to mM, mL, mG.

When writing on electric subjects, Eu would mean units of electricity, Fu units of electromotive force, Ru units of resistance, Qu units of quantity; O would stand for ohm, and V for volt. Thus we obtain a series of symbols, Y, F. I (or i) P, T, Y^2, Y^3, F^2, F^3, M, L, G, O, g, M^2, M^3. and their multiples or submultiples m, c, x. $\bar{m}$, $\bar{c}$, $\bar{x}$. Eu, Fu, Ru, Qu, which, if commonly used, would considerably shorten long phrases or words now necessary.

There is another mode of employing Roman capitals which, in calculations, has saved me the writing of many figures or ciphers, and which I recommend for general use on account of the convenience. It is, wherever decimals occur containing many ciphers, or when it is desirable to write in a line without fractions, to employ Roman numerals to represent the decimal ciphers; also when integers are combined with many ciphers, thereby becoming thousands, millions, &c., to adopt the same plan. When the numerals are written plain they mean so many integral ciphers added; when they are written with the bar over them, they mean so many decimal places. Thus:—

200.000 would be written 2V

$\frac{1}{200,000}$,, ,, $2\overline{\mathrm{V}}$, or $\frac{2}{\mathrm{V}}$

·0001573 ,, ,, $4573\overline{\mathrm{VII}}$, or $\frac{4573}{\mathrm{VII}}$

11·721 could be written $11721\overline{\mathrm{III}}$, or

$\frac{11721}{\mathrm{III}}$ if required

95,000,000,000 could be written 95IX.

$$\frac{\cdot007 \times \cdot0143 \times \cdot000081}{\cdot0000063} = \frac{7\overline{\mathrm{III}} . 143\overline{\mathrm{IV}} . 81\overline{\mathrm{VI}}}{63\overline{\mathrm{VII}}} \text{ or}$$

$$\frac{7 . 143 . 81\overline{\mathrm{VI}}}{63} \text{ or } \frac{7 . 143 . 81}{63\mathrm{VI}}$$

In the last illustration the numerals below the bar being deducted from those above, show the number of ciphers (integral) to be placed below, instead of dealing with so many decimals separately; if they be barred above the bar of the fraction, they become integral below it, and *vice versâ*. Again, employing the numerals in electric diction, we can write, instead of a volt being 100,000,000 units of electromotive force, 1 volt = Fu VIII., 1 megavolt = Fu XIV., 1 microvolt = Fu II. In like manner, 1 ohm = Ru VIII., 1 megohm = Ru XIV., 1 microhm = Ru II.; a method which certainly avoids the writing of very many ciphers. The multiple *mega*, and submultiple *micro*, may be also applied conveniently thus: 1 megavolt = mmV., 1 microvolt = $\bar{m}\bar{m}$V., 1 megohm = mmO, 1 microhm = $\bar{m}\bar{m}$O. I think the above proposals deserve consideration among scientific writers; they cannot be called confusing.

I cannot recommend the use of the Greek numerals, though they are precise. They are very little known, or employed, except in algebra or astronomy. The first nine would suffice for the purpose herein suggested, adding a tenth to represent 6, which is absent in Greek numerals, but may be signified by ξ, which is truly 60. Then the Greek letters—

α	β	γ	δ	ε	(ξ)	ζ	η	θ	ι
1	2	3	4	5	(6)	7	8	9	10

would represent ciphers respectively, integral if plain, decimal if barred above; if they were barred below, as in Greek, they would represent 1,000 times more. But it is very doubtful whether, supposing that 200,000 were written 2ε, it would convey the idea so clearly as 2V., the Roman characters being so well known and accepted. So also ·0000495, written $495\bar{\xi}$, instead of $495\overline{\mathrm{VII}}$., would not be clearly apprehended for want of familiarity. If, electively, they came into use for the purpose herein suggested, they would serve as well as, or better, than the Roman letters.

M. Jonson.

WEATHER FORECASTS.

[20249.]—IN your issue of June 30th "A Fellow of the Royal Astronomical Society" says, on p. 377, letter 20212, "That no one living can foretell the weather in these islands 48 hours in advance, and no vaticination of meteorological change for that, or any longer period, is worth the ink it is written with."

Now, for the last two years Captain Newton has published his monthly weather forecasts in the *Newcastle Chronicle*, 90 per cent. of which have proved to be absolutely correct. He affirms that he has discovered the causes which regulate the winds and weather; that they are as invariable as those which regulate the tides, and that with proper appliances at his disposal he can correctly forecast the weather, the world over, for years in advance.

Indeed, in the North of England, "Captain Newton's Monthly Weather Forecasts" are acknowledged by all who read them, to be of the most accurate and reliable nature, and he only needs proper appliances to make a book on forecasts as dependable as a nautical almanack.

J. Mitchell.

MELLAGEN — ALUMINIUM — LEWIS'S INCANDESCENT GAS-LIGHT—SMALL DYNAMO-MACHINES—FREE OIL.

[20250.]—MELLAGEN (query 47136, page 339), is undoubtedly a product of the action of the nascent oxygen evolved in the electrolysis on the carbon forming the anode. It certainly is not connected with atmospheric carbonic acid.

I think "Zelia Naien" almost deserved the snub he received from Mr. Grey (page 361), but as I am much interested in hopeful methods of producing aluminium (query 47143, page 339), I shall be glad if the querist will communicate with me. The majority of those who have endeavoured to produce aluminium economically have lacked the chemical knowledge which would have told them how difficult a problem it was.

I am much interested by Mr. Sprague's description of Lewis's Incandescent Gas-light (page 343), and think it may become very important. I am afraid the novelty of it is not very great, for I saw an almost identical arrangement fully twelve years since. It was patented by a Mr. Hogg, who had an office in Birmingham, and consisted of a Herepath's blowpipe, surmounted with a cylinder of fine platinum wire gauze. The current of air was obtained by employing a small fan, and it was the necessity for having some such arrangement which prevented me at the time from adapting the light to my lantern. The induced air-current of Lewis's arrangement appears to be the novel feature. I am doubtful whether the gas will be found to be very completely burned.

I am one of the many of your readers who would like to possess a hand dynamo-machine, but have neither the time nor mechanical skill to construct for themselves. Why doesn't some apparatus-maker take advantage of Mr. Tolman's or similar instructions, and supply this desideratum at a moderate cost?

"Free Oil" (query 47222, page 364) can be determined in a mixture of oil, rosin, and soap by an application of the following principles. Agitate the stuff with hot water, separate the aqueous liquid, which contains the soap, and weigh the residual oil and rosin. To this mixture add alcohol and a few drops of a solution of phenolphtaleïn, and then drop in caustic soda gradually, with constant agitation, till the production of a permanent pink tint shows the rosin-acids are neutralised; separate the oil from the aqueous liquid, and weigh it. If it be merely required to ascertain the amount of free oil, the preliminary treatment with water may be omitted, and the sample at once shaken with alcohol caustic soda till neutralisation occurs. Rosin oil is distinct from rosin, and will not be separated by the above process; but may be accurately determined by saponifying the sample and agitating the aqueous solution of the resultant soap with ether, which dissolves out the rosin oil. The querist will find full details of all these methods in the 2nd volume of my "Commercial Organic Analysis."

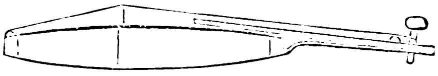
Sheffield, June 30th. **Alfred H. Allen.**

SIMPLE AND CHEAP FIRE DETECTOR.

[20251.]—THE simple and cheap fire detector, described by R. S. Baxter (letter 20143. No. 898), is certainly a very clever device; but he may be interested to know that thermometers can now be bought at a very little extra cost, with a platinum wire fused into the bulb, and another one, which can be drawn up and down to any degree, let into the top. **Seaweed.**

THE BERLINER VIOLIN.

[20252.]—WHILE the correspondence about this invention was carried on in "ours," I intended to describe its results when applied to an ordinary violin. But maintaining, as I have said before, that the violin is acoustically perfect and therefore cannot be improved (excepting the material), I did not think it expedient to interfere. Now, as Mr. Berliner has sent a violin to you, Mr. Editor, for the express purpose of being criticised, and on my application same was handed to me, I have now no reason to withhold my opinion respecting this invention. But, before I point out its results, I must make certain assertions on which my opinions are founded. Wood of a certain quantity and form, if struck or bowed, produces one natural tone only; and to make it of such a size and form as to respond to the vibrations of several octaves would be inconvenient, and would, besides that, be too stiff for the power we have at command. We are, therefore, obliged to use its gravity as tension on a small quantity of wood built up in a form to resist that tension and no more; so that, as "Fiddler" calls it, "action and reaction" can take place. The tension of the strings on an ordinary violin press against the breast with a power of 75, and their deflection is equal to 21½ pounds. Now in the Berliner violin, the tension or pressure on the body or breast is only that which is produced by the deflection of the strings while their tension is on the finger-board; hence, it must be deficient in quantity or intensity of tone. This was proved by a friend of mine, who put a light mute on the bridge of his violin, when by that means, he produced a similar quality of tone to that produced by the Berliner without a mute. He, however, improved it a bit by putting his chin-block or chin-rest in it. Here I crave permission to state, that this gentleman, Mr. James Anderson, of 14, Margaret-street, Cavendish-square, is the inventor of the chin-rest, and as it is now largely used, I thought it proper to give him his due by mentioning the fact. The tension or pressure on the breast of the Berliner violin, is equal all over, which is certainly against acoustical principles. In the ordinary violin, there is an important modification of the tension or pressure on the breast; while the treble portion has to bear the tension as well as the deflection of the strings, in order to enable it to respond to the high notes. The bass portion is supported by the bass bar, which bears a portion of the tension and deflection of the strings, and by that means leaves the breast comparatively slack to respond to the lower notes. On the Berliner violin there is no pull on the back, hence the soundpost is only a support for the breast to prevent it from flapping about. In the ordinary violin each deflection of the string straightens the back of the body a little, and by that means forces the breast up with the soundpost, while at the same time the bridge forces the breast down, so that at each deflection of the strings a wave is formed between the foot of the bridge and the soundpost. The diagram shows this sufficiently; but if any doubt should exist a few strips of wood ½in. wide, ⅛in. thick, glued together with a string on will prove this conclusively. Of course, in the Berliner violin the vibrations of the string will be transmitted to the body from the finger-board on which they are strung; but this is a round-the-corner way and cannot be much. There is also a tension (rarefying) on the breast between the bridge and the neck while that portion below the bridge is without it. I think that this invention put on any violin under any condition must lower its value, whatever that value may be.



J. H. Schucht.

SMALL DYNAMO-MACHINES.

[20253.]—Referring to Mr. Lancaster's reply to query No. 47111, page 360, in which he says that small dynamo-machines are a failure, we beg to state that, although a certain amount of difficulty is involved in designing a small and efficient machine, such a machine has been, and is being made to give satisfaction.

We have, for some time past, advertised in your columns the parts necessary for the construction of a small dynamo-machine, which we also supply fitted up, and which, driven by one man from a flywheel, gives sufficient current to illuminate three or four Swan's ten candle incandescent-lamps, and with two men, or equal power, about double the number.

Mr. Lancaster would not, perhaps, "mislead a single reader of ours" intentionally; but his decided opinion tends to deter amateurs from attempting to construct a small machine, and should not, therefore, we think, be passed without comment. **Patrick and Son.**

15a, White Lion-street, Chelsea, S.W., July 3rd.

THE BARTON ACCIDENT AND THE VACUUM BRAKE.

[20254.]—Upon the 15th of May, a collision occurred at Barton station on the Manchester, Sheffield, and Lincolnshire Railway, between the 8.40 a.m. mixed train from New Holland and the buffer-stops 50 yards beyond the proper stopping place at the platform at Barton.

The train consisted of a tank-engine, fitted with a hand-brake, a van, three carriages, luggage-van, and thirteen waggons (or five more than the regulation load). The front van and all the passenger vehicles were fitted with Smith's vacuum brake.

The driver stated that this brake was in good order when the train started, that he stopped at Barrow Haven, using the vacuum, which worked all right; but that when he tried to apply it approaching Barton, "it did not seem to take any effect on the train; the moment he stopped *blowing*, the indicator on the vacuum dial went back as if the vacuum-pipe was disconnected."

After the train had over-run the platform 50 yards, it came into collision with the buffer-stops.

The driver at once examined his train, and found one vacuum-pipe disconnected between the first and second carriages.

Major Marindin reports that he is inclined to believe the statement of the driver, and the more so because he does not advance it as an excuse, being quite aware that, according to the rules, he had no right to depend upon his vacuum brake for stopping at a terminal station, and stating, as he does, that when he first tried it he had no idea that he would be unable to stop by means of his hand-brake as usual.

Major Marindin also remarks that "If the driver's statement be correct, this case furnishes a strong argument in favour of the automatic action of brakes, for the driver would not have been able to run after the brake-pipe had become disconnected, depending upon a useless machine to stop the train in a case of emergency."

Numerous cases have been referred to in the English Mechanic in which Smith's vacuum brake has failed to act, or been inefficient; and the present instance again shows that it is far safer to have no continuous brake at all rather than one which fails at any unexpected moment, and leads a driver into a trap.

July 1. **Clement E. Stretton.**

THE POSTAL PHOTOGRAPHICAL SOCIETY.

[20255.]—We regret that, owing to the small support received from the readers of the English Mechanic, the committee have been compelled to alter the name of the society started as the E. M. Photographic Society, to the above, and to throw it open to all those who take an interest in photography, whether readers of the English Mechanic or not.

The society is now started, and all those wishing to join should send in their names as soon as possible to the hon. sec., H. H. Cunningham, 7, Fig-tree-court, Temple, or to the undersigned, of either of whom further particulars may be obtained.

G. Allison, North Staffordshire Infirmary,
Harkhill, Stoke-on-Trent.
F. Cowley, 106, Western-road, Brighton.

STONEHENGE AND SUN-WORSHIP.

[20256.]—I have now completed my examination of the Clun 10ft. boulder, and find by testing with the compass (as directed by "F.R.A.S."), and by observation of sunset on and about the longest day, it lies exactly in line with the centre of the stone circle before described, and the point of latest sunrise (Dec. 21). It has evidently stood upright—about 4ft. of it being planted in the ground—for a very long time, and, we may judge, served a similar purpose to the Friar's Heel at Stonehenge. I do not agree with Mr. Stooke that the expression "sun-worship" should not have entered into the question. These stone circles are of immense antiquity, and must date back to a time long before astronomy as a science was thought of. From the polished flint arrow-heads, flint cores, and fragments picked up on these hills, I should judge the Clun circle to be of Neolithic age. In all countries, and all ages, we find the first instinct of man has been to bow before a superior Being; and I think it is undoubted that, the whole world over, the most general object worshipped has been the sun—the most visible emblem of that Being. From the worship would spring the observation of the sun, and thence that of the other celestial bodies. And so I can imagine has slowly developed astronomy as we have it.

Neo.

COLOUR—PHILOSOPHER'S WHITE, &c.

[20257.]—Since writing to the English Mechanic last year on the above subject, I have had the matter constantly on my mind, and upon reading Sir John Lubbock's address to the British Association last autumn, in which he mentioned certain "discoveries" in mixing colour, I decided that it was my duty to endeavour to correct some of these errors.

It may be asked, if artists are so unanimous upon this subject and differ so entirely from the scientist theory, why do they not take the matter up as a body? To this I would reply, that an artist is in a very singular position: his work, to be done properly, is very slow, and requires great concentration of thought. He must, or should, do all his work himself, and has at the same time to maintain a position of equality with people who can get unlimited assistance and whose personal work is often simply to supervise. So that an artist, to hold his own against such odds, must devote all his time and energies to minding his own business, and, indeed, he is generally more or less exhausted when his day's work is over, and is not in a fit state to sit down and write upon a by-subject, to stem a current, in which he knows he will have to meet a compact though small opposition, whose members unite to defend a false position, in which many of them hold a kind of vested interest.

I think this accounts for our having allowed the "philosopher's white" theory to exist so long.

In this letter I intend to confine my remarks to two of the alleged discoveries,—viz., that "blue and yellow combine to make white," by Helmholtz; and that "red and green combine to make yellow," by Clerk-Maxwell.

The results of mixing colours are as exact and invariable as the multiplication table, and to an artist these statements are as fallacious as "discovering" that twice two make nought, or twice three make fifteen; and these two results serve to prove the impurity of the colours used, or, in other words, they show that the discoverers are not good judges of blue, red, and yellow.

Having decided, at the sacrifice of valuable time, to try and refute these heresies, I wrote to Sir John Lubbock, and in his reply he stated that he had "tried several pieces of red and green glass, and they always made yellow" (in a more recent letter he explained that he did not superimpose the glasses, but combined the reflected and transmitted colours; but this does not alter the case at all from my point of view, as I contend that any given colours, on being combined, invariably show the same result, quite irrespective of the manner in which the colours are produced). On reading this I decided to follow up the matter.

On going to purchase some coloured glass, I was not at all surprised to find that the best specimens I was able to obtain were very impure. So much so that a novice, or enthusiast, might have considered that they carried out, or proved, the alleged discoveries; but they simply proved to me, that where the artists and scientists really differ, is in what they accept as pure blue, red, and yellow.

Now, for a red glass, I had to put up with what they called "ruby," which is really a strong orange-red—that is to say, it contains nearly as much yellow as red. For a blue I obtained a purple-blue, which contained, roughly, about 30 per cent. of red to 70 per cent. of blue.

The yellow was still more impure, being what an artist would call a weak orange-brown; that is to say, it contained all three colours—red, blue, and yellow; and then the bluest green I could get was nearly all yellow, say, about 80 per cent. yellow to 20 per cent. blue.

As these glasses do, when superimposed, give more or less the results, called discoveries, I conclude they would be accepted as tolerably pure by the discoverers.

Now, as to Clerk-Maxwell's discovery. There is nothing new, to an artist, in the fact that if an orange-red and a yellow-green glass are superimposed, the resulting colour will be more or less yellow, as the equivalents of red, blue, and yellow neutralise one another, to form a degree of blackness, leaving the surplus yellow visible, or, in other words, if you superimpose any combination of coloured glasses, containing amongst them the three primitive colours, whichever colour is in excess will be visible, and might be called the result of the mixture. But it would be just as reasonable to "discover" that blue and orange make red, for this will be the result if the commercial sample of blue glass and a reddish-orange glass are superimposed.

Then, again, on superimposing the commercial blue and yellow glasses, really blue-purple and orange-brown, the red, blue, and yellow contained in them nearly neutralise one another; but the blue and yellow being stronger than the red, the result is a nearly neutral olive-green, which may be called black or white, according to the circumstances under which it is seen. For instance, if you superimpose these two glasses in front of a lantern, with all else in darkness, the result may be called white; but if they are held up against the sky or any white surface, they would be called black or dark green by comparison.

The scientist's method of examining colours in the dark is the cause of so many errors having been made. The only way to obtain a fair judgment of the purity of any colour is by comparison.

Having obtained these impure coloured glasses, I determined to make some purer samples; and although I have not been able to get them all of equal purity to the colours on an artist's palette, still they are far purer than the commercial samples of stained glass, and quite pure enough for their purpose.

If any of our readers should take sufficient interest in the matter, I will undertake to show them that any so-called red and green that combine to make yellow contain the excess of yellow (which is plainly visible to the properly-cultivated eye) to start with, it being probably contained in both the so-called red and the green. This I would show in the following way:—First let us examine the commercial "ruby-red." Seen by itself, it may be called red; but upon comparing it with a comparatively pure red, it appears so strong an orange, that we wonder how it could ever have been mistaken for a red. Then, to our best red we add glasses of a strong yellow colour, one at a time, until we match the "ruby," and find it takes six or eight yellows and one red to make a good match. This may appear exaggerated; but I shall be only too happy to show it to those who may express a desire to that effect.

Upon examining the commercial blue beside a purer sample, it appears a strong purple, and we find it is matched by superimposing blue and red glass, of which the latter is rather the paler. The commercial yellow is matched by superimposing blue, red, and yellow glasses of suitable strength; and to match the commercial green we have to use several of our strongest yellows to one blue.

We now see that our whole difference of opinion resolves itself into what we accept as pure blue, red, and yellow; and I have no doubt we shall find we differ, not as to the results of mixing certain hues, but only as to the names with which we designate them to start with, and that will, I think, be easily settled by comparing several samples of each colour (when we have fairly pure colours amongst them for comparison), for a colour which looks comparatively pure by itself may be readily detected as a compound colour when compared to a purer specimen. Every artist knows that the effect of a colour depends greatly upon its surroundings.

As a simple illustration of our inability to form a true estimate of the hue of a single isolated colour, I would mention a circumstance with which I was very much impressed.

When in Kew Gardens recently with some other artists, we noticed a green glass conservatory. Upon going inside, one of our party remarked that the roof was clear glass, and not green at all; and another said the ends and sides were not green either; we must have been mistaken in thinking so before we entered. But upon opening the door to go out, we were struck with the pink appearance of things outside, and then upon examining the glass with the door open, we were surprised to find that the whole of the glass was of a deep green colour, although we had all agreed that it was colourless (philosopher's white, in fact), until the open door gave us the opportunity of comparison with the colours outside.

It was observable while the door was closed, that some few portions of the glass being of a much deeper green than the rest, did have a faint green tint, compared to the rest of the glass, which appeared colourless.

I should be glad if amongst our readers some of those who imagine they can judge of the purity of an isolated colour, will take the trouble to visit the Tropical Conservatory for Ferns at Kew, and let us have the advantage of their experience.

S. Calton.

WILDBAD AND ITS CURES IN THE BLACK FOREST.—III.

(*Continued from page 380.*)

[20258.]—If we turn to the ancient records, Gessner, in 1745, declares that if he were to enumerate all the maladies cured at Wildbad, he must take the office of a charlatan. All these records agree that frequently early symptoms are aggravated, and to be regarded as heralds of benefit, if not cure. Old ailments, perhaps long forgotten, are apt to reappear; even old scars and wounds begin to tingle. Even after leaving Wildbad, so long as two or three months may elapse before the full benefit is perceived. The circulation may become excited, lassitude and a powerful inclination to sleep, pains in the head, slight giddiness, and oppression of the breath, may declare the subtle effects of these apparently simple waters. But after a few baths, these symptoms commonly disappear; but if they do not, intermission is advisable. Excessive action of the kidneys, with deposits, redness of the skin, with irritation, are highly favourable signs of approaching benefit. A crisis may be unpleasant, but it is the very result which guarantees a curative process installed in the system.

Dr. Schweckle relates (1844): The heir of a noble and rich family (aged 20), afflicted with an intensely scrofulous constitution, was attacked with a severe affection of the spinal cord, the lower half of his body being completely paralysed. Rejection of food from the stomach; exhaustion, almost fatal: convulsions. He bore pretty well the first bath. He lived on chicken-broth and champagne. He took 26 baths, and quitted Wildbad despairing of a cure. Some months afterwards he regained his vigour, so that he could walk a league. But a cure is not always so rapid.

An Englishman made two visits without benefit; after the third, he was left at home by his father. On his return, he met his paralysed son coming forwards to welcome him home.

Among the maladies referred to by these old writers are especially rheumatisms, stiff-joints, indurations of the joints, maladies of the stomach, cramps, and neuralgia. Dr. Granville relates a case of severe indigestion, which had tormented its victim for thirty years. "*Regardez moi,*" said he, "I was sent to the place to die. *Je suis le meilleur éloge des Bains de Wildbad.* Three seasons have sufficed to work this miracle." Cases are related of loud breathing and incessant cough, with acute pain, being thoroughly relieved. The perfumes of the pine forests probably assist in giving relief.

The literature of Wildbad teems with cases of this kind. Dr. Renz gives, in his latest book, a list of distinguished visitors from 1496 to the year 1874. He also favours us with a catalogue of the various books published on Wildbad for the same period. Of these, the Pastor Deucer* is still much respected as a veracious historian. He states succinctly, "The use of the baths at Wildbad stops the progress of the gout; in this respect they are superior to the other baths of Germany. They cure the stone, as is proved by numerous examples." (This excellent man, persecuted for his Protestant faith, fled from Mayence with his wife and ten children, and escaped into the Black Forest. But Wildbad could not long afford him an asylum. His first account of Wildbad was published in 1617.)

Experiments have been tried on a large scale on the effects of drinking the Wildbad waters without bathing. Swellings of the legs from dropsical affections have been cured here in this manner:—

M—— (of 56 years) suffered a long time with abdominal disorder, bitter taste, loss of appetite, eructations, and indigestion, joined with weight, pressure, and swelling, especially towards the heart, together with lassitude, noises in the ears, giddiness, and headaches. His person had become emaciated; his countenance, and especially the region of the eyes, pinched and tinted yellow. He began with a few glasses, and then took 8 or 12 per day. In the course of four weeks, all these symptoms entirely disappeared; he became light-hearted, with an air of robust health, and took long walks daily. He continued well. Besides these complaints, the drinking of the Wildbad water is a fine remedy against cardialgia and chronic sicknesses, and spasms of the stomach. I shall quote one more case on the authority of Dr. Heim:—

"A young officer suffered for nine months from sickness, which occurred some days 20 or 30 times a day. He could drink very little of the water at first, but the fifth day he nearly lost the affection, which now only returned when he was less guarded in his food. Gradually increasing the dose, however, he was totally cured. *Chronic Catarrhs*, as they are called abroad, mean excessive action of the mucous membrane – whether bronchial, vesical, or intestinal—receive particular benefit by drinking these waters; so much so, that the Wildbad people commonly use no other remedy. 'I will declare with reason,' says Heim, 'that Wildbad operates entirely as a specific for abolishing this bad state of the mucous membrane.'"

Here in this hotel, the Belle Vue, no odour of the cuisine is allowed to float inwards. The *chef* and his assistants are entirely divided from us by a large court. A lift for the invalid baths, also within call; wines of the highest quality, and rooms above at the lowest price, attract a swarm of grateful guests; carriages are necessarily dear, from the shortness of the season and the steepness of the roads.

Excursions innumerable invite the pedestrian or the traveller who can afford tours among the ravines of the Black Forest. Everlasting permutations of mountain scenery, crowned with the black pines of the forest, *greet* the eye. This forest is a wilderness of bright and dark green beauty and towering grandeur. Withal, the ever-grateful pine odours assuage the distress of the bronchial and asthmatic. Wildbad, too, is the only spa which enjoys perfection of beauty combined with a rapid river, abounding in trout, even in front of its best hotel. Yesterday, in the heart of the town, I saw a large trout landed after its desperate struggles: four-pounders are not unfrequent. Fishing is here a most agreeable pastime, obtainable at a moderate charge at the very doors.

As for the town, after much travel, I have never been so regaled with fresh air. For sweet water and perfect cleanliness, the place would gain the prize against all Continental competitors. Out of much evil sometimes comes much good. The town is now *tiled*, and supplied with hydrants 150ft. above, so that the natural force of the water is adequate to any conflagration. Besides which, the drinking water is perfectly sweet, pure, and fresh. No modern *sanitary* arrangement appears to be neglected. This is saying a great deal for a foreign resort.

Something there must be due, no doubt, to bathing in water such as Nature made, unsophisticated by artificial heat. Dr. Granville thought Wildbad infinitely superior to those of Gastein for this very reason. A singular proverb alludes not obscurely to this—"Juste comme Wildbad." At this moment the springs are the same temperature as they have been for centuries. Even earthquakes do not seem to have influenced the sources of the water.

G. W. Royston-Pigott, M.D., F.R.S.

THE EXPANSION OF IRON IN THEORY AND PRACTICE.

[20259.]—The point raised by Sir Edmund Beckett (letter 20206) is an interesting and important one, though I am inclined to question whether the fact he cites can be regarded as throwing any doubt upon the truth of the received coefficients of expansion. Rails do expand, very perceptibly, and so do iron bridges, although in the latter case it is not so apparent, for, where there is any considerable length of span, the expansion, instead of causing the supported ends to move forward, merely permits the whole structure to *bend*, as in the case of a dry cord stretched tightly between two points and then caused to expand by moistening. I am not acquained with the iron dome at Vienna, and so cannot suggest in what direction expansion would make itself evident; but the mere fact of the pillars upon which it rests showing no movement is hardly a sufficient foundation for the statement that the material of the structure does not suffer expansion or contraction at all.

There are other aspects of this question, such as the effect of unequal temperature in different sides of the same structure, as may be caused by the direct incidence of the sun's rays upon one part, while the rest is in shadow; but I must defer discussion of them until a future time.

J. A. Westwood Oliver.

Belle Vue, Springburn, Glasgow, June 27.

USEFUL AND SCIENTIFIC NOTES.

◆◆◆

A New Hygrometer.—In a recent note to the Paris Academy, M. Crova has described an instrument for measuring the moisture of the air not subject to the uncertainty characterising the indications of previous instruments when the air is agitated. The observer looks through a tube towards a source of light. This tube is of nickel-plated brass, highly polished within, closed at the further end with ground glass and at the nearer with a lens. The ground glass plate appears as a luminous disc, and the polished interior, by its reflected light, has the aspect of a bright annular space round the disc. The air, whose moisture is to be ascertained, passes slowly along the tube, entering and leaving by tubulures at the ends connected with a suction arrangement. To cool the tube, it is surrounded by a metallic sleeve filled with sulphide of carbon, through which an air current is passed. A thermometer is inserted in this liquid. When the temperature of the air under examination reaches saturation, dew is deposited, appearing like dark brown spots, which contrast strongly with the bright disc when seen directly. A gradual rise of temperature makes these disappear, and thus, by repeated appearances and disappearances, the dew-point may be estimated with an approximation of one-tenth of a degree.

A New Imitation Ivory.—One of the disadvantages of celluloid is the fact that it burns very readily when a flame is applied, but a new compound, said to be fireproof, and suitable as a substitute for ivory, is thus made:—A solution is prepared of 200 parts of casein in 50 parts of ammonia and 400 of water, or 150 parts of albumen in 400 of water. To the solution the following are added: Quicklime, 240 parts; acetate of alumina, 150 parts; alum, 50 parts; sulphate of lime, 1,200 parts; oil, 100 parts. The oil is to be mixed in the last. When dark objects are to be made, from 75 to 100 parts of tannin are substituted for the acetate of alumina. When the mixture has been well kneaded together, and made into a smooth paste, it is passed through rollers to form plates of the desired shape. These are dried and pressed into metallic moulds previously heated, or they may be reduced to a very fine powder, which is introduced into heated moulds and submitted to strong pressure. The objects are afterwards dipped into the following bath:—Water, 100 parts; white glue, 1 part; phosphoric acid, 10 parts. Finally, they are dried, polished, and varnished with shellac.

A new arrangement of filter removing calcareous deposits from water, in which the water is passed through a succession of filters, worked in series, filled with sawdust, impregnated with magnesia, have been described. Salts of magnesia thus replace those of calcium, and, being more soluble, form no scale in boilers.

REPLIES TO QUERIES.

**** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[46424.]—**Circular-Saw (U.Q.).**—The sketch will enable you to set your saw or saws; but I should not advise you to practise upon a saw first, but get a disc of sheet iron 12in. in diameter, No. 18 or 20 gauge, a small anvil, about ½cwt. (I have set them upon a large flat iron on my lap), and a hand-hammer about 2lb. weight, with a good face. With this practise, and you will soon become proficient. Fig. 1 is a buckled-saw. Now, a buckled-saw is a bent saw, but a bend is not a buckle. For instance, your saw may be perfectly straight at A A A, and strained or buckled at B,—i.e., right at the eye, but stretched at the circumference. Now, to get that out, you must commence from the outside, A 1, and gradually proceed as marked with the pock marks, striking steady, flat, and not too hard, first upon one side, and then turn over for the other. When you have made a little progress, if the saw is very bad, make a fire with some light wood upon an open hearth or in the open air, rub your saw over with some mutton-suet or a common dip candle, and with a split stick or tongs held high enough over the heated air, keep it moving about until it acquires a brown tint; when very near cold, proceed again, until you get it right. The same applies to Fig. 2, a hand-saw that is buckled, A A. When the buckle is taken out, it will present the appearance shown by the dotted line, A B. Fig. 3 is a piece of sheet iron, with several cross buckles. Fig. 4, with a bulge. Fig. 5, a dished disc, the gores show where it wants stretching to bring it flat. Your saw should always be a little tight upon the circumference, and the hollow side next the fence. Never work a dull saw. When a circular-saw has got damaged, or the set taken off with grit or a nail, I have seen it pass through timber like A, 6, and 7, and the consequence is a buckled-saw. If a tennon saw get buckled, tap the back sharp with a light hammer, and it will sometimes right itself; if not, pinch the blade between two smooth pieces of wood and bench-screw or vice, and tap the point of back; if not right, tap the back right off, and see whether the blade is buckled; if so, straighten and insert again. You must not slave at it, or go rashly to work: a few well-directed blows, or the mere fall of the hammer, when lifted from 6in. to 12in., will work wonders; and do not forget it is the tight side of your saw wants stretching to accommodate itself to the buckle; by playing upon the buckle you only make it worse.—JACK OF ALL TRADES.

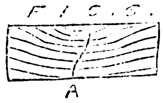

FIG. 7.

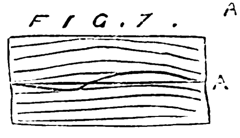

[46598.]—**Problem in Plumbing.**—One answer only was given, and that by P. Mooney, but I had exhausted all corking and plugging with no effect. Being driven to extremes, I got a piece of very thin Morocco leather, 4in. by 4in., and a piece of thin tin 4in. long ¾in. wide; this was doubled and closed on one side of the leather, a hole was made in the two opposite corners for some strings, and at 3ft. 6in. a cork tied to the end, to prevent sinking. The leather was well soaked, and measure taken, then lowered in cistern to level of pipe to boiler, the tap turned on, and a dead stop was the result; it was so easily done that I closed and opened it six times in one minute; a very thin piece of indiarubber would hermetically seal it, as the leather allows a small quantity of water to pass through it.—G. B.

[46694.]—**Brick Kiln with Down-Draught.**—I send a rough sketch which I think will aid you. Fig. 1 is the bottom with flue down the centre; the dark dots are the slabs to set the bricks on; B is where the draught goes through, S is the bottom of chimney-stack. Fig. 2 is the inner side up to the springing of the arch—A are what we call the "bags," that are built in without mortar so as to leave a little heat to go straight into the bottom, the same as with fire-holes, and a brick wide. If the bricks should be soft in the bottom, then open the joints of the "bags" a little more. Fig. 3 is the outside, showing the baulks, end, and stack. Of course, you must have a man that understands the work. When the heat gets to the bottom and a nice bright red, then stop up the holes L and put in the dampers and the heat will fly all over the kiln. You must try and keep the fires regular when burning; give the bricks plenty of drying before burning them.—BRICK-BURNER.

FIG. 1.

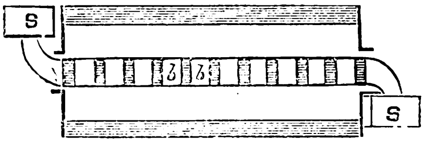

FIG. 2.

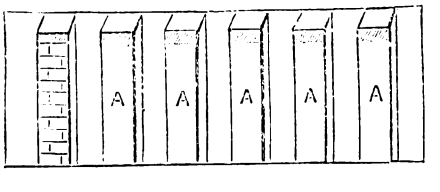
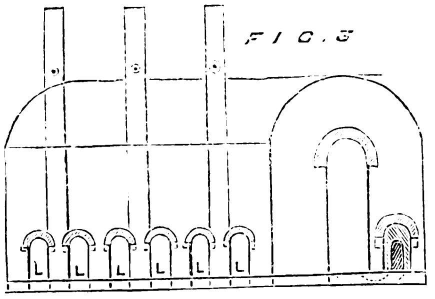
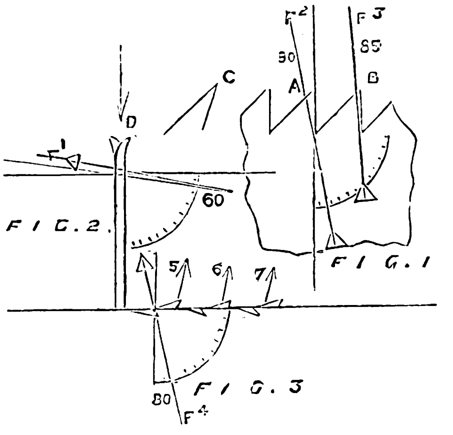




[46719.]—**Reading-Lamp.**—Withdraw the oil vessel, in the lower part of which is a valve, a piece of tin on a wire, working through a tin bridge. The cause of varying flow is usually the valve not falling true. To remedy: take out the bottom, fix the piece of tin true on wire, twirl between fingers and thumbs to test it, adjust bridge and refix bottom.—H. FIELD.

[46748.]—**Sharpening of Carpenters' Saws (U.Q.).**—Very nearly everybody who has cause to use saws think that they know how to sharpen them, but when they have done so and proceed to use them, it is a very rare circumstance that they are satisfied with the operation. You can sharpen a saw that will answer for soft timber with the grain, but come against a knot or across the grain and it is fit to jerk your arm off. And another attempt, and ten to one but what you buckle your saw if you do not break it; but as there is a happy medium that will answer for the hardest and softest wood, even to metal, that will give satisfaction, I will do my best to give diagram and instruction.



Description: Fig. 1, flat face of the saw; Fig. 2, transverse section, showing set; Fig. 3, cutting edge. Fig. 1, Fig. 2, Fig. 3, and Fig. 4, with triangles, showing the angle and path of the file, the quadrants here shown as to how the description and where the angle is taken, the greatest angle should not exceed 80° and not less than 85°. Fig. 2, showing too much rake. Fig. 3, right, A and B showing proper shape of tooth. If you sharp as at C, you will find it very difficult to start on anything, as the saw will tear the fibre, kick and dance about, obliterate your lines, sprain your wrist, buckle or break your saw. The process of sharping is shown at Fig. 3, every alternate tooth marked 5, 6, 7, the file taking the place of the tooth with the set towards you, and the top of that from you. If you follow these instructions, no matter upon what class of hand-saw for wood, you will have a saw that it is a pleasure to work with; the set is shown at D, and should be a little hollow. Never work with a dull saw, or just touch it up; do it properly, and it always pays for doing. The cause of saws running is when they are sharpened at too great an angle, and a needle point is produced. Place your saw down upon the bench, and it comes in contact with another tool, or in working comes in contact with a hard grain or knot, and one or two of your teeth get damaged, your saw will run, and if you continue to work with it it forms a curved kerf; come in contact with another knot, and you will produce a double curve, and it is with the greatest difficulty you drive it at all; perhaps sprain your wrist, buckle or break your saw, and spoil your job.—JACK OF ALL TRADES.

[46805.]—**G.E.R. Locomotives**—If Mr. Hall means the inside-cylinder four coupled tanks, 580 class, they are being built at Stratford. The six coupled goods I have been unable to obtain dimensions, &c., of; but a driver told me that cylinders were 19in. by 26in., and wheels, 5ft.—H. S. P.

[46933 and 47036.]—**Photographing in Cemeteries and Photographing Public Buildings (U.Q)**—Though addressed to Mr. Wetherfield, these queries being still unanswered, I give the following:—No doubt an order is necessary to be able to photograph the monuments in cemeteries, such places being in the nature of private property, even after the consent of the owner of such monument has been obtained. No order is necessary to photograph public buildings, except situated in any of the royal parks or gardens; for taking photographs in the latter, a license is required, such licenses being issued by Her Majesty's Commissioners of Works, &c., at 12, Whitehall-place, London.—DITTON.

[47002.]—**Black Paint for Window-Sashes.**—Any good black paint, properly laid on, will do; but all blacks should have varnish added. If vegetable black is used, grind in boiled oil, not raw linseed, and add a little oak varnish or copal. If ivory-black, grind in turpentine, and dilute with turpentine, gold size, and varnish. The gold size and varnish are required to bind the pigment. The ivory-black will need varnishing after it is dry, as it dries dull; but the vegetable black, which, by the way, should have a little driers added, will probably be glossy enough. Try it first, and if not, add a greater quantity of varnish, or varnish after it is dry.—T. P.

[47009.]—**Naval Architecture Government Science and Arts Exam.**—Thearle's "Naval Architecture" (Collins) will enable querist to answer many of the questions; but I suppose he is aware that practical knowledge, such as can be gained only in the yard, is required. In fact, an intelligent apprentice would pass the elementary stage without studying a book at all.—S. R.

[47013.]—**Steam Launch.**—I am not sure I quite understand what it is querist wishes to know, for he seems to have ascertained that he can keep a boat off any stairs if he does not get in any one's way. Practically, unless you are always on or about the spot, it is good policy to give some one a trifle to take charge of the boat, and especially so in the case of a steam-launch. Cannot you find someone with waterside premises, as a steam-launch kept knocking about near public stairs runs some risk of injury, from the fact that it "has no friends" looking on?—YACHTSMAN.

[47056.]—**Bacteria.**—In further reply to "Cygnet," the treatment of the barm-mash, as described on p. 359, is such as would produce diseased yeast in the highest degree. 185° Fahr., as a mashing heat for malt, or crushed unmalted grain, is a diastase-killing and starch-dissolving temperature that will leave the substances acted on better fitted for pigs' food than the propagation of alcoholic torulæ. In my first letter on this subject, I did not mistake the purpose of the barm referred to. Alcoholic fermentation, whether in boiled wort for beers or unboiled wort and grains for distilling, is due to the reaction of *Saccharomyces cerevisiæ* on inverted hydrocarbons. But these "disease ferments," which have their origin in the non-coagulated endosperm, are also reacting—attenuating—on the same hydrocarbons, and the product of their action is not alcohol, but various acids. Hence the majority, I believe, of the home distillers use and find more purity and profit in the yeast of ale and porter than in struggling with their thoroughly diseased yeast arising from the fermentation of unboiled worts. "Cygnet" makes two distinct mashes: the first or barm mash is for the propagation of torulæ to be sown in the second thick mash for alcoholic fermentation. My recommendation of sedimentary fermentation and yeast was for the first or barm mash. But it is quite possible, by varying his present system of mashing, for "Cyguct" to have a purer yeast. Our system of growing barm for breadmaking differs only from his in details. We use malt, wheat flour, hops, and water. We mash for two hours 3lb. malt in three gallons of water that has been boiled and cooled to 160° Fahr.; the malt grains are then strained from the liquid and pressed, and the liquor, when cooled to 110° Fahr., has incorporated with it 33lb. of thoroughly sound glutinous flour, not too finely dressed. This batter of flour and malt infusion is then scalded with six gallons of boiling water (in which 2oz. of hops may have been boiled for twenty minutes in a tin perforated vessel) in three parts of two gallons each, and stirred briskly and thoroughly between each. The heat of the whole then is 140° Fahr. or a few degrees over, and in 24 hours it has cooled to 80° Fahr., when fermentation is started with 1¼ gallon of old barm; or, we add no old barm, in which case the quantity of malt is 5lb. instead of 3lb., and one handful each of flour and cane-sugar, and the tub holding these things is kept where the temperature is constant within a few degrees of 80. With the addition of old barm the new is fit for bread-making in 24 hours; without old barm, and self-fermented (spontaneous), it is ready for use in 48 hours, if it has been stirred up three times during that time. But mark, if I scald the batter of flour and malt infusion with 8 or 9 gallons, instead of 6 gallons, of boiling water, so as to bring the heat up to 160° Fahr. to 180° Fahr. instead of 140° Fahr., then, after fermentation, the effort to make saleable bread with the barm is hopeless; the bread is low, heavy, and acid, and the barm under the microscope is seen to swarm with all the acid ferments. So much for bread-brewing. What follows relates to patented improvements in the manufacture of yeast for distilling fermentation. The full details will be found in the "E.M." for July 30, 1880:—"1lb. hops, 2oz. quassia chips, and 7 gallons of water are mashed for 20 minutes, then boiled for 10 or 15 minutes, and strained through a cloth or percolator, cooled down to 170° Fahr., and 12lb. malt stirred into the infusion; this, after mashing for 15 minutes, has the malt grains separated or pressed out, and the liquor allowed to cool down to, and is kept at, the temperature at which fermentation (spontaneous) will be excited and carried on"—not over 80° Fahr.—"That is the first or starting yeast. Fermentation will or should commence in from 18 to 20 hours, and continue from 16 to 24; when at its full height take from the toop ½ gallon and place it in a close jar, in which put also one or less oz. bi-carbonate of soda, and then hermetically seal, and keep the jar where the heat is not over 60° Fahr." See the "E.M." for the rest of the details. I prepare the ash of figs, raisins, or malt grains, by placing them in an iron tube, and the tube into a glowing furnace and keeping it there till the tube is at a white-heat, and the organic matter inside stops giving off gas and flame. As to ammonia by itself for the invigorating of yeast, I think it more harmful than useful. Torulæ, as found in worts, are no more nor less than free vegetable nuclei, mostly cereal. They are propagated by spores; but, Professor Huxley and his echoes to the contrary, that is not their origin. They are free nuclei, and the most beautiful and lasting variety are not vegetable in origin but animal in the human mouth. Looking upon yeast, then, in worts as the free components of cereals, what is required for its healthy and vigorous propagation is the mineral elements found in organised substances, without which cell structure and protoplasm, animal or vegetable, cannot be formed. These elements are found in the carbonised ash of cereals and fruits. As before explained, this ash is black, which, for my experimental purposes, is of no importance, but these mineral elements can be obtained in a colourless form, free from carbon. Their kind and proportion has been the subject of much investigation by many authorities. In different plants, seeds, or fruits, they vary in quantity; but for the practical purpose of invigorating yeast the analyses of wheat grain ash by Messrs. Lawes and Gilbert will do, and shows per cent.:—

Wheat Grain Ash.

Phosphoric acid..	49·68	Magnesia	10·70
Phosphate of iron	2·36	Lime	3·40
Potash	29·35	Chlorine......	0·13
Soda	1·12	Silica	2·47

Ash of Yeast (Mitscherlich).

Phosphoric acid	41·8
Potassa	39·8
Magnesium phosphate	16·8
Calcium	2·3

The phosphoric acid and lime may be found in lime or bone phosphates, but one form of the application of this is the subject of a patent by Professor Graham, valued at the modest sum of £20,000. The necessary equivalents of soda and chlorine will be found in common salt—W. A. THOMS.

[47071.]—**Railway Trucks.**—The waggons used for goods and mineral traffic vary upon the different lines, and some companies have as many as six different sizes for the same class of traffic. The average size will be found to be from 15ft. to 15ft. 6in. in length, outside, and from 7ft. 4in. to 7ft. 6in. in width outside.—CLEMENT E. STRETTON.

[47110.]—**Template.**—Reply 46424 will answer all "D. D. M. L." requires.—JACK OF ALL TRADES.

[47143.]—**Aluminium.**—If "Zelia Naien" will give me his address, I think I could help him out of his difficulty, as I have had considerable experience in Metallurgy. I could scarcely give him full particulars in these columns.—E. SELLON, Eccles, Lancashire.

[47159.]—**Heating Greenhouse.**—It is a mistake to have gas-stove inside. The flue-pipe should be taken into a chimney that has a good draught—one that is most in use—say, kitchen. Gas-stove being inside, it is *best* to cut off all communication, by having metal cover made to fit over it, with well-fitted door for lighting purposes, and inlet-pipe (to supply air for combustion) coming from outside. If this is not clear enough, write H. MANFIELD, London-road, Twickenham.

[47174.]—**32ft. Pedal Reeds.**—Thanks to Mr. Huxley for his hints, but I should not care to undertake to carry them out without competent aid. My past experience of meddling with reeds is, that it is a very delicate business, and best let alone by amateurs. In reply to Mr. Fryer, the instrument will be a two-manual of five rows, with independent pedal three rows, each 27 notes (32ft., 16ft., and 8ft.), my object being to avoid coupling manuals to pedals, which I have hitherto found unsatisfactory. I do not know size of reeds: should I have to get them made specially?—ARIEL.

[47175.]—**Varnish.**—I think if "Varnish" will try the following, he will find it useful and cheap: Seed-lac, 1lb.; methylated spirit, 1 gallon. I have used this for some time and have had excellent results. Seed-lac is a cheaper form of shellac, and should be placed in a jar with the spirit and occasionally shaken, and then decanted. If this is then thought too thick, more spirit may be added. If "Varnish" would like a recipe for an amber varnish to be applied to a cold plate, it will be gladly supplied by—F. H. H.

[47184.]—**Special Express Train on Midland Railway.**—In my reply, p. 362, I mentioned that T.R.H. the Prince and Princess of Wales would travel by special express from St. Pancras to Saltaire upon the 22nd of June. The train was booked to run as under:—

St. Pancras	dep.	1.30	p.m.
Kettering	arr.	3. 2	,,
,, ...	dep.	3. 5	,,
Nottingham......	arr.	4.11	,,
London-rd. Junc.	dep.	4.15	,,
Cudworth..........	arr.	5.28	,,
	dep.	5.31	,,
Saltaire............	arr.	6.15	,,

The train consisted of van No. 320; first-class carriage, 226; directors' bogie saloon, No. 1; Pullman drawing-room car, "Venus"; the new Pullman dining car, "Delmonico"; bogie saloon No. 733, and van 434, or a load equal to 11 ordinary vehicles. The train was drawn from St. Pancras to Nottingham by engine No. 1516 (driver Leadbeatter), not by 1483, as previously intended. Although an extra stop of five minutes was made at Harpenden, the train arrived at Nottingham at 4.9 p.m., or two minutes before time. The engine was changed, and No. 1511 conveyed the train thence to Saltaire, which was reached two minutes before time. It may be mentioned that the new dining car used upon this occasion will, on the 10th inst, commence to work daily, with the other new car, as under:—

	p.m.		p.m.
St. Pancras	5. 0	Liverpool	4. 5
Manchester	9.45	Manchester	4.50
Liverpool........	10.35	St. Pancras	9.35

—CLEMENT E. STRETTON, July 1st.

[47193.]—**Nitrate of Lead.**—Nitrate of lead is made by dissolving suboxide of lead in nitric acid, then it is boiled down in a lead pan and crystalised. For stannate of soda you will require two iron pans, one 2ft. deep, 18in. wide, the flange to be 6in. wide, to weigh about 5 or 6 cwt. of the best cast iron you can get. The other must be a common 10-gallon pan. You will also want a flat iron lid for the big pan, with a funnel in the centre. The following is the receipt: 5 gallons caustic soda, 40lb. common salt crushed, 27lb. nitrate of soda, 20lb. feathered tin. You must have the big pan red-hot before you start, and the caustic boiling in the small one; put the salt in first, and then the caustic will not fly; be very careful, or it will fly in your face. You will want two iron slicers or stirrers, and when it is fluxed you draw it out and dissolve in boiling water. There is another method which does not require boiling caustic; but you would have to pay for it.—SHALE.

[47196.]—**Electricity v. Gas.**—I am not so clever as Mr. Grey, and do not understand from what he intends to differentiate the tom-cat. I know if you rub one the wrong way he will prove himself electrical in more ways than one, but I do know that "Fiddler's" query deserves a more courteous answer. It is not because a thing never has been done it never can be; in the present state of science we cannot say that anything is impossible. If "Fiddler" has any theory on the subject, I would advise him not to feel "shut up," but try to work it out. At present, I suppose, there is nothing nearer to his suggestion than Doebereiner's lamp, which was invented in 1824; this forms its own gas by electricity, and burns it by means of platinum. With this to start from, I say, Go on and prosper.—ZELIA NAIEN.

[47196.]—**Electricity v. Gas.**—Why don't you try the experiment yourself? Then you will know why it is that such a method cannot be adopted. Practically, there are any number of beautiful experiments that for practical, everyday use are useless. Yours is one of them. A gentleman came to me, not long ago, with a "splendid" idea. I was to have half the profit of the commercial working of the idea. It was to revolutionise gas-making; to dispense with costly machinery. I could not mention all the great things that the invention was to do. It was to provide high towers, and above them lightning-conductors, with innumerable points. These had to "collect" the electricity in an upper stratum of air and bring it down through immense vats of water, slightly acidulated, and the vats, of course, insulated. Then two electrodes, with receivers over them, were to decompose the water. Oxygen to be stored in one series of gasometers and the hydrogen in another series. I had to cool the aspirations of my client by pointing out to him the failures that would take place, even in the beginning of the process. He went away a wiser, and, perhaps, a sadder man. Still, I never care to damp anyone's spirit; it is better to think and not succeed, than never to think at all.—W. J. LANCASTER.

[47198.]—**Wet-Bulb Thermometer.**—The idea is an old one. You should have a piece of parchment over the vessel containing the water, or have one of the small fountain ink-bottles, with a small neck. You know, of course, that the danger is with a tall supply of water, that the bulb will be too wet, and consequently, warmer than it would be if evaporation could go on only from the immediate surface of the cotton covering. The water in a long vessel is the same temperature as the outside air, and if the supply to bulb is too rapid, the wet bulb will indicate too high.—W. J. LANCASTER.

[47199.]—**Winds.**—The gusts have never yet been at all clearly explained, nor will they be for some time. Electricity has a great deal to do with sudden squalls. I have noticed sudden gusts during a thunder-shower that could be traced as due to an electrical discharge; but there is more that cannot be so definitely traced, but I think will be before long, as due to silent electrical discharges.—W. J. LANCASTER.

[47209.]—**Lever Watch.**—It is somewhat difficult to assign a correct cause for the defect exhibited by your watch. Some part or other cannot be so free as it should be. Is there perfect freedom in the action of the hair-spring? Does it touch the bar of the regulator in vibrating between the two small curb pins? Does the revolution of the balance increase or diminish when held in different positions? Can you perceive any difference in the sound or beat when steadily held to the ear in various ways? The hairspring should work freely between the pins, and should in every way be free from the bars of the balance and from the regulator itself. The action of the balance should be the same, in whatever position the watch is held. The beat, too, should be the same, however placed. Sometimes a minute piece of bristle may hang up and obstruct the freedom of a particular wheel, or a small piece of pegwood may be left in a jewel-hole (when it is a covered jewel), or in putting together you may have slightly burred one of the pivot holes in one or the other of the plates, which would bind the wheel when bearing to that side. You will see that the error complained of may proceed from a variety of causes. It sometimes happens that when a spring gives up the ghost, the chain is violently jerked against the staff, and unless the watch is fitted with a staff-guard pin, the pivots, or one of them, may get a trifle bent—not enough to altogether stop the watch, but sufficient to retard its action. Your best plan would be to take down the watch and closely examine every hole and pivot, if you cannot ascertain the cause otherwise. It is useless to overset the spring. A half or a three-quarter turn of the ratchet wheel generally suffices. In over-setting you run the risk of again breaking the spring, or, perhaps, the chain. You were perfectly in the right in oiling the jewel-holes. The policy of oiling the ruby-pin is open to question. In cases where the lever-fork is indented or rough, a little oil is a help, so long as it is free from coagulation. Should it thicken, it would prove more of a hindrance. A well-finished escapement and roller require little or no oil, excepting where the escape-wheels are made of steel; then it should not be omitted. Write again and report progress.—ALFOJOE.

[47211.] — **Magneto-motive Force.** — See answers to 47179, and also read carefully Prof. Ayrton's lecture on p. 4, and get acquainted with the Ammeter and Volt-meter there referred to. The methods of applying electricity to magnetic motors are very various, but the "Gramme" appears to be reckoned among the best—described in a back number of the ENGLISH MECHANIC.—J. H. HUXLEY.

[47214.]—**A Clock to Strike Quarter-Hours.**—In reply to "A Poor Irish Boy," I must say that I think you may as well try to extract sunbeams from cucumbers, or to make a silk purse out of a sow's ear, as to hope to make your clock strike the quarters. I know of no plan by which a clock of the kind described could be made to do so, unless it was by putting an entirely new set of wheels and levers in place of the present ones. In my opinion the game would not be worth the candle, as the saying is. I should be happy to assist you if I could see my way clear to do so; but I cannot. I imagine your clock is not a *gilt* one, if it is an American. The majority of the American clocks now in the market are lacquered in a manner that very closely resembles gilding. The colour is so nearly alike, and the finish so good, that an unpractised eye may easily be deceived. Unquestionably some of the best *are* gilt. Lacquering is done by boiling or dipping the metal in diluted nitric acid, and after being thoroughly cleansed and dried, it is heated and painted over with prepared and coloured spirit varnishes. A considerable amount of skill is required on the part of the workman to produce an even and satisfactory appearance to the work: so if you attempt the job, you must not be surprised if the condition of your clock goes from bad to worse.—ALFOJOE.

[47218.]—**Circulating Decimals.**—Three years ago I purchased a copy of Henry Clark's "Rationale of Circulating Decimals, &c." A new edition of 215 pages, and 6 copper-plates. London, 1794. It is the best work that I have met with on the subject. A. J. Smith, by appointment, can come any evening and read the 10 pages of preface and 70 pages of matter in the said subject, if he likes to advertise his address.—S. J.

[47226.] — **Picture-Frame Making.** — After trying various methods of making frames, I find I can make the best job by (after mitring) just touching each mitre with glue, letting dry a short time. This stops suction, otherwise the end grain of wood will absorb glue which is intended to hold frame fast. I then take the pieces, two and two, glue them, rub out superfluous glue, setting them to intersect perfectly. Leave them a sufficient time to dry, then put a brad or two in each; then put other joints together in same way, bradding them also when dry. In this way you can set each mitre properly, which is almost impossible to do by nailing at time of glueing. Although the job may be a little longer about, it is the best in the end. A trying-plane must be used, kept sharp, and I set the break-iron well back when making mitres. My mitre-board is simply a piece of inch stuff, with two pieces glued on at the proper angle, and held down on bench by two screws.—COTSWOLD.

[47226.] — **Picture-Frame Making.** — If Savory's mitring board is untrue, I should at once drop down upon him with a letter of remonstrance. He is a frame-maker, and is well-known in his own town and neighbourhood. His book upon frames and gilding gives also full details upon the subject, with illustrations. Mr. Hines, of Norwich, also sells a mitre-board and cramp, and so also do Booth Brothers, of Dublin. With sharp plane and true board, a mitre ought to come out true; but practice has something to do with it. If the pieces are put accurately in place for nailing, they will not remain so. Set one upright in the vice (properly protected) and let the other slightly overlap its true position; then bore and nail, and the act of nailing will drive it down into place. But Hines and others advertise clamps to secure the mouldings in place, which are advantageous to those who are not adepts. Practice on some ordinary bits of moulding: it is a pity to use special stuff until perfect in the manipulation. "J. J. A.," Liverpool, uses a good plane, and evidently succeeds.—O. J. L.

[47228.]—**Telephone.**—You will require from ¾oz. to 1oz. of 36 wire on the bobbin, but if you have only a short circuit you can use No. 30 wire. The bobbins ought not to be too wide; if the width is made equal to the diameter of the core, then wind until the depth of wire is equal to diameter of core, and you will have the most successful telephone you can make.—W. J. LANCASTER.

[47231.] — **Insulating Material.** — Field's Nigrite is the best substitute for indiarubber for insulation. It has nearly four times the insulating power of rubber, and is sold at a much lower price.—ARTHUR SMITH.

[47233.]—**To Mr. Lancaster.**—Any of the steel-tape makers would make the band for you. Perhaps Chesterman's, of Sheffield, would make it for you. Probably a good band-saw maker would do it; but I should prefer the steel-tape makers. You do not say what strength you want the steel; if very light, a clock-spring maker would be about the best to go to.—W. J. LANCASTER.

[47234.]—**Weight of Girder.**—A box girder 12ft. long, to break under a load of 1 ton, would be but a toy or model. The following would give such a model:—Top and bottom plates 3in. by ⅛in., webs each 2¾in. by ⅛in., four angle-irons, each ¼in. by ¼in. by ⅛in.; the breaking weight in centre by calculation of this girder, if fixed at both ends, would be ·94 of a ton; weight 77lb.—DITTON.

[47236.]—**Object-Mounting.**—You will find nothing better than glycerine and gelatine, and one of the simplest methods of making it is given by Beale. A small quantity of gelatine must first be soaked in cold water until it becomes quite soft, then melt it by putting it into some hot water—not too much, but sufficient to make it about the consistency of starch; then mix an equal quantity of glycerine with it, and before bottling it well mix the two together, then bottle it and keep it covered. When wanted to be used, put it in a cup of warm water for a few minutes. You will find this mounting-fluid capital for all tissues.—W. J. LANCASTER.

[47239.]—**Deafness.**—I suffer from chronic catarrh of the ear which has produced deafness. I went to Dr. Dalby, and he gave the same advice as Dr. Edmunds, only recommending Borrough's Inhaler, Snow-hill, London, price 12s., and to take air into the lungs, and to force some through the ears, which he told me would prevent my getting worse, which it has done. The inhaling requires great perseverance, it being six months before I received benefit from it. It has been beneficial to others who have received the same advice Dr. Edmunds gives. Could Dr. Edmunds tell me if he has had any experience in mechanical contrivances for the ear, and what is the best and most convenient? I want something to use in church, and at lectures, &c. Can they be safely recommended? Do they improve or injure the hearing?—JOHN ALEX. OLLARD, F.R.M.S., Enfield.

[47243.] — **Dry-plate Photography.** — If "F. J. N." will follow the instructions given by J. B. Stephen on p. 10 of this volume, I think he will be satisfied with the results. I have made two double dry slides at the cost of 4d. each, that is besides my own labour, not taking that into account. I got my board at a picture-framing shop, and gave 5d. for a 6ft. piece; hinges for the same three-halfpence per pair.—R. T. B.

[47244.]—**To Mr. Lancaster.**—About a month ago I gave the very instructions you ask for. You will find it under Medical Coil. The battery you speak of I suppose means a coil. If you cannot in back numbers find just what you want, let me know, and I will tell you exactly how best to go to work. At the same time, let me know whether you have any cells at all; if not I will tell you how to make the simplest form.—W. J. LANCASTER.

[47245.]—**Electric Bells.**—Most probably the fault is due to bad earth. I saw some time ago just such a case; the earth at one end consisted of a wire pushed into the ground about 1ft. When the ground was very damp bells would ring and all go right; but the moment ground was at all dry the bells and telephones ceased to work. Of course, I am assuming that your iron wires go to earth: if not, then, of course, the fault will not be as above; and I should advise you not to use the iron return-wire, but simply to carry a wire at each end, either to the gas-pipe or to the water-pipe. There is something wrong with the insulation somewhere.—W. J. LANCASTER.

[47256.]—**Surface Condensing-Engine for Launch.**—The difference will not be so much as you imagine, so far as driving and attention are concerned. In the first place, you will not have the benefit of exhaust fire-draught; but the boiler pressure need not be so high, as it is necessary to keep it in the "suffers." The chief extra you will have to watch is the vacuum gauge, which should be tested by indicator, as nine out of ten of them are an inch or so out. The vacuum should stand at least 24in.; the more you get the better. If the vacuum is found to decrease, try your hot-well (overflow from air-pump), for temperature with thermometer. If over 125° Fahr. your circulating-pump is not working well, or the tubes want scaling, and if not soon done, the increased heat will form a thick crust round them and prevent condensation altogether. Irregular, jerky movements of the gauge index point to the renovation of the air-pump packing. You should bear in mind that vacuum costs in production, nothing but the working and wear of pumps, and every 2in. is as effective as a pound of steam per square inch of piston, which cost coal and labour in putting in the furnace. You must also look out for leaks in exhaust-pipes, condenser ends, and tubes, so that no air can enter, and the drain taps on cylinder end kept tight: also piston seen to occasionally, as all these things are fruitful sources of annoyance to those in charge of condensing-engines.—FRED. WALKER.

[47259.]—**To Mr. Lancaster.**—You have insufficient wire and have wound it wrongly; you must wind round and round like cotton on a spool and not as on a shuttle; wind on each leg at least ½lb. to ¾lb. of, say, 16 cotton-covered wire. The armature is, of course, much more like a shuttle, and the winding is in same direction as the cotton on a shuttle; but the magnets must be wound differently unless you want to waste all your current.—W. J. LANCASTER.

[47264.]—**Lightning-Conductors.**—The best form is Vyle's patent easily-tested lightning-conductor, which is a cable made of 96 per cent. of pure copper, with an insulated wire as its core, for testing the condition of the conductor, and also whether it continues to make good earth. To make the best earth, is to carry your conductor undergronnd—away to water, if possible. If not able to do so, get a good clay soil, on which lay a bed of coke; wind the conductor round a large iron plate, and solder it on, laying the iron plate on the bed of coke, and then again covering it with coke; this will give you the best possible earth. I may mention that the cable testing wire for earth connection ought to have the resistance of 1 ohm.—DERBYSHIRE.

[47265.]—**Forecast of Storms.**—About the best book you can read is "Weather Warnings," Houlston and Sons, London. If you read this through several times, you will know more of weatherology than you appear to know now; but don't prophesy until you have made at least 50 entries that have all come true without one failure: then you will be on the right track. Don't endeavour to go further ahead than one day, or you will be wrecked.—W. J. LANCASTER.

[47265.]—**Forecast of Storms.**—My barometers were made as followz:—Two pieces of soft glass tube ⅜in. diameter were sealed each at one end by means of a spirit-lamp; next, one piece was bent about 7in. from the sealed end into a U-shape, allowed to cool, and then filled with mercury; it was then heated in the spirit-lamp until air-bubbles were expelled, and as soon as cool enough to handle the end was sealed. In this manner I had a glass rod 32in. long and turned up 7in., full of mercury, sealed at both ends. I afterwards discovered that good sealing-wax would effectually close the shorter limb if the after operations were carefully conducted. This mercury tube was sealed and suitably framed, the short end was opened by means of the spirit-lamp, and a register for three months was made out and filled up day by day, as my barometer indicated, and in three months I found that storms had passed over us as follows:—September 15th, 1880, an interval of 20 days and storm 5th October; interval of 22 days, storm 27th October; storm 14, 16, and 18th November. Interval of storms then appears to be about 20 days. I again made out a three months' register, with this result—November 18th to December 29th, a double period of 41 days and storm period light, but compensated in 19 days by the great snowstorm of January 17th and 18th, 1881. I next found the storms accelerated during the summer solstice, so that the interval was shortened to 15 or 17 days, and would ask my querist to look through pages 122 and 123 of E. B. Denison's "Astronomy without Mathematics," where he may find a reason for the difference thus noted. But return to our other tube left sealed at one end, then half filled with water, then bent in the spirit-lamp similar to the other tube, next drawn out even and straight, so that the short limb was no thicker at its termination than a pin such as ordinary stockings are knit upon. A turn or two brought sufficient water in my narrow limb of 8in. long, then it was framed and scaled, and hung in a cool shady place, and found to give unerring indications of coming rain, and especially thunderstorms. The two instruments are hung side by side. They are both valuable: the mercurial gives pressure only, while the water-glass gives notice of local rains, &c. If my querist sends me a stamped envelope for reply, he shall have diagrams of past storms, which will show him at a glance what my discovery is. A gentleman F.M.S. wrote me that he used the method, or interval of 20 days, but that certain others of the Meteorological Society wanted no information from outsiders. In reply, I would say, if they have secrets relating to weather science, that such secrets are likely to be discovered. It is singular, but true, that our worst storms have not been foretold by the scientific meteorologists, with all their first-class apparatus.—W. M. Gardner, Byfield R.S.O., Northamptonshire.

[47270.]—**To Mr. Lancaster.**—You can take the front lens to pieces, but be sure that it, the fog, is between the lenses; often the front surface of flint has an oxide on it giving it a foggy appearance; this you cannot remove. If it is between the lenses, then put lens on a plate and place in a warm oven, then when quite warm you will be able to slide the top lens off; clean when cold with turpentine, and re-cement with clean Canada balsam—bake until the balsam round the outside of lens is hard, then allow to cool; clean the balsam from round lens and put into cell again.—W. J. Lancaster.

[47275.]—**Oak Graining.**—You have nothing to do with umber mixed in table-beer; but first paint the ground the tint you require—if light, using white lead and yellow ochre; if dark, adding Venetian red or burnt umber; in fact, many pigments like sienna, burnt and raw chrome, Oxford ochre, &c. You can buy the graining ready made, or you can make it by grinding up burnt umber and raw sienna, or Vandyke brown instead of the umber if it is required dark; thin with equal parts turpentine and linseed oil. The beer business is for distemper work. Why don't you get one of the handy-books on painting, which will give sufficient hints to start you, and if you looked through back volumes of "ours" you would find many hints.—T. P.

[47275.]—**Oak Graining.**—Get a pint of linseed oil and a pint of turps mixed for thinnings, ¼lb. dryers, ¼lb. raw umber ground in oil, and half a ball of whiting. Mix whiting to a stiff paste with thinnings, then place it and the dryers in paint-pot, adding half the umber. Mix well together, then add about a pint of thinnings. When well mixed try it; if too light, add umber; if dark, add thinnings. When got to proper shade, rub a little on and comb it; if the combing shows a tendency to run, add more whiting till it has body sufficient to stand the comb, remembering at the same time that the principal thing is to rub the colour on evenly, which cannot be done unless it is very thin, and even then it requires a lot of practice with the brush to be able to do it nicely. The only difference between light and dark oak is the quantity of umber or other stain used in mixing, the whiting or dryers having no effect on the shade, merely forming the body. To overgrain it rub down with wash-leather damped with whiting and water, then take vandyke brown ground in water. Mix it very thin with beer and water, and darken styles and shade up where required, using a sponge to wipe out the lights and a badger to soften. Don't try to shade it up too much, as you are very liable to get it patchy: but keep it as quiet as possible, then nothing but the want of skill will prevent you doing it well.—E. Coker.

[47276.] — **Electrical Indicator.** — If "Troubled" will call or write me, I shall be happy to show him just the instrument he requires, also an electric water-alarm and register of the fluctuation of the same, as fitted to all locks on the River Thames. The apparatus he requires can be worked through a single wire, and reads the level to an inch for any depth, and can be fitted for a very moderate sum.—T. R. Brailsford, Thames Conservancy Office, 41, Trinity-square, E.C.

[47278.]—**Patented or Not?**—I made a tube magnet about fifteen years ago; it is no patent.—George Tolman.

[47278.]—**Patented or Not?**—Patented it is unless it has lapsed; but the patentee would scarcely fight the matter, seeing that the system was in use many years before the patent. Some applications of it might no doubt be patentable, but not the inclosing tube in itself.—Sigma.

[47279.]—**Spoilt Glass Shelves.**—Wash them in hydrochloric acid, then if that don't remove the cloudy patches, rub them with putty-powder (oxide of tin) and leather.—Albert Smith.

[47280.]—**Legal.**—It is really impossible for me to answer this question without having fuller particulars, as to the kind of name, and as to the terms of the dissolution of partnership. "G. B." begs the whole question by calling the foundry his own, when, up to the date of the dissolution, it was as much his brother's. If the brother went out of the business and left "G.B." the good-will, &c., he also left him the name, if it is not his own name, and he has no right to use it elsewhere. But I say this with reserve, as these points are difficult to decide in the dark.—Fred. Wetherfield, Solicitor, 2, Gresham-buildings, Guildhall.

[47281.] — **Tricycles.** — For good, all-round work I should recommend a double-driving chain machine, back steering, of the "Cheylesmore" style, where the rider is placed well over his work, and in the best position to utilise the greatest amount of power. Rotary motion is also much easier than lever motion, and friction is less than in lever machines. Challenge No. 1 is a very heavy machine, and not suitable for hill work.—Ariel.

[47282.]—**A Foreground Query.**—You should get "Hints on Sketching from Nature," by N. E. Green, published by Messrs. G. Rowney and Co. Get Part I., and read Chapters IX. and X., which will solve your difficulty.—A Student of Landscape Painting.

[47283.] — **Launch Tubular Boilers.** — The specific gravity of the water in the boiler should be under 1·087, as the salt commences to form scale above that point. The best plan will be to buy a cheap salinometer, about 2s., which is graduated to 32nds of saltness; at 3/32 a black line is drawn, and the density of the water should be kept below its flotation. As regards blowing-off, there should be two blow-off pipes to your boiler, one about half-glass, or ordinary water-level, and another at the bottom, both communicating with the sea. The first is a scum-cock, and should be used whenever there is a scum upon the surface of the water in the gauge-glass, that being a sure indication of scum upon the surface of water in the boiler. The bottom cock should be used, say, every two hours in sea-water, and if the feed-pumps throw sufficient water about ¼ of glass should be blown out, and salinometer tried for density and temperature. At specific gravity 1 087, it should boil in open air at 215° Fahr. I have found a good plan in such small boilers (in cases where the launch could stay for a couple of hours, at anchor or alongside a wharf), to draw the fire, save a small spark or so for relighting, then blow the boiler off, keeping the blow-off cock on after the boiler has ceased blowing, the vacuum that will exist within the boiler, will, by the external atmospheric pressure, cause the clean water to rush in through the blow-off, which shut when high enough in the glass gauge; fire up, and you will find that you have a clean start at a small expenditure of time.—Fred. Walker.

[47286.] — **Chromograph.** — Well soak your gelatine in cold water until soft. To every 2oz. of gelatine add 4oz. of glycerine and ¼oz. of oxide of zinc.—Albert Smith.

[47287.]— **Magneto - Electric Machine.** — When the bobbins are parallel with the magnet, the end of spring should be on the centre of the round part of the spindle where it is filed flat, but spring must not touch the flat part.—George Tolman.

[47292.] — **Bunsen Battery Connections.** — You can copper and solder a wire on, but it will need very careful protection against the acid. There is no reason why ordinary soldering flux should not be used in such a case, as it can be washed off; but rosin can be used instead.—Sigma.

[47292.]—**Bunsen Battery Connections.**—You might twist the wire round the top, and give a coating of Brunswick black, or drill a hole in the carbon and screw your wire into it. When you use spirits of salts, well wash the joints, so as to get rid of the acid.—Albert Smith.

[47292.]—**Bunsen Battery Connections** — Cast a leaden cap on top of carbons, inserting a piece of copper wire in the metal before it has set. Solder this wire to the one attached to the zinc. Spirits of salts may be used for soldering, taking care to wash off all traces of the salts afterwards. Arthur E. Morris.

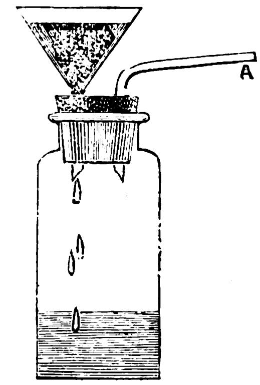
[47292.]—**Bunsen Battery Connections.**—If the carbons are of very hard stuff, drill a hole in the thickest end, tap it, and screw a brass terminal in. Have had some in use seventeen years, and are perfect at present. Carbons must be 3in. longer than porous cell, well waxed and varnished for 4in.—George Tolman.

[47292.]—**Bunsen's Battery Connections.**—Full instructions have been given many times in this journal for depositing copper on battery carbons. It makes a first-rate connection, if done as recommended by "Sigma." If you do not wish to use spirits of salts, all you have to do is to file some portion of the copper surface bright, sprinkle on a little powdered rosin, and solder in the usual way. I, however, never found the spirits of salts give any trouble; and it was much handier.—J. Hezmalhalch, Jun.

[47296.] — **Object-Glass Making and Correcting.**—As "J. C. L.'s" query on this subject really touches the very heart of the matter, and requires a lengthy explanation, I must ask him to wait some time yet. I have no doubt that he will find in the general description it is my intention to give in my letters on o.g.'s what he needs. I should like to read Mr. Godfrey's letters much; and thank "J. C. L." for his offer. Will he kindly send them to "Orderic Vital" for me?—Prismatique.

[47298.]—**Examination of Malt.**—Why not use a vacuum filter? They are very rapid.—Albert Smith.

[47298.] — **Examination of Malt.** — Rapid filtrations are usually performed by connecting the filter and its contents with a Bunsen or other form of filter-pump. When the pump is started, the air within is exhausted and a vacuum is formed; the pressure of the atmosphere on the surface of the liquid causes it to be rapidly forced through the filter. As filter-pumps are expensive pieces of apparatus, and, most probably, the querist will prefer something cheap, I will tell him how to make an affair to fulfil all requirements for a few pence. Get a large wide-mouth bottle, of about 60oz. or 80oz. capacity; fit it with a perfectly sound cork, through which bore two holes; in one hole insert a piece of bent glass-tubing and into the other the funnel. The filter is placed in the funnel, and the liquid to be filtered poured in; the mouth is then applied to the tube A, and the air sucked out; the atmospheric pressure forces the liquid through into the bottle. Too much pressure must not be applied, as it is apt to break the bottom of the filter-paper. A small cone of platinum-foil, pierced with holes, will prevent this accident.—Arthur E. Morris.



[47300.]—**Proportions of Cylinders.**—The rule for finding the proportion of the L.P.C. to H.P.C. in compound engines, is to divide the area of large cylinder in square inches by square root of rate of expansion; result, area of small cylinder. Still it is difficult to go into calculations on compound-engines without an elementary knowledge, at least, of algebra. The advantages of dry steam are (always presuming that superheating is not carried too far), increase of work done by engine, in consequence of pressure being raised; and in the case of well-lagged cylinder and steam-chest, considerable less loss by radiation than by wet steam, and the economy of the heating or drying process, which may be done by utilising the waste products of combustion before passing up the flue. The advantages of wet steam are: first, that it does not destroy the valve-face, cylinder, piston, and packing, like dry steam, nor does it require a superheater. I really am at a loss to answer your third question, without the aid of algebra; but I will cull an extract from Fairbairn's table that, perhaps, may suit your purpose—

Temp. of 1 atmosphere = 212° Fahr.
,, 2 ,, = 250 ,,
,, 3 ,, = 274 ,,
,, 4 ,, = 292 ,,
,, 5 ,, = 307 ,,
,, 6 ,, = 320 ,,

—FRED. WALKER.

[47301.]—**Vacuum Tubes and Coil.**—Your zinc is either broken, or the insulation is bad and the current escapes. Are the connecting-wires in contact properly?—GEORGE TOLMAN.

[47301.]—**Vacuum Tubes.**—The cause of dancing is an imperfect connection somewhere. The most likely place is at the loops of the tubes where the wire is simply hooked in.—SIGMA.

[47307.]—**Mildew on Vines.**—Have you tried permanganate of potassium? I think that might do. I have used it for other things.—ALBERT SMITH.

[47309.]—**Clarionet.**—1. The diameter of bore cannot be determined theoretically. In practice the following sizes are best:—C clarionet, 14·5 millimetres; B flat clarionet, 15·5 millimetres; A natural clarionet, 16·0 millimetres, although some makers bore all the set of clarionets at 15·0 millimetres. The objection to this is that the C clarionet is shrill, and the A clarionet too tubby. As to length of tube, C concert pitch takes a tube of 6¼in., 12½in., or 25in. long if perfectly cylindrical. As to holes, their position depends on their size, the lowest hole being half a tone higher than the cut-off tube, the highest hole being at least one tone high. They must also be placed in a geometrical ratio as to distance. There are no books on the subject that I know of. Boehm's book on the construction of the flute gives a few rules; it is published in German, at Munich; but if "Old Blowhard" chooses to advertise his address, I will give him some information on the subject.—VULCANITE.

[47312.]—**Dynamo-Machine.**—Make the F. M. of the form I described a fortnight ago, p. 354, in cast iron. The wound part must be 12in. high × 3 × ⅜. Perhaps you can fit it to your old pole-pieces, but don't spoil the machine on account of the old pole-pieces; better in one piece. Wind on 16 times the total length of wire of armature and the same gauge as a "shunt" dynamo. More advice if required.—GEORGE TOLMAN, Wolverhampton.

[47313.]—**Tartaric Acid.**—This acid often contains lime. When this is the case, it fails to dissolve in alcohol. It also contains bitartrate of potassium; in this case a residuum of carbonate of potassium is left upon ignition. It should not give a precipitate with chloride of barium. Carbonate of sodium sometimes contains sulphate of sodium, chloride of sodium, and the effloresced neutral carbonate.—ALBERT SMITH.

[47313.]—**Test for Soda Bicarbonate and Tartaric Acid.**—"Commercial purity" is a rather elastic term to apply to chemical substances. What is required, I presume, is to find out if they contain an extra amount of impurities. Soda bicarbonate, the commercial salt, usually contains a little sulphuric acid and chloride. The former is found by supersaturating the liquid with nitric acid, and adding baric chloride, when, if sulphuric acid be present, a white precipitate will be thrown down. The chloride is tested by adding nitric acid, as in previous case, and then argentic nitrate, with which it forms a white precipitate. The impurer varieties contain, in addition to the above, sulphide of sodium and sulphite and hyposulphite of soda; extract these by adding dilute sulphuric, and passing evolved gas through a solution of plumbic acetate. The precipitate formed ought to be white (carbonate of lead), not brown; also, no sulphur should be thrown down on addition of the sulphuric acid. Tartaric acid: The only impurities likely to be found are lime and sulphuric acid: the lime to be tested for by adding ammonia until the solution is neutral, and then ammoniac oxalate; the sulphuric acid by same method used for the soda. The commercial acid is generally pretty pure.—ARTHUR E. MORRIS.

[47314.]—**Rotation of the Earth.**—As the rotation of the earth makes the day, clearly the earth rotates just as many times as there are days—365, or 366 in a leap-year.—E. D. S.

[47314.]—**Rotation of the Earth.**—The querist is right in supposing that the Earth's rotation in space is different by one day in the year from its rotation round the Sun. The time of one rotation in space, as determined by watching transits of stars, is called a sidereal day, and of these there are 366 to the solar year of 365 days. If the querist will watch any star, he will see that it arrives at a given point, or at the meridian, about 3min. 56sec. sooner every day—that is, about 1-366th of a day less than the solar day. This is, of course, equal to the amount of the Sun's motion as seen from the Earth) among the stars.—PLONI ALMONI.

[47315.]—**Harmonium Pan.**—If "Gotha" has never made a harmonium pan before, I should advise him not to commence making one for 2½ sets of reeds. Let him first try his hand at one for one row of reeds, then, if he is successful in that, he will have gained some experience, and be better able to accomplish what he desires to do. To make a pan properly requires practice and some degree of skill. Harmonium pans should be made of well-seasoned wood, as any warping will render it useless. It is one of the most particular parts of the harmonium. Good pans can be bought cheap enough, and if you purchase one for 2½ sets of reeds it will save you a deal of trouble. Should "Gotha" be determined to make one himself, he will find all necessary instructions in back volumes. A pan with beech veneers is preferable to one constructed entirely of pine.—G. FRYER.

[47316.]—**North Pole of Electro-Magnet.**—You can wind from either end. The polarity depends on how you connect the battery.—GEORGE TOLMAN.

[47316.]—**Electro-Magnet.**—If you wind the wire in the direction of the hands of a watch facing you, that is a right-handed helix; if connected to the positive pole of battery, that end will be south. The negative connection to either end makes it north.—SIGMA.

[47317.]—**Lewis's Incandescent Gas-burner.**—I cannot give the particulars sought for; but if the querist wishes I can put him in communication with the parties concerned in the matter who could give him the information.—J. T. SPRAGUE.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

Durability of Tubes.—In a recent paper read before the Institution of Civil Engineers of Ireland, by Mr. Martin Atock, the following is given as to the cost, durability, and efficiency of iron tubes, as compared with brass tubes of the same dimensions, viz., 10ft. long by 1¾in. outside diameter:—The iron tubes being 13 w.g. thick, and the brass tubes 10 and 12 w.g. thick, one iron tube would weigh about 18lb., and one brass tube about 22lb. Assuming 200 tubes to one set, then one set of iron tubes = 3,600lb., at 4d. per lb., £60; interest on £60 at 5 per cent. for 10 years, £30; credit for old tubes, *nil*; total cost of a set of iron tubes, £90. One set of brass tubes = 4,400lb., at 8½d. per lb., £156; interest on £156 at 5 per cent. for 10 years, £78; total, £234; less Cr. for old tubes = 2,200lb. at 4½d. per lb., say, £44; total cost of a set of brass tubes, £190. Both iron and brass tubes are credited with a life of ten years, which is about correct for a running of 20,000 train-miles, average, per annum, and where there are no unfavourable circumstances to affect either metal. Iron tubes are equal in durability and efficiency with brass in cases where the water was not injurious to the iron, and where it was comparatively free from lime. Surface water from bog land seems to suit iron tubes best.

Magnetic Bricks.—Some old bricks having been observed to affect the compass-needle by Herr Kepner, at Salzburg, in the Tyrol, he then had two bricks made from each of eight varieties of clay in the neighbourhood, one brick in each case being baked. The unbaked bricks did not affect the needle, but seven of the eight baked bricks proved polarly magnetic. Some further experiments have been made by Herren Kell and Triontl. Particles of powder of the magnetic bricks adhered to a steel magnet. Breunerite, mica-slate, argillaceous iron-garnet, chlorite, and hornblende were, before heating, unmagnetic, but intense heating produced a magnetic polarity, the axis of which seemed to be perpendicular to the plane of stratification.

QUERIES.

[47318.]—**Ink-Stains on Carpet.**—I should be glad if any of our readers could give me a reliable recipe for a preparation to remove ink-stains from a light-coloured Axminster carpet, if possible without taking it up, without damaging the colour?—NUDA VERITAS.

[47319.]—**Ordnance Datum.**—Would an obliging geologist tell me the meaning of "Ordnance datum," and what is the level of the water in water-bearing strata with regard to the sea-level? Does the water-level pass below Ordnance datum?—CRYFAX.

[47320.]—**Portable Target.**—Can some reader inform me what thickness of steel plate will repel a bullet from a rifle at 100 and 200 yards, and what weight per sq. ft.?—as I want to make a portable target, light and strong for rough usage.—YRNEH NAMSIAH.

[47321.]—**Electro-Deposition of Carbon.**—I have been experimenting in a small way, and have obtained a brilliant black deposit on zinc which adheres firmly; on copper it was not so satisfactory, but I am not quite certain in my own mind if it is pure carbon. Will some one kindly tell me how to proceed to arrive at a certainty? My apparatus are few and not adapted to quantitative analysis. The black deposit will not dissolve in any of the acids.—ZELIA NAIEN.

[47322.]—**Injured Thigh.**—To DR. EDMUNDS.—Some years ago playing cricket I got a severe blow of the ball in the thigh or groin, and after a little it swelled up and came to a suppuration, but healed up, and I have had not any trouble from it since, until a few weeks ago, when I felt it sore to the touch, and it became swollen again, and appeared as if it were going to suppurate again. I do not feel it sore unless anything hits it or it is pressed. I think at first the discharge was not fully drawn away, as it did not recede down quite level with tht skin after being healed up. My health has been always good, and is so at the present, and I am, and have always been, an abstainer from drink and tobacco, and have always minded health and cleanliness.—S. J.

[47323.]—**Steam Launch.**—Will some kind reader be good enough to give a specification, and, if possible, diagrams for the construction of a steam launch 22 and 24ft. long over all, stating strength of ribs, depth of keel, h.p. of engine, size of boiler, and giving a design for stern-post, together with all necessary particulars?—AJAX.

[47324.]—**Sketching-stool.**—Would any kind friend explain how the legs of the above are bolted or otherwise joined? The stool has three legs, and folds up as a round stick; it has webbing for the seat.—S. TAVENER.

[47325.]—**Street Medical Coil.**—To MR. LANCASTER.—Seeing that your hand is all right again, would you kindly give me full instructions how to make a street medical coil, as you promised me that you would about six months ago?—F. ROWE.

[47326.]—**Traction-Engine.**—I have a traction-engine laid in at my mill, and when it is at work with the reversing-lever full over, there is a loud blow heard at each end of the stroke, which entirely ceases when the lever is pulled up to within two notches of the centre, in which position it is usually worked. Would someone please tell me the cause and the cure?—DUSTY.

[47327.]—**Colouring Steel without Heat.**—I shall feel obliged if any reader will tell me how to make the blue, also the straw-coloured, composition which tool makers apply to new steel goods, such as chisels, choppers, &c. I have a quantity of slightly-rusted spectacles that I do not want to have to rub down and repolish: so shall be glad to have a hint anent the foregoing.—ALFOJOE.

[47328.]—**Siemens Armature.**—Thanking Mr. Tolman for his reply to the above, will he please say if No. 16 wire will not do instead of No. 14 for winding on armature, for I have 550 yards of this already? How many layers would it be advisable to wind on the above to obtain the best results if the armature was constructed as follows?—The shaft to be hollow (hole 5-16) and connected to inside of core by several holes; core to be wound in twelve sections with a division between each, and in these divisions several 1-16 holes are drilled—this to allow the air to circulate and keep the core cool. Should the commutator be constructed on Siemens' present principle or his old one?—ENGINEER.

[47329.]—**Boat-Building.**—I am a working man, age 40, married, without children. I have lately suffered a good deal in health, especially in my head, and I have a great fancy that living on the sea for a time would do me good. To this end I have been thinking that I could build a sailing-boat myself, in which, with my wife, I could take short trips round the coast from port to port, and perhaps run over to France or to Norway, and some other ports not far off, living and sleeping on board always, as it seems possible to live a few months very cheaply in this manner. I thought of building my boat about 25ft. long, 8ft. wide, 4ft. deep, of best yellow deal. I have an engine 4 h.p. Could I put this in to work a screw with advantage, or had I better depend on sails alone? Should I find any difficulty in building a suitable boat or in managing it after it was built? I am fairly handy with wood-working tools, but have no special knowledge of boat-building. I shall be very grateful to anyone who will give me practical advice in any of the above matters; more particularly as to size of boat, how to build it, the practicability of having both steam and sails, cost, and as to the difficulties of navigation? I may say I could not spend more than £20 altogether in fitting out the boat.—A WOULD-BE JACK SALT.

[47330.]—**Leaking Vats.**—I have a square wooden vat holding about a thousand gallons of liquid that corrodes metals. Could any reader inform me how to stop the joints from leaking? I have had them caulked, but that does not prevent it, for when the vat is empty I have to fill it with water to swell up the joints before I can use it again.—MANCHESTER.

[47331.]—**Brakes on the Midland Railway.**—With respect to the subject of continuous brakes, which is being so ably discussed by Mr. Stretton in your columns, I should like to ask him if it is true that the Midland Railway Company are about to remove the Westinghouse brake from their Scotch expresses and to substitute the automatic vacuum? I have noticed lately that the "M.S.J.S." carriages and Pullman cars have been fitted with the vacuum brake. I thought at first that the stock was fitted with connecting pipes only; but on inquiry I learnt that they were fitted with the brake itself. The Westinghouse has not yet been removed. A driver told me that the Westinghouse had been removed from engine 816 (one of the large express engines), and the vacuum substituted; also, that the Midland Company had sent fittings to the Scotch Companies which run in connection with them.—METEOR.

[47332.]—**Engine and Boiler for Small Boat.**—Will some reader give me dimensions (with sketch, if possible) of engine, boiler and screw for flat-bottomed boat 14ft. by 3ft. beam by 1ft. 6in. depth?—E.

[47333.]—**Drowsiness.**—I shall be greatly indebted to Dr. Edmunds for his advice on following: About four hours after rising every morning I feel a peculiar tightness and heaviness in the head, accompanied by a drowsy stupid feeling and loss of memory; the brain apparently becomes exhausted and ceases to act, so that it is impossible to work out a simple sum in arithmetic. Symptoms (aggravated by aperients) commenced seven years ago upon recovery from typhoid fever, when I was largely dosed with quinine to recruit strength. Having a large family dependent on my health, consequences are becoming serious. Age 35, spare, but apart from above, healthy, though not muscular; appetite good; total abstainer, non-smoker; occupation sedentary; hours 84 per week. Any assistance will be gratefully appreciated by a—POOR SCRIBE.

[47334.]—**Stiffness in Foot and Leg.**—To DR. EDMUNDS.—I have a pain in my right foot below the ankle when I do much walking, and upon rising next morning can hardly put my foot to the ground from stiffness, until such time as I walk it off. I find by rest and letting cold water run upon it, and using Elliman's embrocation, that it gets much better; also, if I sit cross-legged sometimes I feel pain as if pressing a leader. Can you tell me what it is or what I can do with it? It has troubled me now for the past six months.—G. F. F.

[47335.]—**Packing.**—Will any able correspondent inform me whether valve spindles and piston-rods, &c., that are packed with soap packing should need any oil or tallow to lubricate them? I have always understood that soap packing is a self-lubricant.—R. T. B.

[47336.]—**L.B. and S.C.R. Locos.**—Shall be glad of leading dimensions of Plumpton, 345, Beaconsfield, 211, 303?—H. S. P.

[47337.]—**G.E.R. Locos.**—Shall be glad of dimensions of Nos. 602, 305, and 580. Also, are the old eight-wheel tanks numbered 140—159 broken up, as I see new tanks built by Hawthorn numbered the same?—H. S. P.

[47338.]—**Leclanche Battery.**—I have had a battery of four Leclanché cells given to me. They have not been in use for about three years, so that I think they want a good clean out: the zinc rods are nearly all eaten away, and the porous cells are made of a kind of canvas. Will any correspondent tell me how to put them in working order, and whether I should change the canvas cells for the ordinary earthenware ones? Also, please say whether the four cells would work more than one electric bell?—J. W. B.

[47339.]—**Lameness.**—To DR. EDMUNDS.—Will you kindly give me your advice?—Two months ago I fell and hurt my knee. I was walking along the street when I trod upon a piece of orange-peel. I fell backwards with my foot under me, and my knee was bent right back; it seemed as though there was something tearing just down the left side of the knee-cap. I got up, but could not walk, it was so painful. I was taken home, and was bedfast five weeks. I have been walking about three weeks, but it does not get much better, although I can stand with all my weight on that leg without any pain; but when I commence to walk and bend my knee it pains me very much, and makes me walk as though I had a stiff leg. I may add it is a little swelled above the knee-cap, and my knee is slightly bent; age 24, and by trade a—MILLWRIGHT.

[47340.] — **Silvering Mirrors.** — Would Mr. Brashear, or any other friend, kindly inform me what proportion of water can be added to the 4oz. of solution—viz., 50oz. nitrate of silver to 2oz. water, 50oz. potassa to 2oz. water, or what per cent. of water can be added so as to procure a good film? If a standard per cent. of water could be given for this, it would easily be known what proportion of the solution would be required for a bath containing 50, 60, or 100oz.?—PRISM.

[47341.]—**Electric Locomotive Engine.**—I wish to make a small electric loco. engine about 1ft. long, and would feel obliged to any of "ours" who would kindly give such information in our valuable paper as would enable me to construct the above, having a good lathe and tools at command. I wish to make it on some modified dynamo-machine principle. A diagram would greatly assist.—GALVANI.

[47342.]—**Dialyte Telescope.**—Not so very many weeks ago Mr. Ingall was kind enough to send to the "E. M." a letter on astronomical subjects, and spoke of his observations having been made with a dialyte. Would Mr. Ingall oblige the readers of your journal by giving a description of this instrument, especially the foci and positions, &c., of the intermediate lenses for correcting the chromatic and spherical aberrations? And would Mr. Ingall also kindly inform us something about its performance on the planets—Saturn, Venus, and Mars? It is upon record that some of the very large and costly telescopes were excellent rather for showing minute stars and dividing close doubles, than defining planetary detail.—ARTHUR HINDE.

[47343.—**Rheumatism or What?**—Will Dr. Edmunds oblige by giving his opinion on the following? About six or seven months ago, when walking a considerable distance, I took a pain in the thigh, which next day extended down the outside of the back part of the leg, principally at the part above the knee, the calf, and the muscle behind the ankle on the outside of the leg. It continued more or less for a few weeks, after which I began wearing two pairs of drawers, when it got almost quite well. About three months ago it came on again when walking, and yielded to the same treatment. About 10 days ago it again returned during a walk of about twelve miles. This time it began about the sole of the foot and extended upwards, and still gives me a good deal of trouble. In some positions it is quite easy, and in others very painful. About seven years ago I had a pain in the other leg something like, but not altogether the same. My doctor said muscular rheumatism, and laid me up a month, when it was cured, and did not return for three years; when another doctor said sciatica, and laid me up a week, when it was better, and has not since returned. I cannot lay myself up or give up walking a good deal unless absolutely necessary. If you can help me I shall be very grateful.—HIGHLANDER.

[47344.]—**Small Dynamo-Machines.**—To MR. TOLMAN.—There are several questions I should like to ask about your small dynamo described last week which, I am sure, would interest many other readers of the "E. M." besides myself: 1. How are the wires from the armature joined to the commutator? 2. Does the current from one brush traverse the coils of the field-magnets and then run to one binding-screw on the top of the machine, and does the current from the other brush run directly to the other binding-screw? 3. Would there not be more power if there was a second armature at the top of the machine to supply the field-magnets alone? 4. What would be about the cost? 5. How much wire do you put on the field-magnets and armature? 6. How many Bunsens is it equivalent to, or what amount of light would it give in an arc or Swan incandescent lights?—SEAWEED.

[47345.]—**Indelible Stain for Stone.**—I want an indelible stain for stone so that the rain will not wash it off, either opaque with a body or transparent. How do dyers and clothprinters make the colours fast? Could not some mordant be used by which brick or stonework could be coloured in the same way and be washed down if necessary without coming off?—J. HARTSHORN, Kennington.

[47346.]—**Boomerang.**—Can anybody explain to me the scientific laws which govern the flight of the boomerang—the weapon of the Australian natives?—BUSHRANGER.

[47347.] — **The Moon's Declination.** — By Whitaker's Almanack for 1882, I find the declination of the moon varies greatly from day to day (from 21° 13′ 4″ N. on July 12th to 21° 5′ 27″ S. on the 27th); that the total variation is less in winter than in summer, and that the daily variation progressively increases or diminishes. I suppose it to be owing in great part to the inclination of the ecliptic to the equinoctial line, but should be glad if "F.R.A.S." will kindly explain, and what effect the inclination of the moon's orbit to the ecliptic has in the above. I find no mention of it in any book I have, nor in the letters of "F.R.A.S." on the Moon in Vol. X., with which I have been greatly interested.—J. C. L.

[47348.]—**Bending Copper Tubes.**—What is the practice of coppersmiths in making bends of 6in. radius in copper tube of $\frac{3}{8}$in. external diam.? I tried various ways, but failed to avoid dents on the inside of the bend.—SALOP.

[47349.]—**Dry-Plate Queries.**—(*a*) Pyro development.—What are the processes in the manufacture of dry-plates that determine why, in development, some require more pyro.—some more ammonia—than others? Does the "rapidity" of a plate regulate the proportions of ingredients in the developer—e.g., does a very rapid plate, as such, need more or less pyro. or ammonia or both than a slow one? (*b*) Oxalate development.—What is the effect of an excess of either ferrous sulphate or of neutral potassium oxalate? Assuming the proper proportion of these to each other to be employed, what is the effect of using it in strong or weak dilution—e.g., does a weak solution of ferrous oxalate give a weaker negative, or is it merely a slower developer than a strong solution?—W. H. S. W.

[47350.]—**The Baths of Wildbad.**—Dr. Pigott has benefited Wildbad by his authoritative approval of its baths, but humanity generally (i.e., those most deserving, to wit, the readers of the "E. M.") would be better served if by the doctor's agency the waters could be obtained in bottles or casks, thereby saving the expense and loss of time which a visit to the baths would entail. It would be interesting to know the analysis of the water, temperature, &c., and whether the waters could be used advantageously with apparatus at home, whether they would keep fresh, and how long; what the water would cost per hogshead, &c.? I don't think we should allow our reason to be baffled as long as there is a prospect of knowing the "reasons why, &c."—D. H.

[47351.]—**Mathematical.**—The writer will be extremely obliged if any of your mathematical correspondents will give a complete proof of the following:—

In the expansion of $(1 + x + x^2 + \ldots\ldots\ldots + x^r)^n$.

Where n is a positive integer, show that (1) The coefficients of the terms equidistant from the beginning and the end are equal. (2) The coefficient of the middle term, or of the two middle terms, according as $n\,r$ is even or odd, is greater than any other coefficient. (3) The coefficients continually increase from the first up to the greatest.—Todhunter's "Algebra," ed. 1877, chapter 37.—A. B.

[47352.]—**Ink.—Sealing Wax.**—Could any correspondent oblige with a receipt for a good quick-drying black endorsement ink that will not injure rubber stamps? Also, how to make green sealing-wax? Will an earthenware pipkin do to melt the ingredients in, and how formed into sticks? There is a receipt in a former number for wax, but it does not say what to melt in or how to form into sticks.—COLLODIAN.

[47353.]—**Gelatine Plates.**—Would any reader give me information as to the cause and cure of green fog in home-made plates? It was stated in a back number that insufficient washing was the cause; but I do not find any amount of washing get rid of it. Treating with bichromate of potash and hydrochloric acid before washing will take it away; but I don't like the remedy—it causes other faults. I make my emulsions by stewing at a low temperature for a long time with ammonia and by boiling, and by all three processes get this green fog, the shadows otherwise quite clear. I can dissolve it out of the plate after development, but that is not what I want. I wish to remedy the fault in the emulsion, and which, I am told, is a trade secret.—X. X. X.

[47354.]—**Green Stains for Deal and Other White Woods.**—I have tried without success to stain deal with a solution of one part verdigris and four of water. When sandpapered the stain comes off as fine green powder, and the wood remains but very slightly coloured. I want to obtain a good green that will eat into the wood. Will some practical contributor to ours solve the difficulty?—A. T. F.

[47355.] — **Excessive Perspiration.** — If Dr. Edmunds, or any reader of the "E. M.," can propose a safe remedy for the above, he will confer a boon on a patient whose infirmity the skill of several medical practitioners has signally failed to cope with. Atropia has been administered internally and injected subcutaneously. Sponging with dilute vinegar has been practised for upwards of six months without sensible effect. Tonics have been taken ad nauseam. Indeed, a month of entire cessation from all kinds of exertion mental and physical) and abandonment during that period to medical treatment has resulted in no appreciable benefit. The patient is about 45 years of age, engaged in sedentary office-work, is of strictly temperate habits, married, enjoys good general health, is singularly free from all such ailments as headache, indigestion, bile, flatulency, or any of the complaints most commonly heard of, but has a very rapid pulse, which he is informed arises from no organic disease or defect. He has suffered, but heedlessly, from an immoderate flow of perspiration on the slightest extra exertion or increase of temperature from whatever cause for upwards of 25 years, and has, during that time, often bedewed the surface of snow more than 6in. deep with sweat stained by the dye from his hat, from the brim of which it dropped as from an eaves-gutter after a rapid walk of half a mile. Having hitherto endured no observable inconvenience beyond the temporary discomfort of such a condition, he treated the matter lightly until informed lately that in advancing years nature would lose a certain capability it formerly possessed of withstanding the deleterious effects of what is pronounced now to be highly enfeebling and to absolutely require a check. This query is lengthy, but the facts stated will, perhaps, apologise for its length, and particularly if the additional remark is permitted that the case has been pronounced by several medical men to be, in their respective experiences, unique. If any reader has been subject to a similar ailment, and erived benefit from any source, a helpful hint from such would be gratefully received by the querist, who, singular to add, never perspires while asleep—i.e., is not subject to what is commonly termed "night sweats."—SUDOR.

[47356.]—**Cold Air.**—Can anyone give details of the arrangement whereby storekeepers or shopkeepers in Melbourne have a continued supply of cold air in any part of their premises? I have been told it is by pressure of water, of which, it seems, there is a good supply.—E. FITCH.

[47357.]—**Malleable Castings.**—Will anyone tell me how malleable iron castings are made?—MALLEABLE.

[47358.]—**Shocking Coil.**—Will any reader say what should be the sizes and weight of wire on an induction coil to give shocks, the core and bobbin being each 6in. in length?—ELECTRICIAN.

[47359.]—**Broadwell's Breachloading System**—Can anyone describe the Broadwell breachloading system as used by Krupp?—STEEL.

[47360.]—**Battery for Electric Clock.**—Will someone be good enough to tell me, from personal experience, the best battery for driving an electric clock? The power I require is that of two gravity Daniells, the plates of which are 2½in. in diam. and 4in. apart, the circuit being closed for about $\frac{1}{3}$ of a second every alternate second. I have tried several batteries, but cannot find any superior to the gravity Daniell. I find that by tying the zincs up in parchment paper, which practically forms a porous cell, the consumption of zinc is greatly lessened, whilst the action of the battery is not injuriously affected. I am now trying the effect of tying the zincs up in calico.—H. B. T. S.

[47361.]—**Watch Construction.**—Will anyone kindly inform me what to do with the hair-spring of a watch when it loses time? Ought the spring to be let out more or drawn tighter, and how is this accomplished?—G. FRYER.

[47362.]—**Watch Dials.**—How are dials fixed to watches, and how are old dials removed to replace with new ones? I wish to know how to put a new white dial to a watch which, at present, has a cream-coloured dial, which I dislike the look of.—G. FRYER.

[47363.]—**Watch Cylinder.**—Will "A Fellow-Workman" kindly say how bottom pivot is put in cylinder of Geneva watch, the plut having come out? and oblige.—HALL.

[47364.]—**Silver Filagree Brooches.**—How are they cleaned so as to give them that nice white appearance as when new?—HOPEFUL.

[47365.]—**Gold Coins.—Rings.**—To "ALFOJOE."—I want to hard-solder gold ear-wires to American gold coins, also to mend some broken rings? Will you kindly inform me what quality solder to use, and how to clean the articles after? Will nine-carat rings want recolouring after being soldered?—How is it done?—HOPEFUL.

[47366.]—**Stammering.**—I wish to ask Dr. Edmunds if he considers stammering and stuttering curable, and if so, by what means. Some advice on the above painful complaint would be very acceptable, not only to myself, but to a great number of your readers.—A STAMMERER.

[47367.]—**Heating Apparatus for Greenhouse:**—Would a coil made from a 1in. pipe of 12ft. long, heat about 20ft. of 2in. pipes? Also, would the above coil and pipes be sufficient to heat a house 16ft. by 8ft. for cucumber growing? If not, should be glad of any practical information on the above.—R. H.

[47368.]—**Incandescent Lamps.**—A week or two ago a querist (47084) asked if he might use Leclanché cells instead of Bunsens to light an incandescent lamp, said to be lighted with two Bunsens. Now will this querist, or any other person, say if two Bunsens will really light the lamp, and if the lamp has a carbon filament? The Lane-Fox lamp is said to take 15 Bunsens, and to me two Bunsens seem very little. I was not aware any lamps were sold under 5s.—W. L.

[47369.]—**Preserving Mosses.**—Will any fellow-reader kindly inform me how I can preserve common field moss in order to keep its natural colour? I want it for use in mounting birds, &c.—E. Jowett.

[47370.]—**Dynamo-Machine.**—Will anyone possessing the requisite knowledge give his opinion of the following?—Gramme armature 5in. when wound with No. 16 wire, length of magnets 14in. between the A frames with cast-iron poles, magnets wound with 14 wire, speed 2,000 revols. per minute. How much wire will be required for magnets, and what candle-power may be expected?—W. L.

[47371.]—**Photographic.**—Could any correspondent explain what the "oyster shells" and opaque white spots on wet plates really consist of?—why do they remain white under iron developer? They cannot be dried nitrate silver, as many operators call them, or they would blacken in time. Is any effectual remedy for removing them known? I have some iodide of lithium which by keeping has become deliquescent, and liberated iodine, being now dark red colour. Could any correspondent advise a remedy to restore it so as to be serviceable in photography?—Shah Yehan.

[47372.]—**Lens.**—I have a double convex lens 1½in. focus which I want to convert into a 5in. focus by the addition of an unequal concave lens. The curve or focus of one side of the lens I want to fit the double convex lens. What curve or focus must the other side of the concave lens be to bring it to 5in. focus?—Focus.

[47373.]—**Old Cracked Varnish on Globes.**—Can anyone advise me how to remove this with the least injury to the paper? Under-scraping with a knife is apt to remove letters and figures.—J. C. L.

[47374.]—**Ulcerated Varicose Veins.**—Will some of our able friends give advice?—How I shall keep clear of the ulceration, and how to act if it shows signs of ulcerating? I have been clear of it for four years, but have suffered much pain and inconvenience for six months, twelve months, and five years at a stretch. The wound is at bottom of inner right ankle. I always stand on that leg, and am on my legs from 5.30 a.m. to 10 p.m.; a quick walker, and age more than 72, with a great deal of young blood left yet.—G. B.

[47375.]—**Lightning Conductors.**—To Mr. Lancaster.—Our factory-chimney is about 60ft. high, and in some alterations done at the bottom they have altered the lightning conductor, and now, instead of it going straight down, they have taken the conducting wire round the corner of the basement, and the wire presses on the stonework of the basement, and also on the corner of the brickwork. Will you please tell me if there is any danger?—William Clark, Beeston.

A Remarkable Gas Well.—The well finished in April last by the Niagara Oil Company, in Washington county, Pa., is one of the greatest gassers of modern drilling days. The sands found were not regular, nor as expected, neither did they appear to be oil-bearing. After a six months' struggle with the drill, a depth of 2,200 feet was reached, when a vein of gas was struck which threw the tools clear out of the hole, and more than fifty feet above the top of the derrick. The strength of the gas can be imagined when it is known that the tools weigh about 800 pounds. All work was then out of the question, as the gas made such a roaring noise that the drillers had to go away from the well fully 300 yards before being able to make themselves understood. The company have expended already more than 20,000 dols., and have nothing to show for their money but leases of 60,000 acres of land and the great gas-blower. The well is eight miles north of Washington, Pa., in Mt. Pleasant Township. It is just twenty-two miles from Pittsburg, and may be utilised by the latter city in case the supply does not become exhausted soon.—*Petroleum Age.*

The Hardening of Rubber Goods.—In the opinion of Herr W. Hempel the hardening of vulcanised indiarubber, which takes place with piping and other goods after a short period of use, is caused by the gradual evaporation of the solvent liquids contained in the indiarubber, and introduced during the process of vulcanisation. Herr Hempel has made experiments for a number of years in order to find a method of preserving the indiarubber. He now finds that keeping in an atmosphere saturated with the vapours of the solvents answers the purpose. Indiarubber stoppers, tubing, &c., which still possess their elasticity, are to be kept in vessels containing a dish filled with common petroleum. Keeping in wooden boxes is objectionable, while keeping in air-tight glass vessels alone is sufficient to preserve indiarubber for a long time. Exposure to light should be avoided as much as possible. Old hard indiarubber may be softened again by letting the vapour of carbon bisulphide act upon it. As soon as it has become soft it must be removed from the carbon bisulphide atmosphere and kept in the above way. Hard stoppers are easily made fit for use again in this manner, but the elastic properties of tubing cannot well be restored.

ANSWERS TO CORRESPONDENTS.

◆◆◆

⁂ *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

⁂ Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, July 5, and unacknowledged elsewhere:—

Foster and Williams.—Hickson and Co.—T. Fletcher.—Boyd Moss.—G. Pottier.—Rev. A. Willan.—R. E. Harrild.—J. B. Stephen.—Pat. Steam Boiler Co.—Rev. J. H. Cole.—Phosphor Bronze Co.—W. Granger.—W. Hayward.—Rev. W. H. Wright.—J. Mabson.—W. H. Nelis.—J. Stott and Co.—C. A. Day.—H. Merrifield.—H. Milnes.—R. Bailey.—F. Weatherhogg.—J. T. H.—H. Stooke.—Holmes Bros.—A Fellow of the Royal Astronomical Society.—Metal.—Bone.—Fellow Workman.—Sax.—G. R. T.—Antares.—M. B.—Mechanic.—Electra.—A Young Engineer.—H. J. Nolan.—Ll.B.A.—H. S.—C. Woodhead.

Dog Star. (It is the correction to be applied to the observation of any given observer—in other words, the fraction of time to be added to or subtracted from the time as given by an individual.)—A Fuming Microscopist. (We cannot undertake to say that it does; but we are certain it cannot improve vision.)—D. H. (The "Albo-carbon" is not a purifier, but an enricher of gas. See p. 17, No. 781, for an illustration of the arrangement. We know nothing of the other affair.)—Sportsman. (The easiest process is to heat the barrels until they are pleasantly warm, and then coat them with a paste of chloride of antimony and olive-oil. A little nitric acid hastens the effect.)—F. H. H. (Without knowing the construction of the lamp referred to, how can any one answer? 2. The dynamo would be cheaper and more durable. Secondary batteries are not required when the current is supplied by ordinary batteries. 3. First hand, of course. 4. Diffraction halo, due either to something in your eyes or to vapour in the atmosphere. Looking across a furnace chimney, or a flue from which steam is escaping would produce the effect.)—Plumber. (No, for the piston of the pump creates a partial vacuum, and the water consequently boils or gives off vapour at a lower temperature than when exposed to atmospheric pressure. Where boiling hot water has to be pumped, the working bucket is placed below the level of the water, so that the latter follows it by gravity.)—F. Feist. (The drill is a "spark" of diamond, mounted in a tube rolled up of thin tin. See p. 125, No. 343.)—S. Norman. (What do you mean by "chemical food"? See p. 70, No. 861. If you want the advertised preparation you must procure the patent specification.)—Air. (Certainly; several motors are at work. We do not know of any book specially devoted to the subject, but there are several papers on the subject in back numbers.)—Post. (The principal advantage is that plates can be carried about anywhere and developed at leisure.)—Fait. (If you mean the common process, that is done by pouring mercury over tinfoil and sliding the clean glass on, weighting down for some hours; but if you wish to silver glass you will find many recipes in back volumes. See the last index for instance.)—Halesowen. (Not if it is only kept for private use; but if used in trade probably you are compelled to put the name on.)—One that has been had. (You have no remedy, the month having expired.)—Audio. (If the wife is the sole legatee, the will is quite safe.)—Holiday Seeker. (By North-Western and South-Eastern to Dover or Folkestone, and thence by boat. You will find plenty of English boarding-houses.)—Hopeful. (Yes, can be had through any bookseller, or post free direct for 10d.)—Prismatique. (We have no choice; perhaps it would be as well to finish as we have begun.)—W. M. Gardner. (You seem altogether to misunderstand our correspondent, and really the few successful forecasts you mention can hardly be accepted as establishing the truth of your system.)—An Ex-M.R. Co. Fireman. (Dr. Edmunds would not advise in such a case, we are sure, without seeing the patient. He would probably do so at the Temperance Hospital if you sent your wife there. You should, at any rate, have some medical advice for her.)—Llynvi. (The duty is very heavy on such articles in America, but, on the other hand, you would have to pay more to buy on that side the water.)—A Subscriber, Brook's Bar. (What do you mean? If the Science and Art Department examination, procure the syllabus from the Secretary at South Kensington.)—Kent. (No, the coil is useless for the purpose, and at least six such cells would be necessary.)—Electrician. (Inserted.)—W. Coates. (1. No such cement is known. 2. Is there any starch in it? 3. Asbestos is a non-conductor, the other is a conductor. 4. If you really wish to know, apply to him for the address of the makers.)—An Amateur Polisher. (For full instructions in French polishing, see Nos. 814, 816.)—E. Clyde. (Given many times. See the indices—the last, for instance.)—Cabinet Maker. (We do not insert such inquiries as queries; but if you look in last week's "Sale Column" you will find what you want. The address must be advertised for if wanted; but we can tell you that it is in London. You can hardly expect the correspondent to advertise it.)—Argentometer. (Quite possible, but certainly not cheaper, and rather more troublesome from changes of temperature. See the discussion on sterling silver mirrors in Vol. XXX., and recent back numbers.)—T. T. T. (The composition referred to is made in the proportion of 4lb. glue to 1lb. treacle. Sometimes beeswax is added, ¼lb. to the quantity named, but to render the mould proof against the water in the solution it is immersed in a solution of bichromate of potash and dried in the light, or tannic acid is added to the compound.)—Mancunium. (Will not that described on p. 353 suit you?)—J. Caithness. (The quantity depends on the bore of the tube. All you have to do is to put the quicksilver in, removing the weight. You must adjust by some standard instrument, or a good aneroid.)—Student. (Isinglass dissolved in acetic acid and used warm is the cement recommended in the Physical Laboratory instructions at South Kensington. Cover the joints afterwards with glued paper. Weinhold, in his "Experimental Physics," recommends cutting the prism out of a glass lamp chimney, and closing the ends with flat plates.)—J. W. R. (All windows, doors, &c., should be closed, and the neighbourhood of fireplaces, especially on ground floors, should be avoided. A cellar is usually a safe place.)—H. Field. (The remedy almost universally adopted by the profession is an active purgative, followed by salt water injections.)—Kelt. (It depends upon you, not the book. The volumes issued in Collins and Sons Advanced Series will suit.)—Perplexed. (How can Mr. Wallis, or any one else, tell you what he thinks of your voice without hearing it? If you put the average at two octaves for men and two and a half for women, that will be approximately correct for the most distinguished vocalists.)—An Amateur Electrician. (There is no really satisfactory way of mending broken carbons; but if you take care that the edges join very closely you can keep them together by running a band of sealing-wax over the crack, making it about a quarter of an inch wide, but taking care that none gets in between the edges. Dust, to take the term literally, would be too fine, it would pack too close. Borings and broken turnings are suitable.)—Electron. (Please refer to indices. Several of both have been described.)—H. B. (Yes, certainly. The regulator is always full open whilst running, and the cut-off is regulated by the link. The point of cut-off depends on the load, the gradient, and to a certain extent on the driver. 2. It depends on which kind of catalogue you want. The list in Webb's "Celestial Objects" is quite enough for most amateurs.)—Cleaner, Salisbury. (Forney's "Catechism for the Locomotive" is an American book, which can probably be had of Trübner. Messrs. Lockwood and Co., Stationers' Hall-court, E.C., publish several works on Locomotives and Locomotive Driving; but without knowing exactly what you wish, we cannot pick out the book which would suit you best.)—H. Ashworth. (Probably you mean a notice of Hunter's "Mechanical Dentistry," a work which can be had of Messrs. Lockwood.)—Delta Sigma. (No such substance is known.)—B. B. (How would you propose to work it with another battery? You seem to have a very vague notion of the office of a contact breaker in a coil.)—Omega. (See p. 203, No. 867; p. 33, 808, and the indices generally. If you cannot do that, procure Watts's "Electro-Metallurgy," Lockwood and Co., Stationers' Hall-court, E.C.)—Retailer. (Your questions have been recently answered. See p. 237, No. 868, and the index of the last volume. For the cement, try isinglass dissolved in acetic acid, or shellac cement coloured to suit.)—Erin-go-Bragh. (It was illustrated on p. 14, No. 781. For numbers of specifications you must apply to a patent agent, or search the files of the *Journal* of the Commissioners of Patents, which you will be able to see in Dublin. The specifications, when number and date are given, can be obtained from the office for the sale of specifications, Cursitor-street, Chancery-lane, E.C.)—X. (Sutton's secondary battery was described on p. 414, No. 876.)—Engineer. (See answer to "Sportsman" above.)

Velocity of the Wind.—The mean daily motion of the air at Greenwich Observatory in 1881 was 291 miles, being 12 miles greater than the average. In January and September the mean daily motion was 70 miles and 72 miles below the average respectively: in April, August, and November it was 70 miles, 60 miles, and 71 miles above the average respectively. The greatest daily motion was 999 miles on October 14, the day of the great storm, and the least 59 miles on May 25. A velocity of 61 miles an hour was recorded on October 14, and one of 58 miles an hour on April 29, these being both greater than any recorded in previous years. The greatest pressure was 53lb. on the square foot on October 14; pressures of 46, 47, 47, and 48lb. were also registered during the same gale. On April 29 a pressure of 49½lb. was recorded at a time when the hourly velocity was 50 miles; the pressures corresponding to the maximum velocity of 58 miles an hour were not registered, the cord of the pressure pencil having slipped off the pulley.

The *Moniteur de la Flotte* describes a proposal for placing passing ships in communication with existing submarine cables. The projector would float buoys with the necessary connecting wires and apparatus at intervals of a day's journey along the line of the cable, each numbered and properly lighted at night, and he considers that the plan presents but few difficulties, and would obviate much anxiety and many dangers.

The Channel Tunnel works at Dover are being continued, it is stated, with very satisfactory results. The total length of the heading is now stated to be considerably above 2,000 yards.

SEHGUH.—We always acknowledge correct solutions.

J. W. STAINFORTH.—Your problem is too easy. It can also be done thus—

$$1. \frac{\text{Q to Q 7}}{\text{B to K 2}}.\ 2.\ \text{Q takes B, \&c.}$$

$$1. \frac{\quad}{\text{B to K Kt 2}}.\ 2.\ \text{B to K 5, \&c.}$$

PROBLEMS received with thanks from J. W. Abbott and J. P. Taylor.

A CHESS GARDEN PARTY.—Mr. Gastineau's annual gatherings are always attractive; but the one on June 27th was even more than usually so: the weather being splendid and a large number of well-known chess-players being present. Amongst them we noticed Rev. G. A. Macdonald and Messrs. Adamson, Coster, Laws, Marks, Webber, McLeod, and Lovelock. Games, consultation and otherwise, were the order of the evening, and the greatest satisfaction was evinced by all present—even the losers.

Holloway's Pills thoroughly purify the blood, completely cleanse the lungs, re-invigorate debilitated or vitiated nervous action, strengthen the muscles, and clear the brain. These excellent Pills are particularly recommended to all persons whose occupations are sedentary, or conducted in close rooms, and to the nervous, dyspeptic, and the low-spirited.

Every Workman connected with the Building Trades requiring a situation should advertise in "THE BUILDING NEWS," published every FRIDAY, price Fourpence, at 31, Tavistock-street, Covent-garden London, W.C.

"THE BUILDING NEWS" is the Principal Journal, representing Architects and Builders, and has the largest circulation of any Professional Journal in the kingdom.

Every Workman should insist on seeing "THE BUILDING NEWS" every week at his Club or Coffee House. He will find more "Lists of Tenders" for new work in it every week than in any similar paper, and can thus judge where work is likely to be had. He is also specially invited to make use of "Intercommunication" if he wants to know anything about his trade; to write to the Editor if he has any suggestions to make and to advertise in the paper when he wants work.

The charge for Advertisements for Situations is One Shilling or Twenty Words, and Sixpence for every Eight Words after.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post-free to any part of the United Kingdom. For the United States, 13s., or 3 dols. 25c. gold, to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 3d. each to cover extra postage.

Messrs. JAMES W. QUEEN and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post-free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. XXIV., XXVI., XXVII., XXVIII., XXIX., XXX., XXXI., XXXII., and XXXIII., bound in cloth, 7s. each.

[Vol. XXXIV. Now ready.]

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in March and September, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d each, through any bookseller or newsagent, or 2½d. each, post-free from the office (except index numbers, which are 3d. each, or post-free, 3½d.)

Indexes for each half-yearly volume up to Vol. X. (except Vols. II., III., IV., V., and X.) inclusive, 2d. each. Post free 2½d. each. Indexes to subsequent vols., 3d. each, or post-free, 3½d. Cases for binding, 1s. 6d. each.

*** Subscribers are requested to order Cases and Vols. through their booksellers, and not to send direct. The regulations of the post-office prevent their transmission through the Post.

CHARGES FOR ADVERTISING.

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen Words	0	6
For every succeeding Eight Words	0	6

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions; and in cases where the amount sent exceeds One Shilling the publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement and charged for.

Advertisements *must* reach the office by 3 p.m on Wednesday to insure insertion in the following Friday's number.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a PINK Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

OUR EXCHANGE COLUMN.

Oil and Limelight **Dissolving View Apparatus** for Screw-cutting Lathe, Twist Drills.—D. W. N., Ernest Cottage, Peyton-place, Royal Hill, Greenwich.

A one-horse **Water Motor** in exchange for a good Perambulator (rubber tires), or offers.—WM. O'BRIEN, 113, Haddington-road, Dublin.

Sociable **Tricycle**, for two or three persons, cost £24 nearly new condition. Exchange good Photographic or Dissolving View Apparatus, or offers.—WRIGHT, Photographer, Northampton.

Powerful **Intensity Coil**; for good Field Glass, model engine or offers.—SPENCER, 26, Dysart-road, Grantham.

Half-horse and one-horse **Engine Castings**, cylinders bored, &c.; or two-horse ditto. Offers.—JAMES SUTCLIFFE, Engineer, Princess-street, Granby-row, Manchester.

Medical Coil, Galvanic Battery, Engines, and Lathe, Castings, Field Glass, Screw Press, for Warping Flecks, ENGLISH MECHANIC, *Engineer*, &c. Offers.—JAMES SUTCLIFFE, Princess-street, Granby-row, Manchester.

Wanted in exchange, portable **Gas Bottles** in iron, and boilers.—JAMES SUTCLIFFE, Princess street, Granby-row, Manchester. Works, Levenshulme.

Have a number **Amateur Views**, very good, size about 19in. by 6in. Will send sample, 6d. stamps. What offers?—Address, PHOTO., 182, Trongate.

Will exchange my **Violin**, good tone, for Electric Lighting Apparatus, or what offer?—E. CLYDE, 6, Hale-street, Arlington-square, Islington, London.

Small Treadle **Lathe**, with tools, all iron, and watchmaker's throw. What offers?—11, Queen-street, Belgrave Gate, Leicester.

14 Vols. "**English Mechanic**," 3 bound. What offers?—A. H. VESEY, Knockholt, Sevenoaks.

I have a first-class **Wringing and Mangling** MACHINE, new, cost 50s.—What offers in exchange for it?—JAMES HARROP, Slip End, Luton.

1½ **H.-P. Table Engine**, feed pump, governors, &c. 7ft. vertical tubular boiler, water and steam gauges, nearly new, worth £30.—Exchange to value £25.—Apply, J. ELLIOT, Engineer, Kent-street, Portsea.

Tricycle wanted for a lady, recent make, perfect order, in exchange for a new Wheeler-Wilson's best cabinet sewing machine and extras, cost £16.—Full particulars, J. L. M., 106, Princes street, Edinburgh.

"**English Mechanic**," Vols. **XXI.** to **XXXI.**, bound, XXXII. to XXXIV unbound. All in first-rate condition. Offers wanted for whole or part.—H. CLARK, Inland Revenue, Cleckheaton, Normanton.

Two **Bicycles**, 48in. Singer's, tyres not cut, alarm, brake, &c., cost £3 15. Strong 46in. rubber tyres, cost £1 15s. Exchange for gold watch.—E. GILLARD, North-Curry, Somerset.

50in. **Bicycle Wheel**, good tyre, cranks, pedals, bearings. Exchange anything. Tools wanted.—Particulars, W. W., 82, Bayham-street, Camden Town, London.

Type, several founts, press and accessories, for amateur use. Offers requested. Optical work preferred.—L., 16, Addington-street, Ramsgate.

Astro. Eyepieces wanted for cash, or new books, or other exchange.—Address as above.

"Flat" or Plane **Mirror**, about 1½in., warranted perfect. Wanted for exchange.—Address as above.

Wanted, 6in. gap screw-cutting **Lathe**, for new Domestic Machines. Say what you want.—MONKHOUSE, Gandy-street, Exeter.

Horizontal **Engine and Boiler**, all fittings complete, 4 horse-power boiler, 9ft by 2ft. 7in. Exchange for larger. D. SCREEN, Wolverhampton.

Bicycle, 50in. Roadster, Singer's Special Challenge, suspension saddle, patent cycle bearings, front spoon brake (also trailing brake), good lamp, tool-bag, &c. Cost £13 two years ago. Exchange for Microscope, or good standard scientific books.—C. R., Junr., 9, Woodville terrace, Bradford, Yorks.

I will exchange my large 12-stop **Harmonium**, (slightly out of order) for Harmoniflute, or offers.—ROBERT VENNER, Lynton Villa, Erith, Kent.

Medical Coil and Battery, and two Electric Bells new. Will exchange for good Watch.—J. ASH, 75, Temple-street, Wolverhampton.

Prize Drawing.—First prize: new Printing Outfit, value £30. Second prize: Two Electric Lamps and Battery. Winners' names in E. M., 29 July. Tickets one shilling; 12 for ten shillings; 26 for £1. Will exchange for anything useful.—M. BARNARD, Henfield.

For Sale.

Lantern Photographs, 10,000, with readings, from 6d. plain, 1s. coloured.—A. PUMPHREY, Emily-street, Birmingham.

Gelatine Films for photographs, reduce cost and labour of photography to minimum.—A. PUMPHREY, Birmingham.

The **Filmograph** carries 100 films or 12 plates! Lightest Photo. Apparatus. Illustrated tests.—PUMPHREY, Birmingham.

Filmographic Manual, free 6d., with photograph from Film Negative. Full instructions. Films, Filmograph.—A. PUMPHREY, Birmingham.

100-Fold **Filmograph Slide**, can be used with ordinary camera. Plates changed anywhere.—A. PUMPHREY, Birmingham.

Collographic **Photographs** for Machinery and Trade Patterns. Sample and list for 2d.—PUMPHREY and DAY, Birmingham.

"**The Night-light Clock.**" Illustrated and described on page 370, No. 848. Price, carriage free, 5s. 6d.—F. ROBERTSON, 13, Greek street, Soho, W.

Stocks and Dies, now in extensive use. List one stamp.—F. M. ROGERS, 21, Finsbury-pavement.

Electric Lighting.—Inventors wishing to perfect, patent, or sell inventions connected with electric lighting should communicate with F. M. ROGERS, 21, Finsbury-pavement, E.C.

Micro. Photos.—List of 350 one penny stamp.—E. and A. DANCER, 436, Stockport-road, Manchester.

Lathes, Lathes, cheap good screw-cutting, from £10. Easy payments. Hire system. First-class tools.—MAKIN, Cupola, Sheffield.

Electric Machines, Indicators, Bells, Batteries, Wires, Switches, Terminals, Carbons, &c.—KING and Co., Electricians, Bristol. (List Twopence.)

Beautiful **Cloth Dress**, in all colours, price 8s., or 8d. yard. Patterns, one stamp.—FIRTH, Kirkgate, Wakefield.

Amateur Mechanics.—A complete set of Castings, Tubes and Lenses, for making large Compound Microscope, 12s. 6d., and instructions. Amateurs supplied with materials for Optical Instruments.—MASON, 38, Park-road, Clapham, S.W.

Saw, for cutting all metals, very useful, post free 15 stamps.—POOLE, 303, Fulham-road, London.

Stammering speedily and effectually Cured, personally or by correspondence. Testimonials from all classes.—VOX. M., Ward's Library, Grosvenor-road, Highbury, London.

American Organ Tubeboards, with Munroe voiced reeds. Reduced prices.—RAY, 86, Poplar Walk-road, S.E.

Oval Frames.—CAPELL, Oval Turner, 79, Milton-street, Dorset-square, N.W., London.

Bench Drilling Machine, very strong, invaluable to amateurs. Securely packed for 30s.—BLEACHING and GOOT, Marcham-le fen, Boston.

Photographs (Scottish scenery), extraordinary value, 7in. by 4in. size 4d. each.—FINLAY, 135, Renfrew-street, Glasgow.

Electro-Motor Engine, working model, post free 6s.—J. SUTCLIFFE, 63, Cedar-street, Hulme, Manchester,

Photograph, new and old Eddystone Lighthouses, 7 by 5, post free fourpence.—PUMPHREY, Publisher, Birmingham.

AND

WORLD OF SCIENCE AND ART.

FRIDAY, JULY 14, 1882.

SLIDE-REST TOOLS AND CUTTER-BARS.

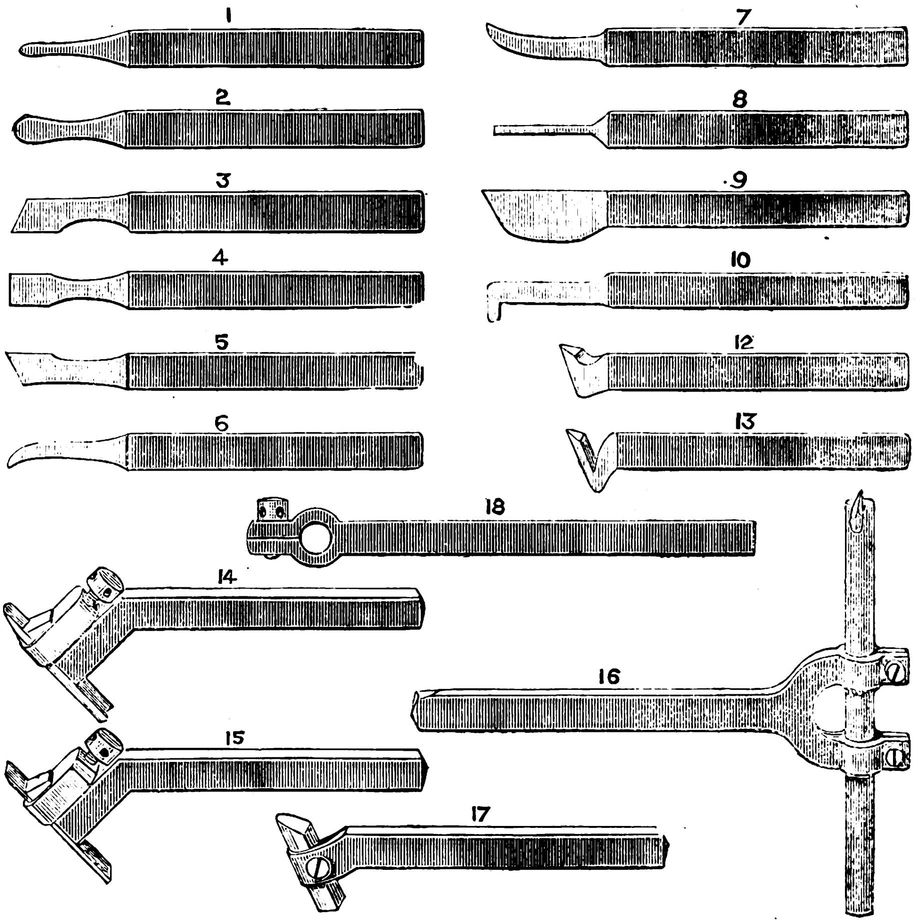
By J. H. Evans.

THERE having been, from time to time, many different tools of this kind illustrated in these columns, I still think that it will be of great interest to our amateur turners to have before them those of the present day. The cutter-bars have, so to speak, exterminated a great many of the old-fashioned slide-rest tools; but, for all that, the latter must not be despised, and they will at times be found more convenient for many purposes than their successors, therefore I have deemed it necessary to illustrate a few of those that are found most useful for general amateur purposes. In making such tools as figures 1, 2, 3, 4, &c., &c., it will be necessary to have them forged from the very best cast steel, and I consider Marshall's steel the finest for the purpose. There are two distinct ways of making them: that is, they may be constructed to suit both the metal-turning and the ornamental slide-rest. If for both, that part extending from the end of the square to the cutting edge must be shouldered down, and then filed, so that the cutting edge is in a line with the centre of the square, which should be 9-16in., to fit the tool-box of ornamental slide-rest; but if to be used with the metal-turning rest only, it is better to file the top surface flat all along; the tools can then be left more substantial. The round-nose tools, Figs. 1 and 2, are used for roughing-out work, brass or gun-metal; but if used for iron or steel, such a tool should be made similar to Fig. 12, which, it will be seen, has considerably more cutting angle—viz., about 80°, that for brass being about 70°. I say about, because, as I have previously stated in other articles, I am of opinion that practically the precise angle within a few degrees does not matter as long as the tool cuts. The diagrams, No. 3, 4, and 5, represent the right and left-side tool and the front tool, which would be used for hard-wood turning more than anything else, the front of each of the side tools being ground to an angle which will admit of them being used to turn out square corners; for instance, the lid or bottom of a box forms a very good example of the work they are adapted for, especially as the bottom can be taken quite square and sharp in the corner without in any way touching or destroying the sides or cylinder part. The next tool, Figs. 8 and 9, gives two views of the parting tool, used, as may be taken from its name, for dividing or cutting off the work done, from the chuck upon which it has been turned; this, it need hardly be said, is one of the most necessary adjuncts to the slide-rest. It will be seen that this tool is narrow on the cutting-edge, being well relieved from the front to back, in order that it will not wedge; but with all this precaution it should be withdrawn occasionally to clear it of the dust that will accumulate during its progress through the wood. Fig. 9 shows how it is strengthened by the blade being made considerably deeper; it is always as well to have two or three such tools, in case of one breaking; at the same time, there is no reason why it should break, if carefully used.

We now come to Fig. 10 which is practically a boring-tool, although it may be used for any internal woodwork or metal, and the cut may be taken in either direction, as the rough edge will suggest. Figs. 6 and 7 show a pair of right and left side tools for brass or metal, for turning out such work as cup chucks, &c., will be found very useful; the same forms, in point of fact, are used for iron as brass in most instances, the difference being that those for iron and steel may be made of less width and angle, the latter being from 65° to 85°, and that for brass from 70° to 95°. These, of course, are varied according to the work done. The materials used differ for roughing or smoothing, and finishing the work. Fig. 12 is a kind of heel tool, and when using steam power, will be found an excellent tool to take off a good shaving. Fig. 13 is descriptive of a spring tool; this, also, is a most useful tool for heavy work, and may be used also in a planing machine to great advantage. The cut may be modified in this tool by taking off some of the spring; this is done by placing a wooden wedge in that part which is cranked down. So far, then, I have detailed a few of the necessary fixed tools generally supplied with such a slide-rest, as figured in p. 295, June 9th., some of which are absolutely necessary.

I will now proceed to describe a few of the various cutter bars now in use. Fig. 14 is what is commonly known as the gouge cutter-bar, it being obvious that such a tool, under the guidance of the slide-rest, must turn the work with greater facility than the ordinary gouge held by hand; such a tool being subject to considerably greater strain than when used by hand, it need not be made so wide, but must be stronger to admit of the increased strain upon it. The stems of these instruments, it will be seen from the diagrams, are rectangular to the holding power of the tool-box or holder. They are made of the best fagotted iron; it is made to hold separate blades, and the latter are held firmly in place by a steel strap and screw, which latter draws the blade tightly to the bar against the bent part, which should be at such an angle that the tool when fixed into it is in such a position that a good clean shaving will be the result of its operation. The blades being short, are capable of being adjusted exactly to the necessary height of the centre. Fig. 15 shows another cutter-bar of this description; but to hold a chisel-blade, which for smoothing a large surface or cylinder is a first-rate tool, more especially for turning wood that is cut plank-ways; but for this it should have a round-end blade, in place of a square-cornered one.

Fig. 16 is a cutter-bar, quite new, and one that I have lately introduced. It will be found a most useful addition to any amateur work-shop, as it saves a deal of trouble in shifting the slide-rest; it will be seen that the bar is made after the same fashion as the others in the stem, and forked at the end, and through the centre of that part a steel rod runs in a transverse direction, the bar is split at the end of each fitting, and a steel screw passing through in front of the bar, when these latter are set up the bar is held firm at any position it may be required in. The steel bar revolving in its fitting it facilitates the setting of the cutter to the centre of the work; but if the tool is correctly made, it should be always at the proper centre when central to the square stem; it is not a difficult or expensive tool to make, and I am able to record a good sale of them, which is the best evidence of their value; therefore, I consider it a most successful idea, and as such things generally do, the same emanated from a very ingenious amateur. When using this tool for turning out a deep box, it will be seen that the bar holding the cutter is in the same position as if an ordinary tool had been placed in the rest, and the latter turned round to the surface; but in the latter case only the depth of the stop-screw can be turned out, and this is not sufficient for many purposes; but with this



improved bar the whole length of the main-screw could be used, if found necessary; but that is not at all probable; but I simply draw attention to the fact to illustrate more fully the advantages of the tool in question, when devoted to the purpose for which it is intended. Fig. 18 is a side view of this instrument, showing how the ends are split to allow the screw to tighten the bar in its place. It is cut through with a frame saw, the screws being tightened. The transverse bar is held quite firmly, and will admit of a heavy cut being taken without its moving. This I may mention has been found a very useful tool for factory purposes, and by those who have tried it for amateur work it is pronounced quite a success. There has been so much said at different times upon the subject of tools and cutter-bars, that it is not worth while for me to expatiate further upon them; but for the benefit of the readers of the English Mechanic who have not probably read all the different works upon the same, I thought a brief outline of those here illustrated would be found useful, and enable those not in possession of them to make for themselves, if desirable so to do. As I have been requested by several readers to continue the illustrations of specimens of work done, I propose to do so in my next article.

THE BEST GAS FOR THE GAS-ENGINE.

At the recent meeting of the Gas Institute, an interesting paper was presented by Mr. Charles Hunt, M.I.C.E., containing the results of a number of experiments with different qualities of gas employed in driving an Otto 12-horse engine. The calorific value of different qualities of illuminating gas is a question that has been much discussed, but it is generally accepted that the higher the illuminating power the greater is the heating value, though not in proportion. Dr. Wallace's estimate gives, taking 14·75-candle gas as unity, a heating value of 1·295 to 26·24 candle gas, while its value for lighting is 1·769. Thirty-three candle gas has, however, a lighting value of 2·230, while its heating value is only 1·496; that is, while its illuminating power, as compared with common 14 or 15-candle gas, is more than double, its heating power is not quite one-half more. To put the matter in another way—increases in illuminating power of 77 and 120 per cent. correspond respectively to increments in heating value of only 30 and 50 per cent. In view of those figures, it might be supposed that the commoner gas is quite good enough to use in a gas-engine, and that gas having a high illuminating power would be out of place. It appears, however, that the value of illuminating gas for motive power increases in a greater ratio than its value for heating, though still falling short of the value for lighting. The action of the gas-engine depends upon the heat of combustion, and the effect produced by any gas or mixture of gases, when tested by a dynamometer applied to the engine, should give an almost accurate measure of their calorific values; but the main object of the experiments made by Mr. Hunt was to determine the relative values of different qualities of illuminating gas, when used in the gas-engine. Before commencing the trials, the engine was thoroughly cleaned, and the bearings adjusted and lubricated. The diagrams were taken with a Richards indicator, six diagrams being taken for each quality of gas, and as they were repeated three times, the summary gives the average of 18 indications. The engine was weighted with its maximum load, which involved an explosion practically every second revolution, and the actual horse-power was obtained by applying a strap-brake to one fly-wheel, so that the actual loss by friction of the engine itself was also ascertained. The gas used in each case was the absolute product of the coal or cannel, distilled and purified in the usual way, without any admixture of air, and the burners used for photometrical purposes were a No. 1 "London" Argand for gases up to 18 candles, and for higher qualities a steatite batswing. The precautions to insure accurate results were apparently all that could be desired, and there seems no reason to suspect the returns on that head. The gas was, in all cases, supplied at a uniform pressure, and it was noted that the speed of the engine depended entirely upon the extent of opening of the gas-valve; for instance, if the valve was adjusted for 17-candle gas, the engine would not start with 29 candle. It was also noticed that once in about 35 or 40 revolutions, the regular explosion was missed, the following explosion being, however, of greater intensity. The general tendency observed throughout the trials, says Mr. Hunt, was towards a deeper diagram with the richer gases, apparently indicating a slower combustion, and slightly greater force exerted throughout the stroke. The quantity of gas expended per horse-power varies, it is found, considerably with its quality, and consequently it becomes a question of relative price of different qualities of gas, before the real economy of the gas-engine can be arrived at. Users of these valuable motors, must, therefore, look to the price and quality of the gas supplied in their towns, for while the small-sized gas-engine is cheaper than its equivalent steam-engine in places where illuminating gas can be had at 4s. per 1,000 cubic feet, it is vastly more economical where gas of say 25-candle power can be had at that price. Taking the whole series of Mr. Hunt's trials, the loss between indicated and actual power shows that about 25 per cent. is absorbed in the friction of the moving parts, an amount which compares favourably with steam-engines, and the summary shows that a 12 horse-engine indicating 19 horse-power may be relied upon to give quite 14½ horse-power actual by the brake. The most interesting figures in the elaborate and reliable tables given by Mr. Hunt are, however, those which show the quantity of gas of different qualities consumed per horse-power per hour, and these we set out in a tabular form, preferring the actual horse-power to the indicated as probably more trustworthy:—

Candle power.	Gas. cub. ft.	Actual H.-P.
11·96	40·08	14·49
15·00	32·55	14·50
17·20	30·64	14·36
22·85	23·56	14·60
26·00	21·55	15·03
29·14	20·34	14·35

It will be seen that about half the quantity of rich gas suffices to yield a horse-power as compared with the common 12-candle gas; and that result holds good with gas prepared in the manner suggested by Dr. Siemens; in fact, the lower the illuminating power of the gas, the greater the quantity necessary to yield a horse-power. Mr. Hunt, for obvious reasons, does not give the relative price per 1,000ft. of the rich and common gas, for that varies with the locality; but a simple calculation will enable any owner of a gas-engine to ascertain which quality will be most economical, and a little extra calculation will enable anyone to discover what advantage is to be gained by enriching common coal-gas with one of the light and cheap hydro-carbons. These calculations obviously depend on the prices in any given locality; but the facts brought forward by Mr. Hunt are interesting and valuable, and will give a stimulus to the introduction of the gas-engine, especially where gas of high illuminating power can be had at a low rate. For instance, to take two qualities which compare readily with the table: 30-candle gas at Galashiels costs 3s. 4d. per thousand, while at Bristol 17-candle gas costs 2s. 10d. According to Mr. Hunt's results, the difference between 17 and 30-candle gas is as 30 to 20 in quantity used, while the difference in price in the towns cited is as 40 to 34; showing that users of gas-engines in Galashiels can have motive power at a cheaper rate than users of similar engines in Bristol.

THE ORGAN: A COMPREHENSIVE TREATISE ON ITS MANUFACTURE, PROCURAL, AND LODGMENT.*

By John Watson Warman,

Associate of the College of Organists, London.

SEE at this stage what was said under Head of Man-to-Ped. Coupler (at *r*, *Bis*, ante and on), concerning an objection to the foregoing method of Regulation in respect of its tending to throw the contact of such Coupler to a point which is *inside* the regular Pallett Action point on the same Key.

i. It is to be noted also that such type of Regulators will be difficult if not impossible to carry out in conjunction with a Swell-to-Pedale Coupler of the *Part* kind (see again *q q q q*, next), even with the aid of the Wire Cranked Sticker (see again at *z*, ante), and of such Crankings' being extended above the Noses which carry the Screw-Wires; because the space between the two Great-Org. Stickers *cannot* even then be rendered wide enough to accommodate the two Regulating Buttons, without risk of a fouling.

j. It is now to be pointed out that the Regulating appliance just described, though quite practicable and effective so far as its own function is concerned (unless, as just intimated, there be two Action-Noses on one Key-tail), will inevitably sacrifice the *Participation* of the Key with which it is connected (see at *n*, ante). To regain this, therefore, something more is required. The method devised by the present writer, and which method will probably be found in practice as satisfactory as any available, consists in the addition to the aforesaid Screwing Button of that which will be termed in the present Treatise a *Button-Clip*. This Clip consists of a strip of thin sheet-metal of suitable kind (common "Tin" will usually do quite well), about 1¼in. long, and rather narrower than the *plan*-width of the [Manual] Key-tail: this Strip is so cranked at its middle as to assume, on *elevation*, a *Bayonet-like* form,—the amount of the cranking being exactly equal to the vertical thickness of the Regulating Button: at one end, it (the Strip) receives a small Screw-hole, and at the other end a short Notching just wide enough to admit the stem or screwing portion of the Regulating Wire. Note:—If the Clip do have to operate between two Stickers (see last preceding parag. but two), its rear or notched end must of course be diminished in width accordingly (see here at *m*, next, 2nd parag.; and at *p*, next, 9th parag.); say that such width should then be about ¼ of inch, or, if possible—as when the Stickers are of the Wire-Cranked form—, a little more. Such narrowing, however, should be for only such portion of the Clip as actually enters between such Stickers, the remaining portion being left untouched. And if there be a Coupler-Regulating Wire passing (see at end of present parag.) through such Clip, the length-total of the latter should be so increased as that the Hole for such Wire shall be made in the un-narrowed portion of the Clip. In all cases the aforesaid decrease in the width of the Clip should be accompanied by a slight increase in its thickness. The Clip as so, or however, formed is now placed upon its Key-tail in such a way that the rear or notched end of such Clip lies on and gently presses the top of the Button—the Wire itself having passed into the said notch—, and, the exact posit, for the fore end of the Clip having been found, a suitable Screw is passed through the Hole in the latter, and turned

---

* All rights reserved.

"home" so as to press only lightly upon it. It will now be evident that (1) the Action-Nose will not be able to rise without lifting the Key-tail with it, that (2) the Button will be left perfectly free to be turned round in Regulation, and (3) that any lateral warping of the Key cannot cause any "binding,"—because the Screw through the Clip will act as a pivot to allow the latter to partially rotate, and so accompany and accommodate itself to such lateral derangement. It will be obvious that the Taking *out* of any Key which is thus "Clipped" will be just as easy as though such Clip were absent, for the Clip-Notch will quite freely leave the Screw Stem; but the *replacing* of such Key will not be quite so quickly done, because the Notch will then have to *find* the said Stem. If this Button-Clip be applied to any Key which is driven by a Coupler the contact of which is made beneath the Tail of such Key—and consequently beneath such Clip—, the *Regulating Screw* of such Coupler (see 88, *u*) had generally better be made to pass —free—through a suitable Hole made in the higher part of the Clip,—so that the said Screw may be brought, on plan, as close as possible to the said Screw-Wire in the Action-Nose (see *m*, ante).

jj. At this point see again what is said in Treatment No. 3 (at *m*, next, 2nd parag., Diff. 8), and in that of No. 4 (at *p*, next, 9th parag., and on), with reference to the more exact posit of the Swell-Org. Key Square Nose, and the relation which such posit has to the question of the Regulation at and by such Nose. It is to be here observed that an additional argument is furnished against such a Regulation by the fact that either the *Clip* just described must partly enter between the Great-Org. Stickers, or the latter must be absent (as in Treatment 5½, see *uuu*, next, 5th parag.), or the said Square or other Action Nose must be elongated frontward beyond such Sticker, or the Participation of the Key must be given up.

k. Finally, as regards the Action, it is to be noted that in all cases where a Backfall, a Lever, or a Square has to possess, in addition to its regular Nose Contact point, a *second* similar Contact point—such as that of the Swell-to-Ped. Sticker just described—, it is essential that such Backfall, Lever, or Square be made of sufficient Radial length to prevent such second Contact point from coming *too near* to the fulcrum center of such Square, &c. This matter, together with that of any Square, &c., extra *elongation* which may be rendered necessary by the providing of Front-Regulation in co-existence with a rear-extended lowermost Key (see *rr*, *Bis*, ante and on), and also the proper *form* which the Square, &c., shall assume for affording such second Contact, or for giving the correct crossing of line of centres with a Regulating-Nose (see here again at *h*, ante, 3rd parag.), will of course be fully gone into in *Departments* COUPLING-ACTION and KEY-ACTION. If it be found impracticable to secure the aforesaid sufficient Radial length *without* giving up the said Front Regulation, then the latter may be considered to at once become inadmissible, unless there be really no other method of Regulation practicable.

kk. It remains here only to observe that in all cases where—as in the preceding—the Noses carried on the Swell-Org. Key-tails extend far enough forward for their Regulating Buttons to be in line with the line of the Great-Org. Key Sticker wires, the said Tails of the Swell Keys will *not* extend back beyond the Tails of the said Great Keys. (See here No. 4 *Treatment*.) Bear always in mind that such extension of the Nose of a Key Square, or any other circumstance that affects the Radial size of the latter, or any arrangement that affects its position (as, for instance, whether such Nose shall be set on the Key-tail, or contained in a Forking of the latter), will determine or modify the exact level occupied by any [horizontal] *Tracker* actuated by such Key Square.

l. As a *Summary* of this No. 2 *Treatment*, we may confidently say that it is the best which is practicable for the particular Lay-out for which it is intended (see at *d*, ante, 1st parag.), unless one of the still better Treatments which include a *Clear Coupler* (see *r*, next and on) be substituted—, on this last point remembering also that the presence of any Stickers rising from the Key-tails is unfavourable to the having of a a *Detached Buffet* (see *r*, next, 14th parag.). The Merits and De-merits of the present Treatment therefore rise or fall along with those of such Lay-out itself. Concerning this latter, the reader has already been referred to the *Pro-Department* ENTIRE ORGAN for a fuller Description and Criticism of the Faringdon Instrument; it will, however, be well to add here a few remarks on those points with which the structure of the Keys is involved:—

(1) The Projection of the Manuals enables the Player to better judge of the effect he is producing, and also to hear more of the Voices he is accompanying. (2) The Key-Action of the Great-Organ becomes very simple,—the Fanned Backfalls rendering more than a few *Rollers* unnecessary. (3) By the Great-Org. Backfalls' being kept above the Key portion of the Swell-Org. Action, not only is (as already said) the Crossing of these Actions avoided, but no part of the Key-Action of either Manual descends below the level of the Great-Org. Key; and thus there exists more space to devote to the Bellows, or to any other portions of the work which it may be desirable to locate just beneath such Key-level. (4) The Skewing of the Swell-Org. Keys does not involve any more workmanship in the Key-Action generally: see on this point what has already been said as to the Setting-out of the *Roller-Boards* (at *c*, ante, 2nd parag.), in the analysis of the present Lay-out.

But there are the disadvantages that:—(1) In consequences of aiming at Fanned Backfalls to the Great Section in conjunction with Projecting Manuals, there here arises necessity for having the Palletts of such Great Section placed at the front of the Instrument: this is bad, because it interferes with access to such Palletts—partly by reason of the presence of Conveyances to the Show Pipes—, and because it throws the Pull-Wires of such Palletts and the rear ends of the Man.-to-Man. Coupling Backfalls more out of reach — so rendering Front Regulation more imperative—, and also because it takes such Palletts away from under the Reed Register (see *Department* WINDCHEST). (2) The mainly Semitonal Pipe-Order necessary to secure the Fanning of the Backfalls brings Pipes of rather larger size to the middle of the Organ, and so partly obstructs the Swell-Section Tone (see *Pro-Department* ENTIRE ORGAN) whenever the Box Shutters are Open. (3) After that this simple Key-Action *is* obtained, its very directness makes it less pleasant in the using than if it possessed more Centers, because there is, in the virtual absence of both Trackers and Rollers, nothing whatever to cut off the Pallett "Pluck" from the player's fingers (see more fully on this in *Department* KEY-ACTION),—the Palletts in this particular Soundboard being of the common kind. (It has already—at *g*, ante, 1st parag.—been seen that the Position and Fanning of the Great-Organ Backfalls are unfavourable to the application of a *Clear* Coupler.)

It is to be observed, in palliation of the foregoing Defects, that the Projection of the Manuals (of course in itself good) was here made obligatory by the very mistaken position of the Instrument,—saddled, I believe, upon the Organ-Builder by an uninformed parochial coterie; and also that, owing to a still further limitation as regarded height, it was rendered very desirable to avoid the obstruction which would have been presented by a second *Whole* Roller-Board s coming beneath the Soundboards. At this stage compare yet once more the arrangement of the Faringdon with that of the Hoddesdon Specimen,—now next following.

m. *No. 3 Treatment.*—This is an Instance afforded in the Organ, so often quoted, erected by Henry Willis, during 1865, in Hoddesdon Episcopal Church, Hertfordshire. At this point refer to *Department* CASE—at 60, *r*—for some further particulars of this Instrument. To this it is to be here added that the two Manual Sections are of the usual kind—viz., Great, and Swell—; and that the General Lay-out of the Inside is, as regards Involution with the Claviers, the same as that of the Faringdon Instrument except;—(1) That the Manuals, though like those in the latter Organ in respect of their not being Reversed, yet do not Project beyond the Face of the Organ-Case; (2) That the Palletts of the Great-Org., equally with those of the Swell-Org., are set at the points nearest to the Passage-board which separates the Windchests of these two Sections; and (3) That the Great Org. Section, as well as that of the Swell, has here its Order so that its smallest Pipe comes at Middle.

The treatment of the Manuals themselves (see here at *r*, *Bis*, ante)—including their vertical distance between Playing Levels—, and of the Key-Action involved with the Manuals, is also the same as in the Faringdon Instrument, with the exception of the following:—(4) The Backfalls of the Great-Organ are, on Plan, not Fanned, but Parallel and Square,—that is to say, *nearly* Square, they being given a very slight slant in order to bring their rear ends into [Plan] correspondence with the Tails of the Swell-Organ Key. Of course, the [Great-Org.] Roller-board is a "Whole" one. (5) In consequence of such Non-Fanning of the Great-Org. Backfalls the Manual-to-Manual Coupler can be, and is now, driven—instead of by a Block affixed to the Great-Org. Sticker—by a short *Wire Tracker* threaded through the said Great-Org. Backfall, and running down to and through the fore Nose of the Coupling Backfall, —the actual posit of such Wire being close behind the Great-Org. Sticker. This Wire has a Stopping Eye and Collar Button (no Screw thread) at its bottom end, and a Regulating screw Button at its top end. (6) The said Great-Organ Stickers are here shorter than in the Faringdon Design; they now, of course, carry no Driving-Block; they are well broadened out where—and *only* where—they pass between the Swell-Org. Keys; and they now carry *no* Regulating Button. The Notching of the said Swell Keys (see *u*, ante) is of course cut to an extent corresponding with such broadening of the Sticker. (7) The Sticker of the Coupler Swell to Pedale is now—instead of acting directly upon its Key-tail—Wired into the [T] Square Nose which rests upon the latter; and by reason of this the said Swell Key-tails do not now extend beyond those of the Great, but the Tails of both the Manuals finish at one same areal line. (8) Although—in consequence of the preceding *Wiring*—there is no need, so far as the Swell-to-Ped. Coupler is concerned, for the Swell-Org. Key-tails to extend back past the Great-Org. Stickers, yet such extension is partly observed in the present Treatment, these Stickers being placed forward [towards player] sufficiently to leave just a long enough amount of such Swell Key-tails behind them for these latter to carry their (Wood) Action Square Noses without such Noses passing in between the said Stickers. The reason for this is simply that as *Crank-Wired* Stickers (see *p*, next, 8th parag.) are not here admitted, the space between any two of the Wooden ones actually employed is not sufficient to accommodate a Wood Square Nose and yet at the same time to leave enough free space to prevent possibility of rubbing or of consequent cyphering on any casting of such Sticker. The Notchings in these Swell-Org. Keys will thus be formed as in the preceding Treatment (see at *d*, ante, 2nd parag.),—or nearly so. Of course the rearward extension of the Great-Org. Key beyond its regular Sticker will be made use of for the Insertion of the Sticker of the Great-to-Ped. *Coupler*, and thus there will exist no risk of the fore-lifting already spoken of (at *rr*, *Bis*, ante), —this last Sticker being set at the extreme end of its said Key: such use, in fact, constitutes the sole reason why the Great-Org. Key-tail is thus extended. See here at *rrr*, *Bis*, ante.

(*To be continued.*)

WATCH-CLEANING AND REPAIRING.

By "A FELLOW-WORKMAN."

(*Continued from page 371.*)

Depth Tool.

MANY amateurs when they consider to what nicety a depth tool must be made, think that it would be an impossibility to make one; and so it would be to those who don't know how to go to work. But if you work the proper way it is perfectly easy, and, with care, you may be able to make a tool that shall not be wrong, even to a hair's breadth. Fig. 63, therefore, shows the centre and third wheel, so placed between centres that the distance between A and B, C and D, E and F, and G and H are *just* the same. Now the question we want is, how to place these two bars so that they may be moved to and from each other, and so that, let the distance between E and F be what it may, the distance from G to H would be *exactly* the same. Now look at Fig. 66, and there you see the bars are so placed in two separate frames, that when you slide these frames to and fro, the distance from the points I and J is exactly the same as the distance from the two centres at F and F and M and M, also L and L.

FIG. 65.

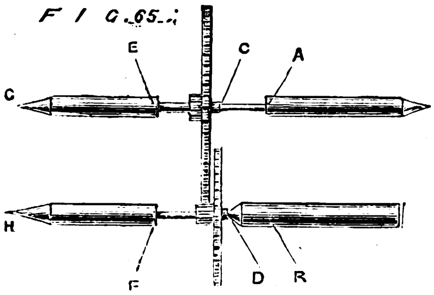


FIG. 66.

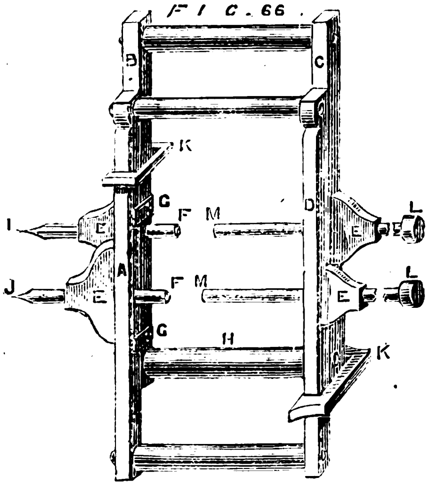


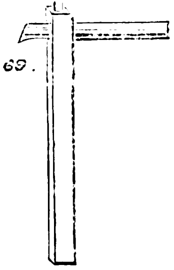
Now we must make four sides, Fig. 67: the right edge should be perfectly straight, and at right angles with the *inside* (see Fig. 66). I used the top-side of the arm, or body of my turns, as a straight-edge, which I found perfect. Now take all four sides and solder them together *at the ends*, so that the straight edges all come perfectly true; now with gauge (Fig. 70) mark the dotted line, as shown Fig. 67; now same the other side, and make a centre mark where the lines cross, and be sure and always work from the straight edge. Now place the sides on to the chuck in your turns and drill holes right through. If you have not a chuck, you can drill half-way through, then reverse and drill the other half, and finish with rimer or broach. Now turn up four posts, Fig. 68; they should be slightly chamfered round the pivot, to allow the outer edge to take its bearing, one side being pinned and the other side riveted, same as American clocks. Now put the frames together and rivet two pieces of brass (G, Fig. 66) on each side. These will keep the frames in position while you slide them to and fro. Now solder on to the plates your blocks (E, Fig. 66), which should stand flush with the straight edge. Now, with your gauge (Fig. 70), mark off for holes for bars (L and L); these should be as near the "straight-edge" as is safe, for the hole not to break out. Mark them all alike, working from the straight-edge. Now mark from the end of the plate, where top-end of dotted line terminates, to the middle of the blocks; measure all four alike, and centre-punch where the lines cross.

FIG. 67.

FIG. 68.

FIG. 69.

FIG. 70.



Now put one centre mark on the male centre in the middle of your chuck (Fig. 54), and the drill (H, Fig. 54) in the other centre mark; set the frame running, and your drill, if properly made, will find its way direct for the other centre mark. When you have drilled through this back, reverse the frame and drill the other side; next turn up the bars to fit the holes, or you could get a piece of straight steel wire the proper size at Cohen's, Kirkgate, Leeds, for 2d. The bars should fit tight; place in turns with the outside running true; make a point at one end, then cut asunder with the graver while in the turns, and leave two female centres; the same with the other bar. Now make two clamps (Fig. 69), hook on the top-end and then squeeze on the bottom-end, and that will hold frames firm together, while you score off on plates.

(*To be continued.*)

THE ACHROMATIC OBJECT-GLASS.—V.

By W. BRADBURY.

(*Continued from page* 393.)

I HAVE recently received the following table of curves employed by Dollond. It is copied from "Smith's Mechanic," 1825.* The numbers given are diameters; if they be taken as radii, the compound focal length will be double the one specified.

Diameter of the Spheres to which the Lenses are Ground.				Compound Focal Length in Inches.
Convex Crown Lens.		Concave Flint Lens.		
1st Radius.	2nd Radius.	3rd Radius.	4th Radius.	
3·2	5·3	5·3	8·8	5
6·4	10·6	10·6	17·6	10
9·6	15·9	15·9	26·4	15
12·8	21·2	21·2	35·2	20
16·0	26·5	26·5	44·0	25
19·2	31·8	31·8	52·8	30
22·4	37·1	37·1	61·6	35
25·6	42·4	42·4	70·4	40
28·8	47·7	47·7	79·2	45
32·0	53·0	53·0	88·0	50
35·2	58·3	58·3	96·8	55
38·4	63·6	63·6	105·6	60
41·6	68·9	68·9	114·4	65
44·8	74·2	74·2	123·2	70
48·0	79·5	79·5	132·0	75
51·2	84·8	84·8	140·8	80
54·4	90·1	90·1	149·6	85
57·6	95·4	95·4	158·4	90
60·8	100·7	100·7	167·2	95
64·0	106·0	106·0	176·0	100

As no mention is made of the kind of glass employed, the table is incomplete. All the numbers have the same standard, so that they serve only for one pair of glasses. The contact of the inner curves is preserved throughout the series.

Whatever may have been the optical properties of the glass used by Dollond in these combinations, the ratio of curvatures adopted is a very curious one. The same ratio, practically, is used for both flint and crown lenses. The first pair of radii are very nearly as 3 to 5, and the second pair are essentially the same. Such a combination would be very much under-corrected, as the spherical error of the concave is far too little to counterbalance that of the convex. It is possible to make such a pair of lenses aplanatic by "local correction," but it must have been a very long, tedious, and troublesome task. "Our" practical master says: "The old plan was simply to smooth over, and *polish* until a fair result was obtained; figuring, as now understood, had no existence in object-glasses in those days. The aim was to produce *definition*, and *suppose* all surfaces perfectly spherical when that was arrived at."

We can thus form some slight estimate of the labour these old artists had to expend in the production of a fine object-glass. Tulley seems to have found the advantage of using a much flatter curve for the back of the flint lens. No less ratio than 2 to 1, and very often 4 to 1, is found in his combinations.

Huyghens had discovered a rule by which the aberration of a lens might be easily computed when the rays were incident parallel to the axis. But this condition can only apply to the front lens of an achromatic combination; those rays falling on the second lens must have a certain degree of vergency. No rule then existed by which the aberration of a lens under this altered condition could be ascertained. Hence, the only way was to find by trial what kind of lens was most suitable to combine with another, and then to compare the aberrations of each for parallel rays. This result furnished a sort of guide to the selections of those curves which would approximately balance the opposing aberrations.

It is obvious that such a method could only be successfully applied by an optician having ample opportunities for experiment. This Martin had not; and it remained for Tulley to devise a rule which should give results near enough for practice. Before treating of the improvement which the latter effected, let us examine the question in the aspect it presented itself to Martin.

Huyghens' equation for computing the aberration of a lens is (R and r being the front and back radius respectively, and T the thickness of the lens):-

$$\frac{4\cdot5\,R^2 + Rr + 1\,{}^1/_6\,r^2}{(R + r)^2} \times T.$$

For the sake of convenience, and to save repetition, let us represent the value of the fraction by A, then (crown. ab^{rn}) = A. T. We can either keep it in this form, or introduce the focal values, which is the better plan. Now, the thickness of a lens expressed in terms of the semi-aperture, focal length, and refractive power is (Y being the semi-aperture. F the focus, and μ the refractive index): $T = Y^2/2 \,.\, F. (\mu - 1)$. Hence (crown. ab^{rn}) $= A\,Y^2/2 \,.\, F\,(\mu - 1)$. We will employ the same smaller letters to represent the same quantities belonging to the flint lens; then (flint. ab^{rn}) $= ay^2/2 \,.\, f\,(\mu' - 1)$. These are the aberrations of the lenses for parallel rays, and in comparing them, some of the terms disappear. (c. ab^{rn}) : (f. ab^{rn}) : : $A\,Y^2/2 \,.\, F\,(\mu - 1) : ay^2/2f\,(\mu^1 - 1)$.

Since the diameter of each lens is the same, we may omit y in each, and also the divisor 2. Also since $F = f \times \delta$, erase f and write δ instead of F. Then we have :—(c. ab^{rn}) : (f. ab) : : $A / \delta\,(\mu - 1) : a / (\mu' - 1)$. Now, if the aberration of the crown be made equal to that of the flint, obviously $A\,(\mu' - 1) = a\,(\mu - 1)$; or $a = A\,(\mu' - 1) / \delta\,(\mu - 1)$. The quantity A is known, for it is the value of the fractional part of Huyghens' equation. By multiplying it by the quantity indicated, we get the value of a for the flint lens, and thus find the ratio of its surfaces.

But it will be apparent that this reasoning can only be correct when rays of the same nature strike on each lens; and as the first incident rays are parallel, and the second diverging, the value of a is very much altered from that found as above. No direct method of computing it was known, and the only resource was to vary the multiplier of A until it gave such a result as agreed with experiment. Martin does not appear to have met with such a number as would generally be applicable; Tulley succeeded better. Observing that the multiplier of A consists of the product of two quantities, the ratio of the *refractive* powers, and the ratio of *dispersive* powers; he confined his investigations to such changes in the first quantity as at length gave a number near enough for practice.

The refractive index diminished by unity $(\mu - 1)$ is a measure of the refractive power; hence $(\mu' - 1)/(\mu - 1)$ expresses their ratio; but in this instance it is preferable to take the reciprocal of this quantity, viz. $(\mu - 1)/(\mu' - 1)$. Let this value be denoted by η; then instead of a multiplier, we get a divisor, composed of the product of two decimal fractions δ and η, for both these numbers are always less than unity. Hence our equation now stands thus, $a = A/\delta\eta$. The result of Tulley's experiments showed him that instead of the simple factor η, it should be $\eta^2\sqrt{\eta}$; and the value of a thus found gave a suitable ratio for combination curves. Therefore the corrected aberration equation is $a = A/\delta\eta^2\sqrt{\eta}$.

---

* For this table I have, through this note, to thank some gentleman unknown to me. The signature "Alpha" appears in his letter. If he should chance to meet with other interesting matter of like nature, I trust we shall hear again from "Alpha," but not from Omega.

Let us state in words what this implies.

First, the refractive and dispersive powers of the glasses must be known; these will give the values δ and η, from which the corrected divisor may be found.

Secondly, assume a pair of curves for one (it is immaterial which) of the lenses, such as will satisfy the required focus: substitute them in the equation of Huyghens and find the value of A. Correct this by the correcting divisor, and thus obtain the value of a. Thirdly, having found a, by an inverse process, determine the radii from the Huyghenian equation, which will satisfy this quantity. These will be the radii of a lens which will approximately correct the spherical error of the other.

If we assume the curves of the crown lens, the quantity $\delta\eta^2\sqrt{\eta}$ is a divisor; but if those of the flint are assumed, it is, of course, a multiplier.

With respect to this method of computing the aberration of a lens for vergent rays, it must be observed that its application is probably very limited. However correct it might be for the kinds of glass used by Tulley, it is by no means certain that it would be equally so for modern glass. In his time the refraction varied from about 1·57 to 1·60 for flint, and 1·5 to 1·53 for crown, and the dispersion from about 0·65 to 0·75; hence the correcting divisor would lie between narrow limits. No matter how nearly correct the ratio of aberrations may be, there still remains this source of error—viz., that the same equation is used for both lenses. Whereas its coefficients, depending for their value on the refractive index, must vary with each glass, and the greater the difference in the indices, the greater will be the error introduced. But as a simple practical rule, for optical data lying near to the numbers above mentioned, Tulley's rule is well worthy to be remembered, for, as I have previously said, the value of an optical rule depends, not so much upon its absolute accuracy, as upon the certainty with which it can be relied on, to give results of one definite character.

The general problem, considered theoretically, of expressing the vergent in terms of the parallel aberration has not, so far as I am aware, yet been solved. It may be possible to find a simple factor composed of the refractive and dispersive values, which shall show the relation between the two quantities. If it can be done calculations for matching two lenses would be much simplified, and tables showing the ratios of curves suitable for combination, might be easily prepared. Tulley's empirical factor embodies δ, and the root of the fifth power of η; it is impossible to say how far these are correct, but I think it highly probable, that if a true factor can be found, it will contain a higher power of δ than the first. Those who are acquainted with Coddington's method of computing spherical error will know that there is much similarity between the aberration equations for parallel and for vergent rays—the second virtually embodying the first. Considered in this way, the theoretical solution of the problem, which Tulley solved practically, does not seem to be impossible.

This optician has left a table containing the optical properties of several of the glasses that he used.

TABLE I. SPECIFIC GRAVITY AND REFRACTIVE INDICES OF SIX KINDS OF GLASS.

Kind of Glass.	Plate No. 1.	Plate No. 2.	Dutch Crown, No. 3.	Ratcliffe Crown No. 4.	Flint, No. 5.	Flint, No. 6.

Flint, No. 5 ..	1·573	1·167	

I do not attach much importance to the numbers in any of the plate-glass combinations. They are apparently mistakes or misprints. It will be observed, that with the standard crown glass, the numerical ratio of refractive powers gives a difference of 0·233 as due to the change in the density of the flint glass. Whereas, if either of the plate glasses be taken as a standard, the like difference is only 0·027, or less than one-eighth of the former. Moreover, the value of δ increases with the density of the flint, whereas, to be consistent with the tabulated results for the crown glass, it should decrease.

I will now give an example of Tulley's method of computing the radii of a combination, taking as data the glasses united in the first section of the second table.

From the refractive powers ·528 and ·5735, we find $\eta = \cdot 92$, the root of the fifth power of this, multiplied by δ, gives ·578, which is the correcting number. Suppose the object-glass to have 30in. focal length: then—

F (focus crown) $= 30\ (1 - \delta) = 8{\cdot}64$. f (focus flint). $= F/\delta = 12{\cdot}13$.

Next, assume that the crown radii are in the proportion of 2 to 3, that is $R : r :: 2 : 3$ or $R/r = \frac{2}{3}$, which value we will denote by q.

Then, to find R, we have $R = F\ (\mu - 1)\ (1 + q) = 8{\cdot}64 \times \cdot 528 \times {}^5/_3 = 7{\cdot}6$. $r = 7{\cdot}6/q = 11{\cdot}4$.

To determine the aberration due to these radii, it is not necessary to know their actual value, but their ratio (q) only. For, if we substitute q for R/r in Huyghens' equation, it becomes—

$$\frac{4{\cdot}5\,q^2 + q + 1\,{}^1/_6}{(1 + q)^2} = A.$$

And since the value of q is $\frac{2}{3}$, the value of A is found to be 1·38. This must be divided by the correcting number ·578. and the quotient is 2·387.

This is the value of a, and by putting it in place of A, and solving the equation, the value of q' for the flint lens is found to be 2·06, or practically 2. Hence $R : r^1 :: 2 : 1$. (R is the outer, and r the inner curve of each lens, so that in this case the back curve is longer than the inner one). By the same formula as for the crown lens, $R_1 = f\ (\mu' - 1)\ (1 + q') = 10{\cdot}43$, and r' is $10{\cdot}43 \times q = 20{\cdot}86$.

Therefore, the combination is:—

$$\left.\begin{array}{ll} \text{Crown lens} & R = 7{\cdot}6 \\ \text{bi-convex} & r = 11{\cdot}4 \end{array}\right\} \begin{array}{ll} \text{Flint lens} & r' = 10{\cdot}43 \\ \text{bi-concave} & R' = 20{\cdot}86 \end{array}$$

Compound focus = 30.

By referring to the table of Tûlley's curves previously given, it will be seen that these numbers vary very little from the first combination there specified.

If the above example be worked out according to Coddington's formula, it will be found that with the same values for the crown radii, the flint curves will be almost identical with those calculated by this method.*

I shall now quote an example of the radii of a triple object-glass computed by Tulley's rule. In this case, as the refravtion is divided between two lenses, the aberration is much diminished; and as the convex lenses are of equal foci, each of them must be double the focal length of the single convex, producing the same refraction. The same kinds of glass are supposed to be used, as in the previous example on the double objective—viz., crown, index 1·528: flint, index 1·5735. Dispersive ratio, ·7127.

In adapting the formula for computing the curves of a triplet, it was found by a number of experiments, that the best results were obtained when the calculated aberration of *each* convex lens was equal to that of the concave. From this it would seem, that the correcting factor gives too great a spherical error for the concave, since it needs double the amount of positive error to correct it. But I think the true explanation of this seemingly paradoxical result may be found in the fact that the separation of the lenses will greatly reduce the error; and, moreover, the convexes being of the same form, but placed in opposite positions, would tend to counteract each other's errors. So that the whole effective aberration of the two outer lenses would really be much less than its theoretical amount; and as appears from experiment, very little if anything in excess of that due to the inner lens.

(*To be continued.*)

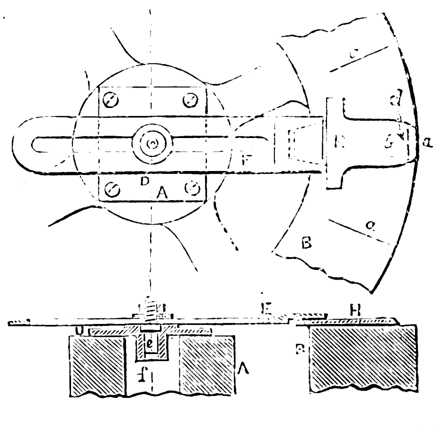
---

* Brewster gives tables for calculating the radii of lenses for object-glasses in his article "Telescope" in the *Edinburgh Encyclopædia*; and at the end of his edition of Ferguson's Lectures. Professor Robinson has an article on the "Telescope" in the *Encyclopædia Britannica*, in which an explanation is given of Boscovitch's formula. Brewster's tables are, I believe, founded upon this formula. An example worked by this method is given in Rees; but as no general explanation of the formula on which it is based appears, I have not quoted it. It would appear from this example that Boscovitch takes as one condition the equality of the interior curves and makes the front radius longer than the inner one. I trust this notice may induce those who can examine the above books to copy out and send to these columns the tables at least, and if not too intricate, the essential parts of the formula also.

DEVICE FOR LAYING OUT THE TEETH OF GEAR-WHEEL PATTERNS.*

IT has often occurred to the writer that a device something like that shown in the accompanying sketch, would be useful in laying out the teeth of gear wheels on wooden patterns, particularly as tending to greater exactness in the operation. As this is usually practised, the curves of the teeth are struck with the dividers directly on the pattern, and in the instance of a wheel with a large number of teeth, there are a great many chances to make slight mistakes, to say nothing of the chances of making one or two large ones. This is without questioning the propriety of laying out the teeth with the dividers. Then again the job is somewhat tedious. The chief point to be made, however, is the probability of greater accuracy.

In the sketch (which is not to scale, and in which some of the parts are purposely exaggerated for the sake of clearness), the rim B is supposed to have been divided in the usual manner, and radial lines *a a a* representing the centres of teeth drawn on the edge. The hub A is recessed, or it may be bored entirely through, as shown at *f* somewhat larger than the boss of the plate D. This plate has a hole bored entirely through it, which hole is recessed from the outer surface, and the pin *c* with the collar near the centre, is fitted to be revolved without lost motion. This pin, which may be ½" or ⅝" diameter, extends above the collar and is provided with a thread and nut, also with a blank portion on which the slotted bar F is fitted to be moved the length of the slot, or to be securely clamped by the nut. One end of this bar (which may be 3-16" by 2", or of any other convenient dimensions), is made thicker and grooved to receive the shank of the templet tooth H. The templet tooth, of metal, say steel 1-16" thick, has a notch in the end, as from *d* to its periphery, and from *d* it is beveled back, as shown in the section, and a plain line *d*–*b* is made on the beveled part.



---

* By F. F. HEMENWAY, in the *American Machinist*.

In using this device, the plate D should be laid on the hub, and using the bar F as a tram, should be set and held by the four screws shown in plan. A better way for setting and holding the plate than the one shown, would be to make the screw-holes in the plate considerably larger than the screws, and cover them with thin washers; then, when the plate is screwed down, it could be rapped a little to tram the wheel.

To mark off the teeth, bring the line on the templet to coincide with the lines *a* as in using a vernier, and as shown at *d*, and scribe around the tooth. Of course, as fitted up, the tooth template must be radial, but it is not absolutely essential that the line *b*—*d* should be either central or radial.

The template can be laid out directly by the use of the marking point and rolling segments, or in any way thought advisable. However it is done, there is but one tooth to lay out as against a good many, if laid out directly on the pattern. To make such templates would not be a very troublesome nor a lengthy job for a good tool-maker. The template could be used as a guide by the pattern maker as the work progressed.

The particular detail of construction is not offered as the best, but simply as a illustrative of the idea. One suggestion might be the fitting of the template tooth to a piece separated from the bar, but adjustable on it to compensate for projecting hubs.

Incidentally, this templet business suggests the propriety of enticing our tool manufacturers to furnish the device with a full set of teeth (or as many as required), by which means something might be done towards bringing about uniform practice.

ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.—XIV.[*]

(*Concluded from p.* 372.)

IN conclusion we have but little to say. We have endeavoured in our "lessons" to give as clear and as practical instructions in the various manipulations connected with negative making and printing as possible. It must be understood, however, that few rules or instructions appertaining to photography are absolute; they are all varied by circumstances. All that can be done by written instructions is to guide the intelligence of the beginner. When he ceases to be a beginner, he should depend on his own intelligence and faculty of observation more than on any instructions. Let the beginner not be discouraged by failure. Failures he is certain to have. Even the most experienced fail occasionally, the majority more often than they are willing to allow; and if they do not always succeed, it is unreasonable for the tyro to expect to do so. Nevertheless, he should aim at perfection, and should not be satisfied until he reaches it. Let him remember that at least in landscape work no amateur need despair of reaching the highest degree of perfection. Amateurs and professionals compete continually against each other, and the former as often as not carry off the palm. The young photographer should, from the first, exercise his faculty of observation, and note the most minute departure from received rules. Frequently, a fact noticed by one comparatively inexperienced in photography may give the hint to a more experienced investigator, who may make good use of it. Another thing to be impressed on photographers is that they should not fear to give others the benefit of their observations merely because it is possible that similar observations have been made before. It is sufficient that a fact is not generally known or appreciated to justify its publication, and the oftener it is published until it is appreciated the better. We have before remarked that, if the beginner can get the help of a photographic friend, he will find his first labours much lightened. We would now urge upon him that, whenever he has begun to feel his way, he should, if possible, join one of the numerous photographic societies which there are in the country. Let him not suppose that he will meet with ridicule or contempt on account of his comparative ignorance. We were for some time ourselves deterred from joining a photographic society for such a reason; but, on attending the first meeting, all our fears were dissipated. The terrible "professional" whom we had dreaded to meet we found to be a most kindly individual, willing—nay, apparently anxious—to give what aid he could to anyone who asked advice or assistance from him.

Finally, we repeat our advice that the reader, while he is still unfamiliar with the various manipulations, should follow to the letter our instructions; but that when he begins to feel his way, he should trust to his own intelligence as his great guide. If he does so, we are sure that from the time he first succeeds in producing by development *something* on his plate, till the time when he has arrived at such perfection that he need not hesitate to hang his pictures on the walls at photographic exhibitions side by side with those of the first photographers of the day, he will feel that every step in advance which he makes is a triumph, and will find his work—or play, as he likes to consider it—a more absorbing and delightful one than almost any other that he could have taken up. Let him bear in mind that every operation is but a means to an end (the end being the picture), and that *any* means that conduces to the end is permissible.

We believe that we have filled a little gap in photographic literature—that we have produced the first set of instructions for working modern dry plates which pre-supposed no knowledge of any other photographic process.

ELECTRICAL ACCUMULATORS OR SECONDARY BATTERIES.[*]

By Prof. OLIVER J. LODGE, D.Sc.

(*Continued from page* 373.)

I NOW proceed to the complete investigation of the most advantageous conditions when charging a set of similar secondary batteries with a shunt dynamo driven at a constant speed:—

Let P be the horse-power actually applied to the driving of the dynamo when it is in full action, at the given speed, as determined by a dynamometer.

Let P^1 be the power required to drive the dynamo at the same speed when it is not allowed to produce any current whatever; that is, the power necessary to overcome the friction and the resistance of the air. So that $P - P^1$ is the whole horse-power available for electrical purposes, and of this some will be expended in heating the armature and field magnet wires.

Let A be the resistance of the armature wire in ohms.

B the resistance of the wire on the field magnets.

R the resistance of the leading wires conveying the current to the cells.

r the resistance of each of the cells.

Let N ($= n\ m$) be the number of cells being charged—arrange *n* tandem and *m* abreast.

e the maximum electromotive force in each cell opposing the charging current in volts.

c the current flowing through each cell in ampères.

b the current flowing through the field magnets of the dynamo.

E the difference of potential between the terminals of the dynamo when it is in action charging the cells.

Of these quantities it is essential that E shall be greater than $n\,e$ if the cells are to be charged at all. If $n\,e$ is the greater they are slowly discharging themselves through the dynamo and are helping to turn it. The nearer $n\,e$ come up to E the easier will it be for the engine to drive the dynamo, and as soon as $n\,e$ exceeds E it will begin to drive the engine instead of the engine driving it. If the engine strap is slipped the dynamo will go on turning at the expense of the now discharging battery in the same direction as when it was charging it.

The following relations hold among the above quantities:—

$$E = n\,e + n\,r\,c + m\,R\,c \ldots\ldots \quad (1)$$

$$E = B\,b \ldots\ldots \quad (2)$$

$$746\,(P - P^1) = E\,(mc + b) + A\,(m\,c + b)^2 \ldots \quad (3)$$

$$E + A\,(m\,c + b) = \Phi\,(b) \ldots\ldots \quad (4)$$

The last being a statement that the whole electromotive force generated by the revolving armature is a function of the current flowing round the field magnet; but what that function is depends upon the construction of the machine, and especially upon how near the iron of the magnets is to being saturated. If it is saturated the function is a constant; if it is nowhere near saturation, the function is simple proportion. It can be determined by experiment and plotted.

Of all the above quantities,

P^1 has a fixed value determined by the speed employed, and ascertainable by direct measurement.

e and *r* may also be taken as fixed and known quantities, for the size of the cell is a matter of convenience, and this determines *r*; while *e* is a function of the materials used in the cells, and for Planté or Faure it is about $2\frac{1}{2}$ volts.

R is easily measured, and can be made as small as convenient.

A and B are also easily measurable, and though not uncontrollable, must yet be considered fixed for a particular dynamo.

n and *m* are of course completely under control, and we have to determine what is the most economical ratio $n : m$. But at present they can be regarded as given quantities.

The remaining four of the above quantities, viz., *c b*, P, and E, are dependent variables, and are given in terms of the others by the preceding four equations.

The number of thermal units (water—gramme—degree—centigrade) produced every second is:—

At the bearings and in the air churned by the machine, $178\,P^1$;

in the armature $\frac{A}{4{\cdot}2}\,(m\,c + b)^2$;

in the field magnet $\frac{E^2}{4{\cdot}2\,B}$;

in the cells $\frac{1}{4{\cdot}2}\,N\,r\,c^2$;

in the leading wire $\frac{1}{4{\cdot}2}\,R\,m^2\,c^2$;

The energy utilised as chemical work is $N\,e\,c$.

What we want of course is to make this last term as great as possible in comparison with the preceding five terms. Now it goes without saying that the smaller P^1 and R can be got the better. It also appears from the second and third of the above terms that it is good to have A small and B large. But what about N? N appears as loss only in the fourth term, and as gain in the sixth; hence it must be advantageous to make N large. But then N contains two factors *n* and *m*; and the second of them appears squared in two of the above loss terms; hence, though it is good to have *n* as large as possible, it is quite a question how big *m* should be. We find, however, by a little calculation, that to make $N\,e\,c$ as large as possible, compared with the other terms, that is to make the ratio of useful work to the waste a maximum, we must have—

$$\frac{m}{n} = \left(r + \frac{e}{c}\right)\left(\frac{A + B}{B^2\,(A + R) + 2\,A\,B\,R + R^2\,(A + B)}\right)^{\frac{1}{2}} . \quad (5)$$

or since R and A are, in practice, small, compared with B, we may say that the best possible value of the ratio $m : n$ is very approximately

$$\frac{m}{n} = \frac{e + r\,c}{B\,c}\sqrt{\left(\frac{A + B}{A + R}\right)} \ \ldots\ldots \ (5^1)$$

We perceive, therefore, that the best value of *m* depends upon *c*. If the current flowing through each cell is very weak, a large number may be arranged abreast; but if *c* is pretty strong *m* must not be great. Now, the permissible value of *c* depends entirely upon the size of the cell, for it is the "intensity," or as some call it the "density," of current—that is the current per unit area of electrode—which is to be kept small. But though a very small current is economical, not only because it reduces the waste heat, but, more important still, because it allows the chemical changes to go on slowly and steadily without evolution of gas or secondary disturbances; yet in practice a charging current of only one ampère through large cells would be felt to be somewhat tedious, and an allowance of five ampères would still be very moderate.

I will therefore suppose that the actual value of *c* is determined by practical convenience, and is measured by a galvanometer. Equation (5^1) fixes the best value of *m* in terms of *n*—but what is the best value of *n*? The equations indicate that the nearer $n\,e$ is to its maximum permissible value the better. This maximum value is

$$E_0 = \Phi\,(b_0) - A\,b_0 \ \ldots\ldots \quad (6)$$

But if it is too near this value, not only will the charging be very slow, but, unless the engine is absolutely steady, there will be a risk of the cells sometimes helping to drive it. It need not be so very far short of this upper limit, however, for the current tapped off through the outer circuit ($m\,c$) will not be usually great enough to reduce *b* much below its maximum value b_0, nor E much below E_0; and so we may put pretty nearly

$$\begin{aligned} n\,e &< E_0 - A\,m\,c \\ &= B\,b - A\,m\,c \ \ldots\ldots \quad (7) \end{aligned}$$

Or, putting in the best value of *m* from (5^1) we get

$$n = \frac{b\,B^2\sqrt{(A + R)}}{c\,B\sqrt{(A + R)} + (e + r\,c)\,A\sqrt{(A + B)}} \ldots (8)$$

The current through the field magnet which enters into this expression is not an absolute constant, even at a given speed, since it depends somewhat upon how much current is tapped off through the outer circuit—that is, upon $m\,c$. Nevertheless, if the wire on the magnet has a properly high reristance, it will be found that *b* is very nearly independent of $m\,c$, unless the latter is enormous. And as we have expressly said that $m\,c$ is not to be very great, we may regard the value of *b* at the given speed as nearly constant, and may measure it with a galvanometer.

---

[*] Condensed from the *Photographic News.*

[*] From the *Engineer.*

Practically, the value of *n* would be determined by adding to the series of cells until the current is brought down to the desired small value, taking care that the limit E is not too nearly approached, for fear that a diminution in the speed of the engine might cause it to fall below *n e*.

Observe that the greater *n* is the greater *m* may be too, so as to maintain the most economical ratio (5).

INJECTING SPECIMENS FOR MICROSCOPICAL EXAMINATION.*

By T. CHARTERS WHITE, M.R.C.S.

I HAVE placed under my microscope this evening an injected preparation from the small intestine of the Guinea-pig, not as an example of perfect injection, but to show more clearly what I mean by having a regard to the other elements of a structure besides the vessels; and I will describe the *modus operandi* by which I produce that preparation, and advise such of you who may wish to follow up this branch of work to undertake it with the full assurance that what I have but imperfectly performed would, with more time and attention than I could give, be attended by far more beautiful and instructive results. I do not wish to say anything relative to *opaque* injections, because I have had no personal experience in their production; but I shall confine myself to the making of transparent injections with cold injection fluid, although I believe that very beautiful preparations could be made by the amateur with a little attention to temperature, by using a warm injection of gelatine stained with carmine. With regard to the instrument to be employed, I may say that although a syringe is generally recommended to force in the injection, I found it attended by so much unsteadiness and fatigue, followed often by bursting of a vessel and consequent extravasation, that, however deftly it may be employed by the professional injector, I gave it up, and resorted to gentle and continuous pressure by a falling column of the fluid injection. The injection I used was Beale's Blue fluid, and as this requires a little care in its preparation, directions for its proper combination may be fitly inserted at this stage of the description. The formula I have found most satisfactory is that given by Dr. Beale in "How to Work with the Microscope," at page 114, and is as follows:—

Glycerine, 2 ounces.
Wood naphtha, 1½ drachms.
Spirits of Wine, 1 ounce.
Ferrocyanide of Potassium, 12 grains.
Tincture of sesquichloride of iron, 1 drachm.
Water, 3 ounces.

The ferrocyanide is to be dissolved in one ounce of the glycerine, and see that every particle is dissolved before proceeding to mix. The tincture of iron may be added to another ounce of the glycerine, and well stirred in; now add these two solutions gradually to each other, well shaking them in a bottle after each addition.

The iron must be added to the solution of ferrocyanide; this is strictly imperative. When thoroughly incorporated this mixture should produce a dark blue fluid without any flocculi, and with no sediment; the naphtha may then be mixed with the spirits of wine and the water, and gradually mixed with the blue fluid.

Having now made your injection, it may be placed in a wide-mouth glass jar on a shelf, about five feet above your table; cut two holes in the cork, which should fit the bottle accurately; in one hole place a small funnel, so that air may get to the interior of the bottle, and should the injection threaten to become exhausted before the completion of the process, some more can be poured in; in the other hole insert a bent glass tube, one end of which should reach in the inside of the bottle to the bottom; the other end may be left four inches long and turned over in a good arch; on this end fit about six feet of indiarubber tubing of a size to tightly embrace the glass tube; in the distal extremity of this tubing fasten a small stop-cock. If now suction be made at this, the injection will flow out of the bottle down the tube; the stop-cock can be turned, and thus the tube will be charged without containing any air. Having now your injection so far ready, prepare some nozzles of a suitable size to the vessel you intend to put the injection in. The best can be made from a piece of the glass tubing of the same calibre as that inserted in the bottle; draw some pieces of about two inches in length to capillary points in a flame, and then break off the tips to correspond with the diameter of the blood-vessel you select to operate on; twist some fine wire round the wide end of each of these canulæ and fix them with some sealing-wax; slip over the end of that you intend to employ a short length of the same tubing that you have attached to one end of your stop-cock. Now, having all these appliances at hand, select the subject to be injected. This may be either a young kitten, or a rat, or such-like small mammal; it must be procured alive, and may be drowned or chloroformed to death; and *directly* after death, the sooner the better, the thoracic region may be well laid open by cutting with a stout pair of scissors through the ribs on each side of the chest; never mind the intercostal vessels, they will not let out much injection, at any rate nothing to signify.

Now, although life may be perfectly extinct, the muscular contractility of the heart will exert itself, and the pulsation of that is an indication of the elasticity of the vessels; when once that has ceased the injection will not flow so freely, as an impending *rigor mortis* will have taken possession of the coats of the vessels, and will be a serious hindrance to the access of the fluid into the capillaries; lay open the pericardium, the bag which envelops the heart, and you will see the aorta springing from the left ventricle, and arching over by the left side of the spine, descending to the abdomen; cut off the apex of the heart, and insert the nozzle you have prepared first taking the precaution to fill it and the attached tube with water; push it gently upward though the cavity of the heart till you see it enter the aorta, when with a curved needle you may pass a ligature under aorta and pipe, and tie them, securely fastening the ends of your ligature to the wire studs twisted on your glass tube, that will prevent it slipping out again; see that it is filled with fluid to the top, so that all air may be excluded, and then make your connection with the stop-cock, first letting a few drops of the injection flow through it, when your tube is continuous turn on the stop-cock, and you will soon see the various organs become tinged with blue, the larger vessels first, and coursing along these it will branch off into innumerable fine channels, till the whole capillary system is full, and the excess coming out of the right side of the heart will tell you your work is complete.

Your subject may remain to be cut up at your leisure, for the glycerine in the injection will act as a preservative for some considerable time. This, then, was the process adopted for the injected preparation under my microscope this evening. You will see that the blue fluid has run into the finest capillaries. But it is said we learn more from our failures than from our successes, and therefore, as that preparation is far from what you can admire from an æsthetic point of view, it will prove all the more instructive if I point out an error I fell into. You will see that in a great many places the blue injection has entirely faded out, and in others that it is very pale. I believe this has arisen from the blue fluid not being sufficiently acid to neutralise the alkalinity of the blood remaining in the vessels; and this seems substantiated by those specimens where the preparation has been put into ammoniacal solution of carmine, which has entirely obliterated the blue, only sufficient traces of it being left to tell of its departed beauty. The next time I do this I shall put a little acid into my blue injection. I once derived much good from having two wide-mouthed jars, one containing a weak warm solution of salt-and-water, which I allowed to flow through the capillary system in a similar manner to that I have described as employed for the blue fluid prior to sending in the injection, while my subject was manipulated under warm water; this excluded every possibility of air getting into the circulation, which is always to be avoided as most ruinous in its results. These perhaps wearisome details comprise the whole of the process I have always employed. Of course, others have tried the same process, but I thought that it would be better to tell you how I acted, as if no one else did the same thing, because I could make my short paper more didactic, and you will see by my poor specimen that with greater care this process is capable of producing some beautiful and instructive results. You will, in the subsequent examination of it, be able to determine how much is the result of the mounting medium in which I have placed it. For my part, I believe it is entirely due to this that not only the villi but the Lieberkühnian follicles are most clearly shown with the capillary vessels coursing all though and around them; and I must aver that had this specimen been mounted in balsam or dammar, every detail would have been sacrificed. I consider balsam to be the greatest bane Histology has to fight against. The specimen I show to-night, after being saturated with the glycerine from the injecting fluid, only required a little weak glycerine and camphor water to put it up in, and you will see the consequence is a preservation of everything that would be otherwise blotted out.

ELECTRIC LIGHTING FROM A PHOTOGRAPHIC POINT OF VIEW.*

WE have, from time to time, laid before our readers particulars of progress in electric lighting as bearing directly or indirectly on the work of the photographer, and nearly a year ago we referred to the Pacinotti machine as having been mainly instrumental in bringing about the present condition of electrical activity. Not only did Professor Pacinotti anticipate, by the construction of his now celebrated machine, the so-called dynamo or regenerative principle, as enunciated seven years afterwards by Siemens and Wheatstone, but he gave to the world the first magneto-electric armature, in which the magnetic changes are progressive rather than sudden, a condition of affairs which not only enables us to obtain a current of absolute equality and constancy, but also much of the heating which ordinarily results from the quick reversal of magnetism in soft iron is obviated. For these reasons, and more especially on account of the diminished heating of the rotating armature, the Pacinotti machine has been found to be by far more effective than the older machines constructed with the armature of Siemens. Although the *Nuovo Cimento*, which contained a description and drawing of the Pacinotti machine, found a place in several of the public libraries of Great Britain, and fell into the hands of most scientific men, it appears that very few appreciated the importance of the invention, and probably not half a dozen models of it were made in this country until M. Gramme constructed the Pacinotti machine on a much larger scale than had been attempted by the original inventor, and called prominent attention to its industrial value. It may interest our readers to know that about fifteen years ago M. Gramme assisted Mr. Woodbury in the arrangement of a magneto apparatus and Lenoir gas engine, used in the production of the electric light for photographic purposes at his premises in Brompton, and after this M. Gramme remained for some time helping Mr. Woodbury in the manufacture of his gelatine reliefs. This was, however, before the commercial advent of the Pacinotti machine.

Gramme, after having devised several new commutators, so far modified the commutator or collector of the Pacinotti machine as to replace the alternately placed strips by parallel conducting rods mounted somewhat like the staves of a barrel or tub; but the experience of more recent times seems to show that Pacinotti's original method of so alternating the strips as to insure the contact of each brush with two successive studs or strips is preferable, and calculated to reduce sparkling at the commutator. We see a return to Pacinotti's original commutator in the Brush machine, while the Weston machines are made with slightly bent strips, and a similar end is attained by the use of two brushes on each side of the commutator, as exemplified by the Hefner Altneck machines.

In October last we detailed some particulars as to the use of the Swan incandescent lamp for photographic portraiture, and described a number of experiments in which an ordinary or full-sized Swan lamp was used in conjunction with thirty cells of Grove's battery. We mentioned at the time that the lamp could not be satisfactorily worked by a small hand Gramme (Pacinotti) machine, with which we tried it. Since the time referred to the smaller, or five-candle, Swan lamps have been introduced into the market, and it was found that the hand-machine in question would work from three to five of these when arranged in parallel circuit; in fact, this was shown not long ago at a meeting of the Society of Arts; while on the occasion of one of Mr. W. H. Preece's juvenile lectures at this institution the same hand-machine was used to generate a current by which more than 500 buttons were electro-plated with silver in a few minutes.

In order to render the machine in question more effectual as an electric generator, we determined to try the effect of a small electro magnet so placed as to form consequent poles with the permanent magnets of the machine, and the result proved so satisfactory that it became possible to produce a sufficiently actinic light for ordinary portraiture by the current produced when the motive power is no more than can be generated by easy turning with one hand.

The diagram (Fig. 1) represents, in a manner which will be sufficiently intelligible to any one familiar with electrical matters, the machine with the additional magnet; and the machine in this form may be regarded as standing between a magneto machine and a dynamo machine. Non-electrical readers must understand that the representation of the wire is intended only to indicate the manner of coiling, not the amount used.

The advantages of the arrangement in question will be understood if we point out the way in which a current arises in a dynamo machine. When the armature is turned, a weak current is generated, owing to the residual magnetism of the field magnets, and this current circulates round the field magnets in such a direction as to tend to increase their activity. If, however, the resistance in the exterior circuit is very great, it may happen that the intensity of this current is below that minimum which should suffice to induce an amount of magnetism corresponding to the residual magnetism of the soft iron field magnets. In this case the dynamo is practically inactive, as the cumulative principle does not set in. If, however, the speed of the armature is so far accelerated as to bring the intensity of the current above the before-mentioned minimum, the cumulative action will set in; or the machine may be put into full action by temporarily reducing the external resistance. It follows, from the above considerations, that there is a certain external resistance, which will serve to prevent any given dynamo machine from starting into full action for each rate of speed, and this limiting resistance will be higher as the coercive force of the metal of the field-magnets is greater; but, as the coercive force of the field-magnets is raised, the machine approximates more and more nearly to a magneto machine, and is so much less serviceable as a pure dynamo or regenerative machine. The apparatus figured above unites in itself the principal advantages of a magneto machine and dynamo machine. When the armature is made to rotate, and the external circuit is left open, a considerable difference of potential arises between the poles, although this is, of course, not so great as would have been the case if the soft iron of the electro-magnet were not so placed as to form a keeper to the permanent magnet; and this initial potential is sufficient to insure the efficient action of the machine even when a very high resistance is included in the circuit. When a five-candle Swan lamp is placed in circuit, and the machine is turned with the full force of one hand, the lamp is almost immediately destroyed, the thread breaking, and volatilised carbon being deposited on the inside of the bulb; but, by working the machine at a lower rate of speed, any required temperature, from a low red heat upwards, can be readily maintained.

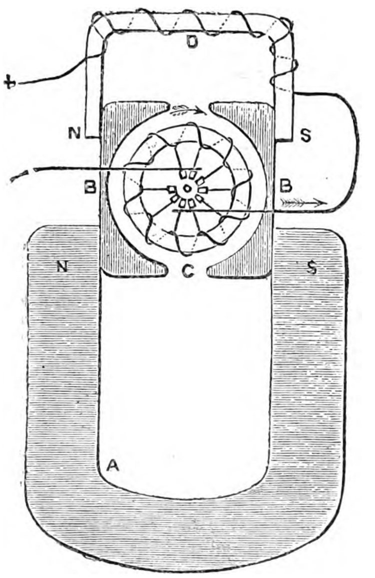
* From the *Photographic News*. We are indebted to our contemporary for the loan of the blocks.

Fig. 1.



A, compound permanent magnet; B, B, jaw pieces; C, five-inch Pacinotti ring; D, electro magnet. (One of the commutator strips, with its conducting wire, has been omitted from the diagram).

By keeping the carbon thread at a temperature somewhat short of that required for its rapid destruction, a highly actinic and intense light is produced, and this is so effectual as a photographic illuminant, that when the lamp was placed at a distance of 4ft. from the sitter, a bust portrait was readily obtained with an exposure of from two to three seconds, a 1 B lens being employed. Here we have an advance of nearly twenty times, as regards rapidity, on our previous experiments; and instead of thirty cells of Grove's battery, a machine which can be easily turned with one hand is used. Several determinations gave us from 200 to 300 as the candle power of the lamp during the experiment. It will be understood that under these circumstances the incandescent lamp will not remain effective for a very long time; but several experiments indicate that on an average from fifteen to twenty portraits may be made with each five-candle lamp as at present sold. Considering, however, that in most cases the rupture of the thread took place at a weak point, and long before the whole of the filament had become considerably attenuated by the volatilisation of carbon, there is every reason to hope that as the manufacture of the lamps is improved, two or three times as many exposures may be reckoned on from each lamp.

At the present time, it is evident, from various estimates which have been made, that the cost of incandescent electric lighting is approximately equal to that of gas-lighting; or that the difference is, at any rate, not very great. If it could be made practicable to work incandescent lamps at a high temperature, as in the case of our experiments, the cost of incandescent lighting would immediately fall to about one-fortieth that of gas, as the high incandescence does not require a correspondingly increased consumption of electric energy. It is, however, difficult to conjecture as to what body, considerably more refractory than carbon, and yet a sufficiently good conductor, we may hope to make available; but problems seemingly more difficult than this have been solved by modern research.

Assuming that the incandescent lamps are finally sold at fifteen pence each, each exposure will cost rather under one penny; but if, at the same time, the durability of the lamp is increased, the cost will be notably lessened.

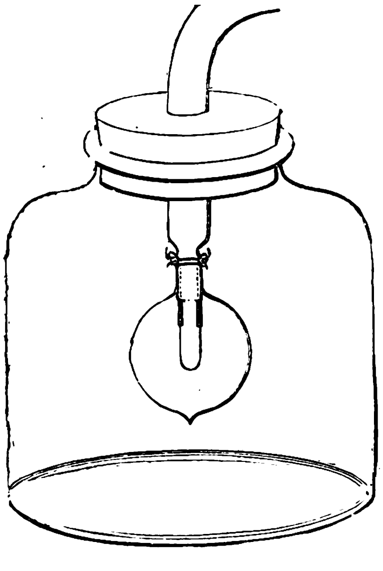
It must be remembered that the experiments we have described were performed with the small, or five-candle, Swan lamp; but, by using the larger lamp, and a proportionately powerful current, there can be little doubt that still more satisfactory results might be obtained.

Mr. Peter Mawdsley—who was with us when some of our experiments were carried out—suggested that in many cases it might be advantageous to employ a powerful gas-light to lower the intensity of the shadows cast by the electric light.

It appears to us that the incandescent lamp, actuated by such a hand Pacinotti machine as we now describe, would form a very suitable arrangement for optical lantern work.

The subjoined cut represents an arrangement which we found convenient for mounting Swan lamps, the conducting wires passing through the cork of a wide mouth bottle. The bottle forms a protection against fragments of glass, should the lamp fly on the powerful current being suddenly passed through it.

Fig. 2.



The same arrangement would probably be a most convenient one for the non-actinic incandescent lantern, a ruby or orange bottle being employed.

We hope, before long, to be in a position to give our readers some useful information regarding the use of the Planté secondary battery as a means of producing a light for photographic purposes.

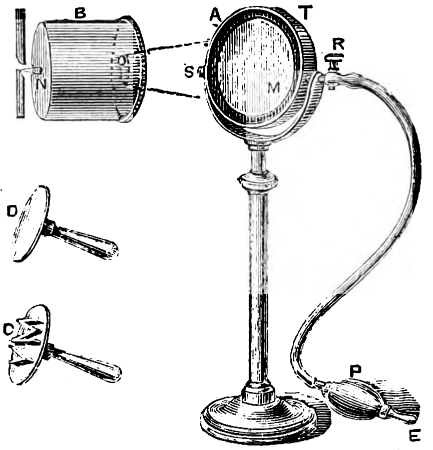
MAGIC MIRRORS OF SILVERED GLASS.

A YEAR or more ago, the scientific world was much interested in the very curious effects obtained with the magic mirrors of Japan, and several successful efforts were made in Europe to imitate them, the material employed being, as in the imported article, metal.

Recently, M. Leon Laurent, an optician of Paris, has greatly improved on these curious apparatus by constructing them of glass—a material which is found in some respects much better adapted for the purpose than metal.

M. Laurent has succeeded in constructing two series of the apparatus for lecture and experimental purposes: (1) Compressed and curved mirrors; and (2) mirrors of various thicknesses and forms (plane, concave, and convex), heated in a peculiar manner. For the first of these he uses commercial glass of about one millimetre in thickness, upon which he engraves designs of uniform depth. Glass thus engraved is more flexible than when the designs are in relief. After engraving, the glass is silvered, and the silver is polished. The mirror thus formed is mounted on a standard with the necessary accessories for manipulating it. (Fig. 1.) The following is a brief description of the arrangement, as shown in the figure:

M is a plane mirror silvered on the outer surface. The design is engraved on the back, and is consequently invisible in the ordinary state. The mirror rests against the hollow frame or drum, T, which is movable on the pivots, R S. A is a binding ring lined with cloth for fixing the mirror in place. There are three of these mirrors, one being concave, one convex, and one plane. These may be changed, one for the other, at will, as may be also the rings, A. P is a rubber bulb with which the air contained in the frame may be exhausted or compressed. At R is a cock which permits the exhaustion or compression to be maintained for some time. B is a special cap, having two apertures, O and N, and which is substituted in the lantern for the ordinary tube that holds the lenses. The apertures N and O limit the size of the luminous point and restrict the divergent fascicle. Finally, in front of the cap B, and the aperture N, are seen two carbons, between which is produced the electric light designed to illuminate the mirror.



The apparatus thus arranged is manipulated as follows:—

The cap B is placed in front of the light support, and at about one metre away from it, and the magic mirror is placed at about two metres from the cap. The screen is set up near the light, thus making it about three metres distant from the mirror. Thus arranged, if the mirror be left at rest, it gives on the screen only a white light, without any figure or design. But if the bulb be compressed with the hand so as to compress the air in the hollow frame, the glass, M, becomes convex, and there is thrown on the screen a *black* and magnified image of the invisible design engraved on the back of the mirror. On removal of the pressure, the mirror assumes its former shape, the image becomes white, and the design disappears. It should be remarked that it is not absolutely necessary to use the electric light; for the oxyhydrogen light, or even a good kerosene lamp (and, under some circumstances, sunshine) will answer just as well. In all cases, these experiments are very curious, and it is, indeed, truly *magical* to see these mirrors, on which no design can be perceived, reproduce on the screen, through the simple compression or exhaustion of the air, the most varied figures, such as flowers, animals, arabesques, &c.

In the second kind of apparatus, M. Laurent has obtained another property of mirrors through the dilatability of glass by heat. In this form of the mirror he substitutes ordinary silvered-glass of commerce of about four millimetres thickness for the engraved mirror, M. The implements for producing the figures consist of metal discs, on which are formed the designs in relief, like the one shown at C. One of these is heated to a point where it can be just touched without burning the hand, and then applied to the silvered part of the mirror, when the designs will immediately exhibit themselves *in white* on the screen. As the mirror becomes heated by the application, a cold disc is substituted for the hot one, with the result of giving on the screen a design *in black*. By placing two of the figured discs, one of them cold and the other hot, on the mirror, two images may be obtained—one white and the other black. The thickness of the glass makes no difference in these experiments; nor does the varnish which protects the silvering have any effects on the results. As the metallic dics, with figures in relief, are pretty expensive, there may be substituted for them designs made as follows:

Take an ordinary visiting card, and trace upon it any design whatever; then, with a pin, prick through all the lines of the drawing so as to have the design in relief on the other side. Or take a piece of tinned paper, such as that usually used for covering chocolate, and make the drawing on the plain surface, bearing down pretty hard so as to have the design in relief on the metallic side. By applying a design made in this manner to the sildered side of the mirror, and holding lightly against it a plane heated disc, D, the design will be reproduced in white on the screen.

An explanation of the theory of these interesting apparatus may be given in a few words, as follows :—If we suppose a mirror to be absolutely plane—that is, without the least elevation or depression on its surface, it will reflect light uniformly, and the image that it gives on a screen will be perfectly white. But if there be a slight irregularity in the surface, the rays that such irregular part receives will no longer be sent normally to the surface of the mirror, and hence there will be a diminution of the image on the screen—that is to say, the production of a shadow. If this irregularity follow the lines of an object—of a flower or of a letter, for example—the shadow will conform thereto, and there will appear on the screen an image of the object; and, according as the designs are depressed or in relief, the image will be black on a white ground, or white on a black ground. The description given of the apparatus as modified by M. Laurent, shows how the compression or exhaustion of the air, as well as the application of heat, has for result the production on the surface of the mirror of very slight elevations and depressions corresponding to the elevated or depressed designs, invisible on the mirror itself, but rendered visible on the screen because of the power of the luminous source employed to reflect the image from the mirror.

IMPROVEMENTS IN BOILER CONSTRUCTION.*

REPORTS have been made heretofore covering nearly or quite all matters pertaining to the subject of the best material, form and proportions for locomotive boilers, and there seems to be but little matter that has not already been brought to your notice in reports and the different points discussed. As regards material in the construction of boilers, the use of the best quality of homogeneous steel, as now made by our manufacturers in this country, leaves but little more to be desired. Yet, notwithstanding its excellent quality, we are not entirely free from ruptured side sheets in the larger class of locomotive boilers, where the box is deep and water used such as deposits a hard scale on the sheets. The fault, in most cases of failure, is not with the material, but rather that it is required to stand what in the nature of things may be said to be impossible—strains from compression and elongation beyond the elastic limit, without final rupture. That firebox sheets, under circumstances frequently occurring, are subject to such strains was, I believe, conclusively demonstrated in a series of tests made by the writer, and published in the tenth annual report. The formation on the sheet increases the expansion of the metal by allowing it to attain a higher temperature than it otherwise would, developing strains in the sheet that sometimes produce a permanent elongation or shortening, as the case may be, in a comparatively small section of the sheet; and, when the temperature becomes uniform in all parts of the sheet, the part under tensile strain is liable to rupture, beginning always at a stay-bolt hole, but extending through the sheet between the stay-bolts as likely when once started as from one hole to another.

On some of the divisions of the road with which I am connected, a large number of engines have been in service more than 10 years doing heavy work, and not 5 per cent of the steel firebox sheets in them have cracked during that time. The water used in these boilers is such that hardly any scale is formed on the sheets. More than 80 per cent. of these engines have their original fireboxes, which are still sound and apparently good. On several other divisions the case is somewhat different, more particularly the St. Louis division, north of the Ohio river, through the State of Illinois, where the water used is more or less impregnated with lime and other impurities, forming a hard scale, and in consequence reducing the life of the fireboxes to about one-half of that in the case of engines on most of the divisions south of the river.

The character of a water used in a boiler, as regards the deposits left in it from evaporation, determine, to a great extent, the durability of the fire-box and tube-ends, yet, with the best quality of water, a fire-box has its day. It perishes, however, from a different disorder than the one in a boiler supplied with water that deposits a heavy scale. In the former case, the flanges of the flue sheets and the back sheet from the top of the grate to about 36in. up are the points that ordinarily give out first; the flanges become overheated or burned and crack from the rivet out, and the cracks gap open and leak. The sheets also become thin at the corners below the grate from corrosion, while in its other parts the fire-box remains sound.

In the latter case, the life of the fire-box is too short for producing this effect on the flanges of flue and back sheets, as the side sheets give out at the stay bolts from cracks extending from them to a greater or less distance, until renewal becomes necessary.

It is important in all cases that the flanges of fire-box sheets be as short as possible. The closer the seam is to the corner the longer it will last. It remains cooler than if more exposed to the effect of the fire. I have noticed a number of flue and back sheets within the past two years that had to be removed simply on account of the burning and cracking of their flanges, that were otherwise good for several years' service, and many more that must soon be removed from the same cause. The flanges were originally made too long, extending out from the face of the sheet as much as 3in. Had they been but 2in., they would doubtless have lasted much longer. This is a matter which, from my observation, I conclude is very often overlooked in the construction of the firebox. All laps exposed to the fire should be as short as possible, more particularly where the heat is great. The flanges, if properly turned, need not at most be more than 2in. from the face of the sheet in the vertical seams for a distance of 2ft. or 3ft. above the grate. A lap of $1\frac{3}{4}$in. for the seam is sufficient at that place. At greater distances from the grate, the lap and length of flange may be greater without any evil results. I have noticed many cases also where tube-sheets were much worn around the end of the tube in the form of a counter sink, about $\frac{1}{4}$in. wide and the same in depth, around the lower and central tubes the sheets becoming so thin as to require removal, while at all other parts they were apparently good. Such sheets were in nearly, or quite, every case in fireboxes of engines doing heavy work, and having boilers comparatively small for their cylinders and work. In the case of copper tube-sheets, this defect seems to be greater even than with steel sheets.

The cause of this cutting away of the sheet in the form of a groove around the tube-end is due, I suppose, to the particles of coal and cinder drawn towards the tube by the force of the draught, and those striking the outer slope of the head on the end of the tube, where it projects into the firebox, turn outward toward or from the tube, striking the sheet and in time cutting a groove or valley around the end of the tube, as stated; while the projecting end of the tube itself suffers comparatively little—the action of these particles of coal and cinders on the sheet around the tube being the same as that of sand in the sand-blast machines for sharpening files. If this theory is correct, then it will be best to have as little projection of the tube end as possible beyond the face of the sheet in the firebox. To countersink the tube-hole sufficiently to receive the head of flange on the end of tube, without leaving a sloping projection on its outer edge, will add to the life of the sheet.

In the matter of improvements in the designs of boilers and in their construction that is new and valuable, I have little or nothing to offer. What may seem to be new in these latter days is generally found to be some slight change in an old plan or pattern, or something long known to the public presented in a modified form.

The first successful locomotive boilers made were of the tubular pattern, the fire-box surrounded by a water space; and we are using the same form today, not having found a better one; and until some new method of generating power is discovered we may be obliged to continue the use of the present pattern without material alteration. The "Verderber" without water space around the fire-box, tried on several locomotives on one of the Hungarian State roads, in Europe several years ago, seems to have been a failure as regards an improvement on the common form of boiler for generating steam.

There may be in the economy of nature "thus far shalt thou go and no farther" for a time at least, and until such time the wisest course will be to endeavour to perfect that which we have. That we have arrived at perfection in the construction of the locomotive boiler no well-informed person will, I think, assert; nor that some one class of boilers will answer best for all classes of engines, kinds of fuel, and different qualities of water that must be used. The character of the water as regards the impurities held in solution in it, the quality of the fuel to be used, as regards its evaporative power, the grate area, the quantity to be evaporated in a given time, and the class of engine, must all be intelligently considered in fixing upon the form and proportions of the boiler in order to give the best results.

In illustration of the fact that the character of the coal to be used should be considered in proportioning the grate area of the firebox, I will give the results of a series of tests made in the boiler of one of the passenger engines running on the Louisville and Nashville R. R., between Louisville and Nashville, in the months of April and May, 1882, in testing the difference between seven different kinds of coal. The engine had 18in. by 24in. cylinders, 5ft. 3in. drivers, was an eight-wheeled engine, with a boiler 54in. in diameter, the waggon top raised 6in. above the cylinder part and a 30in. dome. The firebox was 72in. by 34in. at the grate; 191 2in. tubes, 11ft. $5\frac{1}{2}$in. long.

The firebox was fitted with the brick arch supported on four water-pipes tapped into the sheet below the boiler tubes and into the crown sheet 13in. from the back sheet. Grate area, $12\frac{1}{2}$ft.; (live grate) tube surface (inside diameter), 1,052ft.; heating surface of of firebox, 115ft.; total, 1,167ft. (deducting for tube holes, fire door, and surface below the grate).

During these tests the engine was run and fired by the same men, the coal carefully weighed, and the water accurately measured.

The average speed of the train, including stops, was 27 miles per hour, and the average number of cars per train 67-10. The condition under which the tests were made were as near alike as it was practicable to make them. Wood was used for firing up, the water was gauged when the first coal was put into the fire-box previous to starting on each trip.

Average temperature of water in tender 65° Fahr.
,, steam-pressure in boiler, 130lb.

The total engine mileage was 3,366 miles, and the average evaporation was 6·002lb. of water to 1lb. of coal consumed. Each trip or run was 187 miles.

Coal No. 1 was the best quality of Pittsburgh, No. 2 an inferior quality, No. 3 Alabama coal, No. 4 Tennessee coal from near Chattanooga, No. 5, 6, and 7 from mines in central Kentucky. The difference in evaporation between the best and the poorest of these coals was 26 per cent.; in other words, the poorest coal (No. 5) evaporated 26 per cent. less water to the lb. than the best coal (No. 1); to evaporate the same quantity of water in a given time, 26 per cent. more of the No. 5 coal must be burned than if the No. 1 coal were used; and if the grate area was the correct proportion for burning the best coal, it was too small for the poorest, and *vice versâ*.

The train average in cars was the same in both cases, and the speed the same, and the tests made going the same way (south). The difference in the results, therefore, was due to the difference in the coal. This will serve to show that our monthly reports of coal burned per mile and per car hauled are of no practical value for comparison except where the coal is uniform in quality.

Comparing the performance of an engine using coal No. 5, with one using coal No. 1, would be very unfavourable for the former, taking quantity only into account. The boiler using that coal would be considered very inferior, or the one using coal No. 1 would be credited with merits not due to it if the quality of coal consumed were not considered; the whole difference being due to the fuel, and not to any difference in the boilers.

As a rule, it may be said that the area of "live grate" should be as small as possible that will burn the amount of fuel necessary to generate the required amount of steam. The area of grate to give the best results will depend largely on the quality of the coal used.

For instance: a grate area of the proportions generally used in the Wooten boiler would certainly be wasteful in fuel where a good quality of bituminous coal was used, but would, perhaps, be the most economical where a very inferior quality of anthracite or semi-bituminous coal is burned.

As nature has made the coals to differ greatly in kind and quality, equal variety in the proportions of grate, and to a certain extent of fire-box and boiler, seem necessary, in order to obtain the best results in its consumption. Careful tests and observations must be relied on mainly to determine the proper modifications necessary to suit each variety of fuel. No one pattern will answer best for all kinds. It is important, more particularly, however, where bituminous coal is used that is rich in gas, that the area of fire-box be large enough to give time for the perfect combustion of the gases before they enter the tubes, that the heating surface be as great, and the boiler as large as possible, within the limits allowable for the class of engine in which it is used.

A large quantity of water in the boiler gives a large capacity for storing away heat (power), accumulating it when the demand for steam is comparatively light, and giving it out as required in the variable quantity of steam required in a given time, in the ordinary use of the engine, without causing the great variations in boiler pressure that occurs when the boiler is deficient in capacity.

---

* The report of Mr. Wells, Chairman of Committee on boilers at the Master Mechanics' Convention, Niagara Falls, New York.

A large boiler, like a flywheel, accumulates power when it would otherwise be wasted in part, and responds to sudden demands for it, for a time at least, without much apparent diminution of its force.

As regards the material for boilers, and character of the workmanship, there need not be any great differences; all should be as nearly perfect as possible. A boiler that is strong enough may be said to be as strong as it is worth while to make it, no matter how constructed; but a boiler may be strong enough when new and yet not be strong enough to withstand with safety to a good old age the weakening influences of corrosion, unequal expansion, the springing of the sheets from their original shape by pressure, and the strains from boiler attachments.

Theoretically and practically our boilers are ample in strength when new, but in the course of time the influences referred to have in many cases so operated on the boiler that it is found to be in parts, both theoretically and practically, too weak. Where the metal is $\frac{3}{8}$ or 3-16in. thick originally, it is found to be perhaps less than than $\frac{1}{4}$in. thick in places; and at others, where the thickness has decreased but very little, cracks or furrows are more or less developed, caused by expansion and contraction, or other strains that spring the sheet —I refer to the shell of the boiler and not the firebox—and this, too, before the boiler has been in service half its natural lifetime.

Patching or replacing these defective sheets then begins, probably too, at a time when it is most inconvenient to do it.

Testing a large number of boilers by hydraulic pressure, that have been in service a number of years, as they came to the shop for repairs, convinces me that the margin of safety between the ordinary pressure carried and that necessary to produce rupture in the weakest place is unpleasantly narrow, in the case of many old boilers in service on the roads in this country.

At the base of the dome seems to be the weakest point in many old boilers, insufficiently braced, as far as my observation goes. Much improvement has been made of late years in increasing the strength of boilers by the use of thicker sheets, a better plan of joints and seams, and better bracing; but, as a rule, there is still room for improvement in that direction.

Our English friends are far ahead of us in the strength of their boilers. We think they go to the extreme in using butt-joints, outside and inside welt-pieces, drilling and reaming all rivet-holes, and in the thickness of plates used, &c. And perhaps to a certain extent they do; yet I am satisfied that if we imitate them a little nearer in the thickness of plate for the shell of the boiler, and strengthening the base of the dome, it would be a paying investment in the matter of durability and lessening the cost of repairs.

As a rule, the metal used in the shell of our boilers is not thick enough; not that the boiler is deficient in strength to withstand the steam pressure with perfect safety when new, or that the seams are not strong enough, but there is a want of stiffness or rigidity about it. In other words, the shell of the boiler is not as strong proportionately as the other parts of the engine, and it is generally the first among the expensive parts to require repairs.

When the diameter of what was considered a large boiler some years ago was 44in., the thickness of the sheets was seldom or never less than $\frac{3}{8}$ of an inch. Now, when the common size for a large engine is 54in., the thickness is seldom more than 7-16 of an inch. The diameter has been increased 22 per cent., while the thickness of the sheets has only been increased about 16 per cent.

Consider that the steam pressure has also increased with the increase in the diameter of the boiler, to the extent of perhaps 8 per cent., the thickness for the sheets for the shell of a 54-in. boiler should be half an inch, to be as strong proportionately as the 44-in. boiler, when that was the general size in use.

The "Belpair" boiler, extensively used in locomotives in Europe with very good results, has heretofore been but little used in this country. The Rogers locomotive and machine works have, however, built several of these boilers within the past year for the Denver and New Orleans Railroad.

The Belpair boiler has an arched crown-sheet supported by radial stay-bolts from the shell, with no crown bars. A number of plugged holes are located along the sides for the introduction of a hose nozzle for washing the mud off the crown sheet.

The water used in them is said to be very bad, but they have not yet been in use long enough to determine their advantages as compared with the common form of boiler; but, so far, it is claimed that the results have been very satisfactory.

A slight curve or oval in the shape of the crown head, or a slope backward, would, I think, be an improvement in allowing any loose deposits on it to work off and pass down to the mud ring.

The Rhode Island Locomotive Works built two of the Belpair boilers for burning anthracite coal for the State Line and Sullivan Railroad in 1877, a tracing of which I inclose, which was kindly furnished me by Mr. J. A. Durgin, the superintendent of those works.

I have failed, however, in my efforts to obtain any information from the parties using these engines, as to how they compared with those having boilers of the ordinary type; but I learn from Mr. Durgin that so far they have given entire satisfaction.

The connection sheets between the firebox shell and the cylinder part of the Belpair boiler should, in my judgment, be made of thicker plates than the other parts of the boiler; otherwise they would be liable to furrow on the inside at the short curves, from unequal expansion and contraction. Experience has shown that with light plates furrowing manifests itself, sooner or later, in sheets of that form connecting the two parts of the boiler.

Where water is used that deposits little or no scale on the firebox sheets, the Belpair or any similar plan, without crown bars, would, perhaps, show but little superiority over the common plan in evaporation or durability, if the crown bars are high enough above the sheet—say, 1$\frac{1}{2}$in. or 2in.—to permit a free circulation; but in the case of water, such as is used in a large proportion of the boilers in service, containing lime and other impurities which is deposited in the form of scale on the inner surface of the boiler, it would seem that the boiler, having the least area of surface where this deposit on it would have an injurious effect, would be the best; other things being equal.

Where bad water is used, the difference between the two plans of boiler, it seems to me, is this: In the one having crown bars the whole of their surface affords area on which the deposits of scale are formed. They are not heating surface, and the deposits on them would do no harm, except that when they became heavy more or less of the scale breaks off and falls on the crown sheet, preventing the water at such places from coming in direct contact with the sheet, and if not promptly removed the sheet becomes overheated, and in time "bags" down between the bolts, making a pocket in which additional scale falling from the crown bars is held, and the evil increased. In the case of the boiler having no crown bars, this source of evl does not exist to so great an extent, and in that particular, at least, it is the best.

Now, if we assume that a crown sheet, 72in. by 46in., is supported by crown bars, 14 bars made of two pieces of 5 by $\frac{3}{8}$ iron, will be required. These have their outer and inner surfaces in contact with the water. Each bar (pairs) has a surface of about 1,000 square inches of surface exposed to the deposits of the impurities in the water, in addition to the surface of the sheet itself, and that of the braces and stays that may be situated directly over it and below the water-line.

In the case of a crown sheet of the above dimensions stayed by bolts to the outer sheets of the boiler, about 126 bolts 1in. in diameter would be required. If the depth of water carried over the crown sheet averaged 12in., the surface of these bolts exposed to deposits of scale would be 4,747 square inches, or only 33 per cent. of the surface presented by crown bars.

From this it is safe to conclude that the crown sheet stayed by bolts, without the use of crown bars, will receive only about one-third as much of this detached scale falling from the surfaces of the bolts, and bracing directly over it, as the one supported by crown bars; and, as the detached scale falling from the crown bars and braces where the water is very impure is a troublesome and expensive matter, the question of reducing the dead surfaces, as they might be called where these deposits are formed, to the lowest practical point, is one that seems to me worthy of more consideration than is generally given to it.

Preserving Yeast.—For the conservation of yeast the following has been recommended in the *Chemical Review*:—"The thick portion of the yeast is filled into a champagne bottle, and on top of it is poured about 2$\frac{1}{2}$cm. of olive oil. The bottle is then closed by tying a bladder over its top, and in order to protect it from explosion a pin is put through the bladder. So the yeast will keep well for a long time if kept in a cold place. Yeast, if mixed with about one-eighth of pure glycerine, also keeps well for some time if kept in a cool place."

THE National Association for the Promotion of Social Science will hold their Congress at Nottingham from the 20th to the 27th September.

SCIENTIFIC NEWS.

TO No. 2434 of the *Astronomische Nachrichten*, Dr. Vogel of Potsdam contributes some observations on the spectrum of Comet Wells, in which, following Dr. Copeland and Mr. Lohse in the Dun Echt circular 52, he calls attention to a remarkable bright line corresponding to sodium line D. This notable feature in the spectrum of the comet has been seen by Drs. Müller and Kempf, in company with Dr. Vogel, and also by Prof. Bredichin, and others at Moscow. Since 1864 about twelve comets have been spectroscopically examined, but Wells' comet appears different to all, as its proper light proceeds principally from incandescent vapour of sodium, and it is consequently, in Dr. Vogel's opinion, among the most interesting subjects of observation in the new department of spectrum analysis.

We understand that, despite the announcements made by the daily press, the results of the recent eclipse expedition amount to very little beyond what was expected, and throw no light whatever on the so-called dissociation of the elements.

Baron Dembowski's double star observations are to be published under the superintendence of Prof. Schiaparelli, in the *Atti* della Reale Accademia dei Lincei. They will occupy about three or four volumes.

The Emperor of Brazil, in a telegram to the Academy of Sciences of Paris, reports that Comet Wells was seen on June 17 at Rio de Janeiro, and that three days later, the nucleus was very bright, and the tail 45° long. As to the latter statement, it is legitimate to suppose there may be an error in the telegram.

Besides the transit of Venus observations in December, other efforts will be made to determine independently the solar parallax, Mr. Gill having arranged for corresponding observations, to be made at several places in both hemispheres, of the minor planets Victoria and Sappho, the former of which will, when in opposition on Aug. 24, be distant ·89 of the earth's mean distance from the sun, and the latter be within ·85 on September 24. In the *Astronomische Nachrichten*, Mr. Gill gives a list of the proposed comparison stars.

Messrs. Longmans have issued, under the title of "Studies of Venus' Transits," those portions of Mr. Proctor's "The Universe and the Coming Transits" which relate to the transit of 1882 and to that of 1874. Some of this matter is out of date, but all that relates to the coming transit, and to the comparison between that and the transit of 1874 is as trustworthy as when originally published in the *Monthly Notices*.

Messrs. Crosby Lockwood and Co. have issued Mr. Michael Reynolds' book on Continuous Brakes. It contains illustrations and discriptions of all the best known brakes, with accounts of the various trials. We shall take an early opportunity to notice it at length.

We have received Vol. III. of the "Geology of Wisconsin," accompanied by an atlas of maps. It is a portly volume of about 750 large octavo pages and numerous plates, many of them coloured, and is an excellent example of how thoroughly the Amercians do the work of surveying their enormous country.

Dr. K. Remeis has, it is said, left a large sum of money to found an astronomical observatory in his native town of Bamberg. He has also bequeathed the observatory his 10in. refractor, and some other instruments.

The Darwin Memorial Fund amounts to about £2,500, and the memorial will take the form of a marble statue, to be placed in the large hall of the new Natural History Museum at South Kensington.

The *Panama Star* of June 8th, gives some news which should be of considerable interest if true. In repairing the cable of the West Coast of America Telegraph Co., the break was found some 400 nautical mile south of Chorillos, off Point Pescadero, in a depth of about 800 fathoms. The cable, when grappled, brought up great masses of trunks, roots, and branches of trees, and the question is, how came the trees there? as Indian tradition, like history, is silent as to any great convulsion.

The attitudes of the horse in its various paces are difficult to represent correctly in painting. Artists will doubtless be greatly aided by recent progress in instantaneous photography. A recent device for their benefit, by M. Cuyer, enables an artist, knowing the position of one limb at any period of a pace, to find directly that of the three other limbs. A jointed figure of a horse is supported above a board, on which are placed sheets of pasteboard, with figures representing the positions to be occupied by the hoofs. The hoofs have all different colours, and the figures on the pasteboard are coloured to correspond. These figures are numbered, and are in sufficient number to give several periods of the same pace. The hoofs are placed on their corresponding colours and on like numbers. Other figures give the position of other parts of the body.

A suggestion lately made by Mr. Porter, of New Haven, for deepening the Mississippi, is to produce mechanical disturbance of the bed, so that the silt, which is extremely light and soft, might be prevented from accumulating, being thrown again into suspension in the water. He proposes that a series of endless chains, running over pulleys at various distances, sunk in the stream, should be kept in motion by windmills on the bank, so as to scrape a continuous furrow in the mud.

An automatic instrument for closing a gas-supply at a given time is a welcome aid in the chemical laboratory. One such has been recently described in the Berlin Chemical Society by Herr Michaelis, and is said to have given good results in practice. It looks like a small, round alarum-clock, and has on either side a nipple, for connection of the caoutchouc tubing (thus passage is afforded through the body of the clock). A hand corresponding to that of an alarum, is set to the hour at which the gas is to be shut off; a wheel liberated at that hour closes a cock on the tube within the instrument. There is a slit in the top of the clock, with a projecting brass arm connected with the cock; by turning this, one may, independently of the clock-work, lessen, or shut off altogether, the supply of gas. The apparatus, it is noted, will serve for other kinds of gas besides luminous; and another application is, automatic stoppage of gas-motors.

From an examination of a number of firing arrangements for steam-boilers and in dwelling houses in Stuttgart, it has been inferred (we learn from the *Chemiker-Zeitung*) that the increase of carbonic acid in the air is due to other kinds of fires more largely than boiler furnaces. It is reckoned that house-fires increase the carbonic acid about 100, boiler-fires about 60, breweries about 8·5, bakehouses about 0·5, forges about 2·7, and casting-houses about 5·4 per cent. The 222 boilers produce daily 194,000 cubic metres of carbonic acid, and 467 cubic metres of sulphurous acid.

It is noted in the Berlin *Reichsanzeiger* that a violent thunderstorm which burst over Berlin on Whit-Monday did no damage to the telephonic lines or insulators—an evident proof that these lines do not attract lightning, and present no danger. The lightning conductors, at offices where telephones were in use, did good service. While these were in action, communications were, of course, temporarily interrupted.

At a recent meeting of the French Physical Society, M. Bouty described a form of the Daniell devised by M. Terquem. It differs from the Callaud pile only by addition of a stopcock at the lower part of the vessel, allowing, from time to time, part of the liquid to run off, so as to avoid the deposit of copper on the zinc, due to diffusion of sulphate of copper. By removing every 24 hours a litre of liquid, and replacing with an equal amount of sulphate of zinc solution, the battery is kept in good condition. The liquid removed rests on granulated zinc, which precipitates the copper and produces sulphate of zinc; it is this liquid that is introduced anew into the battery. The resistance of these elements is pretty great, but it varies very little.

The Committee of the Municipal Council in Paris, which has to do with the question of a Metropolitan Railway, has recently had a table prepared, showing the traffic on the various lines of omnibuses and tramcars in the city. It appears that the line on which most passengers are carried is the omnibus line Madeleine-Bastille. This is also the shortest line in Paris, being only 4,588 mètres, while that between the Panthéon and the Place de Courcelles is 7,567 mètres. On the Madeleine-Bastille line, the number of passengers last year was 14,803,632. Next comes the tramway between Montrouge and the Chemin de fer de l'Est, which has about 10½ million passengers. Then, in order, the tramway Etoile-La Villette, over 9 millions; the tramway Saint Ouen-Bastille, nearly 9 millions; the omnibus line Clichy-Odeon, ditto, &c. The lowest number given is that for the line Forges d'Ivry-Mont St. Michel, 333,095.

The history of that important invention, the Giffard injector, is related by M. Barrault, in a recent number of *La Nature* (July 1st). Again, we note that, in *La Lumière Electrique* (June 24th), M. De Chanzy traces the early history of electric incandescent lamps—a matter he long occupied himself with. He was incited to invention in this sense by his professor and friend, M. Jobard, of Brussels, who, in 1838, published his idea that "a small carbon, as conductor for a current in a vacuous chamber," would give an electric lamp of intense fixed and durable light. M. de Chanzy first tried to make such lamps in 1844 with retort carbon; and having made this homogeneous by filling the pores with melted resin, or saccharine matter, and annealing, he produced a lamp which was an experimental success, but not applicable practically. He next tried platinum; but for the rest, we must refer to his paper.

M. Moinceau has lately urged upon the French Minister of Agriculture and Commerce the importance of forming a professional school in Algeria for the manufacture of Eastern carpets. The Algerian carpets are at present far from having the reputation of those of Turkey and Persia, which are remarkable for the originality of designs, beauty of colours, and solidity of dyes. The velvet is very thick and the tissue excellent. The Algerian carpets are made for use in the country, and there is little effort after progress in workmanship. The Arabs usually weave in the tent for their own requirements, or for sale in a limited district. If a school, or a number of schools, were instituted, where young workmen and workwomen might learn the best methods extant, excellent results might be looked for. This industry appears to be increasingly occupying the Algerian natives. At the Paris Exhibition in 1855, there were 15 exhibitors; in 1867, 35; and in 1878, 79—indicating that the manufacture has, even now, considerable vitality.

The celebrated rosebush at Hildesheim, in Hanover, believed to be 1,000 years old (tradition says it was planted by Charlemagne), never bore so many roses as this season. The shoots grafted on its trunk in recent years are growing admirably. The bush stands at the outer wall of the cathedral crypt. Its branches extend about 3ft. 8in. high, and 3ft. 4in. in width. It is an object of much curiosity.

A new automatic regulator for engines of screw steamers (to prevent the "racing" of the screw when out of water), has been patented by Herr Windemann. From the account in *Dingler's Journal*, we gather that it consists of a bell crank lever with axis at the angle; one end weighted and resting, when the ship is still, on an elastic buffer, the other end connected by chains with the throttle-valve. When the screw rises, the weighted end is raised from its seat, and the chain is loosened, allowing a spring to close the throttle-valve. This closure takes place before the lever-end has completed its rise, and before the screw leaves the water. The return of the lever-end to its seat is retarded by a brake in which a piston acts on water in a cylinder, driving it out.

An interesting telephonic experiment was tried on Tuesday at Malta, according to the *Standard*, during the bombardment of the forts at Alexandria. A telephone was attached at Malta to the Alexandria cable, and connection was made with the other end of the cable on board the *Chiltern*, off Alexandria. It was found that, owing either to the distance, or to the vibration caused by the firing, it was impracticable to send a verbal message, but the firing at Alexandria was distinctly heard, through the telephone, at Malta—a distance of more than a thousand miles.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made Payable to J. PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."
—*Montaigne's Essays.*

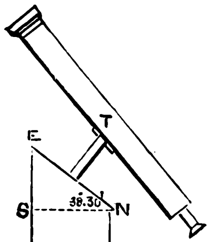
PROFESSOR PICKERING ON THE WEDGE PHOTOMETER — COMET WELLS—SMEATON'S BLOCK—DECIMAL OF THE YEAR—ROTATION OF THE EARTH—THE COMING TRANSIT OF VENUS—WEATHER FORECASTS—THE MOON'S DECLINATION.

[20260.]—AT the meeting of the Royal Astronomical Society, on November 11th, 1881, Professor Pritchard described a contrivance of his own for measuring the relative brightness of stars. (ENGLISH MECHANIC, Vol. XXXIV., p. 250). It consisted, as may be seen by reference to your last volume, of a wedge of coloured glass sliding in front of a diaphragm on the eyepiece of a telescope, such diaphragm being pierced with a small hole to direct the eye. The originality of Dr. Pritchard's device was questioned at the time (somehow it would seem that "some German" had indefensibly anticipated more than one of his previous inventions) without, however, as it appears on this occasion, much warrant. My object in reverting to the matter here is, though, to call attention to the valuable testimony which has been borne to the practical use of the learned Professor's application of the dark wedge, in a paper by Professor Edward Pickering, read before the American Academy of Arts and Sciences, on the 10th of last May, for a copy of which I am indebted to a friend. As may be expected from so thoroughly practical and experienced an observer as Professor Pickering, however, he suggests more than one very obvious improvement in the contrivance itself, and in the mode of using it. One of Professor Pickering's simplifications will be best described in his own words. "It is," he says, "only necessary to insert in the field a bar parallel to the edge of the wedge, and place it at right angles to the diurnal motion, so that a star in its transit across the field will pass behind the bar and then undergo a continually increasing absorption as it passes towards the thicker portion of the wedge. It will thus grow fainter and fainter until it finally disappears. It is now only necessary to measure the interval of time from the passage behind the bar until the star ceases to be visible, to determine the light. Moreover, all stars whether bright or faint, will pass through the same phases, appearing in turn of the 10, 11, 12, &c., magnitude, until they finally become invisible. For stars of the same declination, the variation in the times will be proportioned to the variations in the thickness of the glass. But since the logarithm of the light transmitted varies as the thickness of the glass, and the stellar magnitude varies as the logarithm of the light, it follows that the time will vary as the magnitude. For stars of different declinations, the times of traversing a given distance will be proportional to the secant of the declination." The fundamental constant (A) was determined by Professor Pritchard by the method of limiting apertures. Professor Pickering's simple, and (theoretically) more accurate mode of determining this constant, must be sought in his own paper. I have said "theoretically," because, in practice, Professor Pritchard's results have been found to correspond very closely indeed with those obtained by totally different methods. At all events, Professor Pickering's personal testimony to the efficiency of the Savilian Professor's ingenious adaptation can only tend to inspire additional confidence in it.

I do not think that either your readers, or Mr. Mills himself, can now complain of the reproduction of his excellent and truthful drawing of Comet Wells, which appears in letter 20215 (page 378).

"Smeaton's block," concerning which "J.C.L." puts query 47294 (p. 387), is nothing in the world but a wooden cylinder with its top bevelled at an angle equal to the co-latitude of the place of observation.

If, then, the pillar of the ordinary table-stand of a telescope be screwed into the bevel, and accurately square to it; and if, further, the bevel itself be placed so as to coincide with the plane of the Celestial Equator, we shall have a form of equatorial mounting at once. The annexed figure



shows a Smeaton's block cut for the latitude 51° 30′. The angle E N S = 38° 30′, the co-latitude. N S. is the direction of the meridian, and T is the telescope.

In reply to "J. C. L.'s" next query (47295, p. 387), the decimal of the year is calculated by the very simple process of dividing the number of the day of the year (supposed to begin at noon on January 1st) by 365·242. Thus, what fraction of the year is it at noon on July 14th? July 14th is the 194th day of the year, and 194 divided by 365·242 will be found to be ·5312. Hence, any phenomenon stated to have been observed 1882·5312 must have occurred at noon on July 14th of the present year—and so on.

The answer to query 47314 (p. 388) entirely depends upon the particular body to which "Cymro" refers the Earth's rotation; because while with reference to any fixed star she rotates 366 times on her own axis during the year; as referred to the Sun, she only turns round 365 times. This is, pretty evidently, because she is revolving round the Sun, and that hence the Sun appears to be moving (in the opposite direction) among the infinitely distant fixed stars. When, therefore, any meridian—say that of Greenwich—is synchronously opposite to the Sun and a fixed Star, at apparent noon on any given day, when the terrestrial rotation again brings that star on to the meridian the next day, the Sun will seemingly have moved nearly two of his own diameters to the East, so that the Earth will have that piece more to turn upon her axis before our supposed station again comes up to him. "Cymro" will find this all illustrated and explained at length on p. 595 of your Xth Volume.

With a preliminary protest against the too flattering terms in which "Orderic Vital" refers to me in the final paragraph of letter 20242 (p. 402), I would say that, as soon as I have a little leisure, I shall be happy to do what I can to render intelligible the principles on which the observations of the coming transit of Venus will be made.

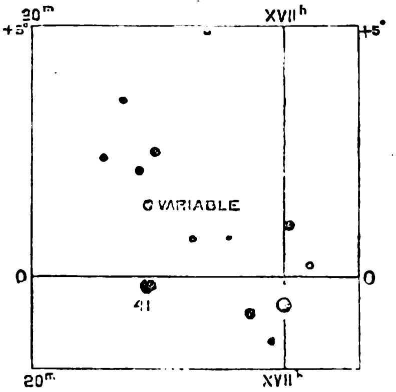
If (as alleged in letter 20249, p. 404) Captain Newton really "has discovered the causes which regulate the wind and weather . . . and that with proper appliances at his disposal, he can correctly forecast the weather, the world over, for years in advance," I can only say that the sooner the Government shuts up the Meteorological Office and subsidises Captain N. to reign in its stead, the better for the interests of the British nation. Unlike most prophets, however, Captain Newton's honour would seem to be confined to his own country; although it seems odd—to say the least of it—that the name and fame of a man possessing the quasi-miraculous powers of prevision asserted for him should be so utterly unknown beyond Newcastle. Mr. Mitchell's claim, though, for this Northern Light, seems to me to partake altogether of the character of what is called, in society slang, "rather a large order." "You may as well," says the schoolboy whose ethics are a little hazy, "tell a good 'un at once!"

To reply to query 47347 (p. 412) in extenso would require a pretty long article, instead of a paragraph at the end of a letter written in the very extremity of haste; but I may just say here that the inclination of the Lunar Orbit to the Earth's Equator is a very material factor in her diurnal change in Declination. To begin with, the mean value of the inclination of the Orbit of the Moon to the Ecliptic is 5° 8′ 42″; but sometimes it will be inclined to our Equator at this angle more than the Obliquity of the Ecliptic, and sometimes at 5° 8′ 42″ *less*. Here is a preliminary source of considerable variation in the total difference in her declination. Then, again, when she is crossing the Equator, her movement in her Orbit tells most in changing her declination; and when she is moving parallel with it obviously has the least effect in doing so. And, further, when she is in perigee, her motion is notably more rapid than when she is in apogee. If, then, we consider that the line of Nodes of the Moon's Orbit is perpetually shifting round on the Ecliptic in the opposite direction to that in which she is travelling (and this, be it noted, at a rate which is not uniform); that her line of apsides (or her perigee and apogee) goes right round the heavens in a little less than nine years, and that the eccentricity of her Orbit is very appreciable, indeed; that, in fact, neglecting further detail, her path in the sky is a most complicated one, consisting of a series of spirals, contained within a zone extending nearly 5° 9′ on each side of the Ecliptic, and varying most materially both in direction and velocity, it will be easily seen that her change both in Right Ascension and Declination must be of a perpetual and most varied character.

A Fellow of the Royal Astronomical Society.

SAWYER'S VARIABLE STAR U OPHIUCHI.

[20261.]—THE very interesting notice of Mr. Chandler's discovery of the short period of Mr. Sawyer's variable D.M. + 1·34·08° leads me to forward to you a small chart, by which it may be easily found by those of your readers who care to look for it. The chart is taken from the "Uranometria Argentina" of Dr. Gould, and as it is the copy of a copy, there may be slight inaccuracies; but it will be correct enough to allow of the star being found easily with the aid of an opera-glass.



The history of this star is very brief. Its variation was suspected by Dr. Gould first, who fixed its limits at half a magnitude 6·0 to 6·5. Its R.A. = 17h. 10m., and its Decl. + 1° 21′ for 1875. Mr. Sawyer, in 1881, found a period for this star. He made its period D. 5 24. Mr. Chandler now gives its period as D. 0·83, as given in your "Scientific News."

I made some observations of this star in May, which led me to believe that the period given by Mr. Sawyer could not be correct. Here are my observations:—

May	14		6·4
„	15		6·8
„	16		fainter.
„	18	11½h.	6·0
„	19	11½h.	5·9
„	21		6·0
„	22		6 6
„	25		6·7

My observations were then necessarily discontinued. These observations were all made with an opera-glass.

The new variable lies 1½° N. of 41 Ophiuchi. This star nearly marks the Equator. It is the second of a delicate curve of five stars, the first of which is β Ophiuchi, while the third is 30, the fourth 23, and the fifth the big star ρ Ophiuchi. Mr. Sawyer's new variable will be U Ophiuchi.

T. E. Espin.

γ VIRGINIS, α VIRGINIS, 70 OPHIUCHI, CASTOR, &c.

[20262.]—VERY few measures of the small and distant *comes* of γ Virginis have ever been made, owing probably to its faintness and present distance from the bright stars, as γ has usually been measured in twilight or daylight. It is an interesting object, however, from the fact that about 200 years ago it and the binary formed a fairly close triple star, though of course none of the telescopes then existing were capable of showing it as such. Sir W. Herschel does not mention it in his observations of γ from 1780 to 1803, though its distance from the bright stars was about 53″ in 1780. It is first noted in Sir John's first Catalogue as a 15*m* star at 90° + 60″ + (1826·2), and is alluded to in his 4th and 7th Catalogues; but, as in the case of the first Catalogue, the data are mere estimations. Smyth also alludes to it in the "Cycle" and "Spec. Hart." H_2 measured the angle (88·5°) in 1832·4 with the 5in. Tulley, and remarks "exceedingly difficult," but he did not measure the distance; Lamont measured the distance (82 5″) in 1838·4 with the 11in. at Munich, but not the angle. The only complete and other measures I know of are β's, 88 0°: 102·78″; 1880 27 (3*n*), magnitude 11·6 Σ; the southern star (B) of the binary pair being taken as the initial point. This faint star has been distinctly seen by Mr. Ward and myself with 3in. aperture. There is a $9\frac{1}{2}^m$ star (Arg. (− 1° 2600) about 280″ *s* a little *p* γ.

α Virginis. In *Monthly Not.* XL. p. 517, Mr. Burnham mentions a faint (12^m Σ) companion to Spica at 32·9° : 144·8″ : (1879·2.) This minute star was discovered by Mr. Ward of Belfast (and independently by myself), in April 1874; both of us using 3in. refractors. It is a much fainter and closer object than Smyth's star at 62° : 360″. Smyth says of Spica, "This beautiful star is in a clear dark field, and, in a manner, insulated, for it has no *comes* nearer than the one described."

70 *Ophiuchi.* This interesting binary has two distant companions, alluded to by Smyth, but first measured by Se. He gives *a* 11^m. (Σ) 215·08° : 87·514″; *b* 12^m (Σ) 67 2° — 1856·627. Se unfortunately omitted to measure the distance of *b*. The only other measures I know of are Hl, *a* 197·84° : 71·304″; *b* 49·59° : 87·209″ : 1878·84. Hl. calls them both about 13^m Σ; but this estimate is certainly too low, as they are both easily visible with a 6½in. reflector. If *a* is fixed, its place in 1878 should have been about 229° : 75″, instead of the observed position. If Se's measures of *a* are correct, and I have no reason to doubt their accuracy, the motion of the small star is very remarkable. It should be carefully observed.

Castor. H and So measured a very distant comparison to Castor on one night in 1823, finding 224·25° : 177·114″, "measures, perhaps, a little inaccurate." Smyth alluded to this as "another very small acolyte at a distance, in the *s.p.* quadrant of the field," to which Mr. Chambers, in his new edition of the "Cycle" adds, "[which, however, appears to have no physical connection with the primary: at least the alteration in angle and distance are so small in half a century as to seem accidental."] I do not remember any measure of this object which could warrant this strange statement. If no change has occurred, the presumption would be that this small star *is* physically connected with Castor. I should be glad to hear of any recent measures of this star.

With regard to some of the stars mentioned in Mr. Perry's interesting and valuable communication (letter 20181, p. 319), I would remark that his distance of Σ 1777 (by a misprint 1772) is considerably too small. Hl. gives 230·10° : 3·450″, 1879·40. In β 224 and 355 the measures attributed to β are De's. De's distance of η Coronæ in 1875 should be 0·86″, and Mr. Perry's distances of ζ Herculis are too small. In 1875, I found a 14^m companion to σ Serpentis (xvi^h 16^m + 1° 19′) at about 40′ distance, which I should be glad if Mr. Perry would kindly measure; about 11′ *n.*, a little *p.* σ, is the lovely pair Σ 2011 (OΣ 308).

H. S.

ζ HERCULIS.

[20263.]—THE distance of ζ Herculis, given in the little list of test objects, on p. 382 of Vol. XXXI., referred to by Mr. Simms (letter 20213, p. 377), was the best and latest I could obtain at the time of writing—viz., β's with the 18½in. at Chicago, 127·0° : 1·51″ : 1878·4 (the distances in the Mt. Hamilton (Lick) Observations are "far from satisfactory"), and knowing that the small star was approaching that part of its orbit in which it would be at its farthest apparent distance from the primary (at which period it had been seen with telescopes of about 3¼in. aperture), I included ζ in my list, placing it, however, as the last, and, therefore, most difficult object among the tests for the dividing and defining powers of a 3¼in. achromatic; and I confess I have not as yet been able to see the "absurdity" of so doing, as asserted by "F.R.A.S.," on page 110 of Vol. XXXII.—the more so as "F.R.A.S." had previously given this very star as a test for this aperture in a list on page 349 of Vol. XXXI. (a list on which I have some remarks on page 380). β's measured distance in 1880 is probably rather too small, one or two more measures would possibly have altered it somewhat, for the *comes* in 1880 had certainly not commenced to approach the principal star, but had, and has, not yet arrived at its farthest point. If Mr. Simms will refer to the measures of OΣ and Da, which were made when the small star was in about the present part of its orbit, he will see this for himself. Of course, a difference of 2-10th of a second is a very small quantity; and measures of a star of this description differ considerably *inter se.* I have before me nearly sixty observations of ζ, made by a most experienced observer, using a very fine 9½in. refractor, armed with a power of 940, and driven by an excellent clock, the measures all being made by daylight or twilight; yet, on one occasion, two sets of measures, taken at an interval of only three weeks, vary from 0 88″ to 1·18″, and on another two sets made within a fortnight of each other vary from 1·10′ to 1·64″. Perhaps it may not be out of place, in connection with this question, to draw attention to a fact which I believe is not generally known—viz., that Σ's so-called "measured" distances below 0·8″ are not measures, strictly speaking, but only careful estimations; "non mensuratæ proprié, sed potius taxatæ," he says. It should not be forgotten that though Da's rule was founded on a very large number of experiments, yet those experiments were made many years ago, and the largest instrument employed in them would be considered of quite a moderate size at the present day. According to his formula the separating power of the Dorpat reflector was 0·48″, yet this telescope on some occasions showed stars only 0·35″ asunder, "disjunctæ lineola subtilissima," and a modern refractor by, say, Alvan Clark, of the same aperture would, I think, be unquestionably finer than the Dorpat.

A short time ago I was reading an account of the performance of a 6in. (French) refractor by MM. Brunner, which has lately been mounted at the Lyons Observatory. This telescope (to quote from the account in the *Comptes Rendus*) "avec un grossissiment de 200 fois dedouble nettement le compagnon de γ d'Andromède." This seems almost incredible, excellent as the telescope appears to be, for β with the 18½in. at Chicago found the distance to be only 0·36″ in 1880·06, while Hall with the 26in. at Washington obtained 0·33″ from three nights' measures at the same epoch; therefore, according to Da's formula, it would require a 13in. aperture, and of course a high power, to separate the components. Yet M. André says he could measure the distance with the Lyons refractor !

H. S.

COMET *a*, 1882 (WELLS).

[20264.]—THOUGH this comet has not been the conspicuous object that, in accordance with theory, it should have been, it has nevertheless been a most interesting object to astronomers. Not only on account of the great difference between its observed and computed brightness, but because its spectrum has differed so considerably from all the comets that have been spectroscopically examined since 1864.

Sodium appears to be one of the chief constituents of this comet; indeed, the D lines have been so conspicuous in its spectrum, that, according to the Greenwich observers, "the comet might almost be said to shine by monochromatic light." From the observations of Dr. Copeland at Dun Echt, and Prof. Vogel at Potsdam, both of whom have succeeded in dividing the D lines, it is evident that the density of the glowing gas must be very great. In fact, there was a sufficient amount of this substance to impart a decidedly yellow tinge to the nucleus; this I particularly noted on May 31st.

From these revelations of the spectroscope, I think we may conclude that it is owing to the presence of sodium that the comet has not proved itself so brilliant an object as it was expected to be.

London, July 9. **B. J. Hopkins.**

PTOLEMÆUS—TESTS FOR 3in. TELESCOPE.

[20265.]—ON July 8th, 12.30 a.m., 3½ hours after last quarter, I had a good view of Ptolemæus with 3in., p. 160.

One of the so-called pits, seen by your correspondent, Mr. A. S. Williams (20236), viz., the one under S. E. wall, appeared as an indistinct ring; but it gave me the impression of a shallow saucer-shaped depression. There appeared to be no trace of shadow, either inside or outside. Just N. of the crater was a similar appearance. The ring of this was more clearly defined than the first, and slightly larger than the crater. Here again there seemed nothing to indicate depth. Another ring, about 4 diameters of the crater S. was by no means so distinct, indeed, scarcely held satisfactorily at all. I fancied they were all getting more distinct as the terminator approached the W. edge of the wall; but clouds interrupted observation for the night, and I saw no more. The ridges, &c., mentioned by Mr. Williams were not seen at all.

Will "F.R.A.S." kindly give me the present distances of the pairs λ Ophiuchi, τ Ophiuchi, and ξ Ursæ. In the case of the two latter I get a clear black line division between the discs with 160; and the first I divided easily last night by screwing off the field lens of 160 eyepiece. Are these sufficient tests for 3in. aperture? I am a beginner, and my telescope is a new one (not a five-pounder by the way), whose performance has pleased me much so far as I am able to judge of it.

E. S. Beaven.

CATALOGUE OF SUSPECTED VARIABLE STARS.—II.

Aries—Auriga—Bootes—Cancer—Canes Venatici—Canes major et minor—Capricornus Cassiopeia.

[20266.]—WE beg to continue our catalogue of suspected variable stars:—

		h. m.	° ′		
	ARIES.				
49.	Arietis	—	—	6·3	Herschel.
50.	25	—	—	5·7	Herschel.

(*To be continued.*)

RAILWAY-SIGNALS.

[20267.]—RAILWAY-SIGNALS are things on which a great deal depends, and on which no misapprehension should exist; and yet, when we come to examine the arms at different places, we find many different angles are shown for what is intended to be the same signal. Be this as it may, steps are now being taken by one of the large companies to make every signal work uniformly, and to establish a rule by which this uniformity may be brought about; and, for all that I know, other companies may be doing the same. The reason for submitting this question to your readers is to see if they approve of the following angles for the various signals:—

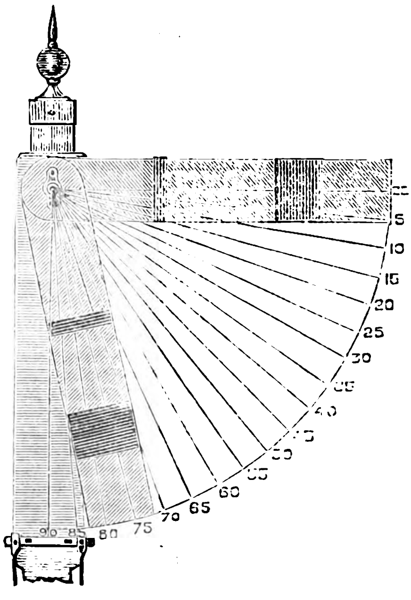
Danger.—Arm to be horizontal; but to be taken as a danger-signal 5° above or 5° below that position. From 5° to 45° to be treated as a "Doubtful signal," and worked on as "Danger."

Clear. — Arm-in-arm position between 45° and 85°.

No Signal.—Arm down into post, and obscured from view—85° to 90°—to be treated as "Danger" signal, if it should occur after the arm has been brought into use.

If anyone disapproves of these angles, will he be so good as to say so, as by doing this assistance will be rendered in settling a somewhat important question? Some controversy also exists as to how the quadrant is to be taken—i.e., whether the degree should be opposite the centre of the arm or the bottom. This latter may seem ludicrous, but a sketch in my possession (just received from an authority) shows the bottom of the arm cutting the degree intended, and not a line drawn from the axle through the centre of the arm. The line is, however, taken from the same centre in the former instance, but the arm is drawn as stated.

The inclosed tracing shows the arm at zero, that point being opposite its centre; and the arm as shown for 85° by the authority in question. I see, on perusal, that I have drawn this second arm about 2° too far to the right—friends will note this correction—and then say what they think of it for 85°!



H. Stooke.

THE BERLINER VIOLIN.

[20268.]—To see one's efforts and experiments appreciated by the approval of experienced critics should be the first consideration to every inventor, hence I feel grateful for the most encouraging words of "Fiddler" in his critique on the violin which I sent to the Editor of this paper. But I would consider the battle only half won if I could not soon draw from my worthy critic further concessions, particularly in reference to his doubt, that first-class made instruments are not improved by the resonator. Permit me to state that, since I sent the violin, I have made a further step ahead, and I soon will take pleasure to ship to our friend "Fiddler" an instrument illustrating the improvement. I agree with him in that portion of his remarks which refers to the distribution of pressure, and his assertion that the treble strings gain more than the lower ones; but I can meet this with my latest resonator, which is all of metal, cast in one piece, and on which the hole where the bass is attached lies lower, proportionally, than the others. I am unable to judge the result of the resonator on a violin without a post, but hope to have occasion to see the results of "Fiddler's" studies on double soundboards. In the mean time I expect to prove that, whatever weak points may occur in the beginning of a new departure, they are subject to, and capable of, correction. Until then, I intend to withhold the sale of resonators, as I mean to put the invention on sale only after I am fully satisfied with it.

Boston, U.S.A., June 27. **E. Berliner.**

[20269.]—In reference to this modified violin, I have made the addition to an indifferent instrument which I possess, after the published drawings of Mr. Berliner. It is beyond contest that the bass, the two strings D and G, are improved. I cannot, however, say the same for the treble, the two strings E and A. With the particular instrument which I experimented upon, the treble was not improved, though modified. This being the case, I cut away the end of the soundboard to free the E and A strings, and strung them up, as usual, upon the tail-piece, and allowed the other two strings alone to have the soundboard to themselves. This results in the instrument being permanently improved; but the tone on this common instrument certainly falls short of the tone which I have heard and got out of good instruments made in the usual way without any addition; but this particular violin is certainly improved. **B. Warwick.**

Highbury, N.

A NEW FORM OF STEAM-ENGINE.

[20270.]—I have pleasure in handing you a description of a new form of steam-engine designed and patented by Robinson and Heath, engineers, West Bromwich, which I have inspected by permission.

The principle claimed for this engine is that it has two moving parts, the cylinder moving and performing a stroke as well as the piston, each operating on the same crank-shaft, and dividing or distributing the force applied to the crank in the same manner as is usually effected by a pair of cylinders.

The cylinder is so contrived as to move or slide between guides or motion bars in the same manner as the crosshead of the piston moves, and has a pair of connecting-rods coupled to cranks on the shaft which are set at an angular distance from the piston-crank on the same shaft, to equalise the motion and overcome the dead points.

The slide-valve and ports are on the cylinder as usual; but the steam-pipe has a telescopic joint with a stuffing-box, so as to vary its length to accommodate the stroke of the cylinder.

The steam being admitted, drives the cylinder and piston in opposite directions, alternately separating and bringing them together again, each moving half the distance that the piston would have to travel if the cylinder were fixed; these half-strokes are, in fact, the strokes of the cylinder and piston respectively as applied to the cranks, the whole distance moved between cylinder and piston being a double stroke or revolution. This arrangement produces a near approximation to a uniform rotary motion.

The advantages possessed by the moving cylinder over a fixed cylinder engine are very apparent, for, in all cases where two cylinders are placed side by side, as in the locomotive, or in other position with respect to each other, for the purpose of dividing the force applied to the crank-shaft and overcoming the dead points, this engine effects the same object with its one moving cylinder.

The test of an engine on this principle clearly demonstrates the great freedom with which this kind of engine works, the friction and vibration being reduced to a minimum, and in consequence of the shortness of the stroke the gearing is stiff and compact.

There appears to be also an advantage in the admission of the steam between the two yielding surfaces of cylinder and piston, its elastic force coming more directly into action, and the recoil and back pressure being considerably reduced.

One of these engines has been tested against an ordinary engine of the following dimensions, both being new engines:—

Robinson's.—Diameter of cylinder, 16½in.; area, 204·21ft.; stroke, 30in.; double, 5ft.; steam pipes, 3in. diameter; area of ports, 8 sq. in.; pressure in boilers, 25lb.; flywheel, 7ft. 6in. diameter; weight of flywheel, 1·1 ton; weight of cylinder C, 9 cwt. moving. Force to move is 9lb. per stroke.

Ordinary.—Diameter of cylinder, 16in.; area, 201; stroke, 36in.; double, 6ft.; steam pipes, 4in. diameter; area of ports, 12 sq. in.; pressure in boilers, 25lb.; flywheel, 9ft. diameter; weight of flywheel, 3 tons; cylinder fixed. Force to move is 9lb. per stroke.

$204\cdot21 \times 25 \times 5 = 25526\cdot25$, working 54 revolutions during experiment; $\frac{54 \times 25526\cdot25}{33,000} = 42$ H.P.

$201 \times 25 \times 6 = 30150$, working 40 revolutions during experiment; $\frac{40 \times 30150}{33,000} = 36\cdot5$ H.P.

Each engine was tested by means of a brake and lever attached.

Each engine had a 4ft. pulley, and these were used as brake wheels; the levers were of timber, the fulcrum 6in., and the leverage was 13·5 to 1, the friction band consisted of a leather driving-band.

Leverage, 13·5 to 1 on 4ft. pulley; weight of lever, 59·5lb. $\frac{59\cdot5 \times 13\cdot5}{2} = 401$ constant weight to be added in each case for lever.

Robinson's Engines.	
79·5lb. on lever	78lb. on lever
$79\cdot5 \times 13\cdot5 = 1073\cdot25$	$78 \times 13\cdot5 = 1053$
Lever 401	Lever 401
1474·25	1454
Speed, 54 revolutions.	40 revolutions.
$54 \times 5 \times 1474\cdot25 = 398018$	$40 \times 6 \times 1454 = 348960$

But these are over a brake 4ft. diameter, which is nearly 12·5 circumference.

$\frac{398048 \times 12\cdot5}{5} =$	$\frac{348960 \times 12\cdot5}{6} =$
995120 ft. lb.	872400 ft. lb.
$\frac{995120}{33000} = 31\frac{1}{2}$ H.P.	$\frac{872400}{33000} = 26\frac{1}{2}$ H.P.

Extra weights were added to pull up the engines, and it was accomplished by—

1st weight 79·5	1st weight 78
2nd " 57·0	2nd " 29·5
136·5	107·5 lb.

showing a difference of 29lb., or ¼·7 more work, being over 27 per cent. in favour of Robinson's engine in pulling up, and running with the load Robinson's shows 20 per cent. more h.p.

Robinson's engine, while possessing all the advantages afforded by a pair of cylinders, occupies only half the space, and it is evident that there is only half the friction, and the usual rigid foundation required for a fixed cylinder would be unnecessary for this engine. **George H. Wood.**

West Bromwich.

THE WILLANS ENGINE.

[20271.]—It would be interesting to know what are Mr. W. Trathern's objections to the above engines (letter 20202, June 23rd). They have proved so very successful in launches, tugs, &c., that any scientific criticism would interest greatly your readers. Considerable credit, I think, is due to Mr. Willans for his judicious abolition of slide-valves, eccentrics, and link motions in launches, together with the attendant noise and irritation. I know of no engine which makes so little noise and requires so little attention. **Octurus.**

MR. JEFFREY'S TRICYCLE SEAT.

[20272.]—Perhaps Mr. Jeffrey will permit me to suggest that a more appropriate name than the one he has used for his new tricycle seat would be to christen it the "Blood" seat, after the inventor (see "E. M.," No. 865, Oct. 21, 1881); or the "Dublin" seat, after the tricycle on which it was first used. All I have done is to describe it and advocate its great merit.

Here it may be well to state that the "Dublin" seat, to be fully appreciated, should be used on a machine having a more or less forward thrust. It is not so well suited to tricycles with vertical action. These latter would appear to necessitate a saddle.

July 8th. **W. H. Stacpoole Westropp.**

STONEHENGE AND SUN-WORSHIP.

[20273.]—It may be probable, as "Neo" states, that the stones in question are connected with sun-worship: we will grant him that they are; but we must, of course, work on assumption when speaking of a structure set up in such remote ages. At any rate, I am certainly of opinion that the stones were connected with astronomical observations, and that they were put into position to register the point at which the sun stood at a certain time, that time being the date of earliest sun-rising. This was, perhaps, the only measure they had of the year, and it is very probable that the formation of a yearly register was the chief object of the stones pointing towards the sun. Be this as it may, it will be admitted that no inconsiderable amount of observation must have been made to ascertain the earliest point of sun-rising in those ages. The two stones were perhaps put into position at first so as to point at what was supposed to be the earliest rising, and this reading might have then been corrected during the next year. No little trouble must have been experienced by the performers of the task. "Neo" states, we "must date back to a time long before astronomy, as a science, was thought of." But I cannot agree with him, seeing that astronomy had to be studied, however limited that study might have been, before the stones could be put into position. I mean the particular stones directed towards the sun. The other large stones arranged in circles might have supported a roof of wickerwork or skins, or both combined; but the probability is that they formed some mysterious circle connected with religious rites.

I see no grounds for assuming that these gigantic stones were erected in the Neolithic or Palæolithic ages, for they weigh from ten to twelve tons each, and there is no similar material to be found for a very considerable distance off, and how they were conveyed to their destination is a mystery. But this is not so mysterious as the hewing, and the forming of the mortice and tenon, which keeps the horizontal stones in position. Could this be done with pieces of flint? These horizontal stones also have to be raised some 15ft. or 20ft. All these feats seem in advance of the Neolithic or more advanced Palæolithic age.

Again, because flints have been found on Salisbury Plain which formerly constituted weapons, it does not follow that Stonehenge was erected during their age—a man might die to-morrow in a cave full of these flints, and in twenty years hence we might see advertised in bold letters—"Discovery of a Wonderfully complete Skeleton of Neolithic Man," together with extenuated accounts of his accompanying weapons. To sum up, I should fix the time of the erection of Stonehenge as that in which the Druids held sway in England. Even at this advanced date, the mystery of erection does not, to my mind, appear clear.

Paddington, July 6th. **H. Stooke.**

GAS-ENGINE EXPLOSIVES.

[20274.]—With regard to the power that can be developed by explosions of a mixture of gas and air (letter 20221), it is not difficult to calculate what will be the limit of the power developed. If we burn one gramme of hydrogen with sufficient oxygen to form water, we develop about 34,000 (gramme degree centigrade) units of heat.

Now, by Joule's experiments on the mechanical equivalent of heat, 1 gramme degree unit of heat is equal to $4\cdot156 \times 10^7$ ergs (an erg being the unit of work, in gramme centimetre second units). One foot-pound is equivalent to $1\cdot356 \times 10^7$ ergs.

To find the value in foot-pounds of the combustion of one gramme of hydrogen, we have—

$$\frac{4\cdot156 \times 10^7 \times 34000}{1\cdot356 \times 10^7} = 104,200 \text{ foot-lb.}$$

Now, whether the gas be burned explosively or quietly, with or without compression, we can never get more than 104,200 foot-lb. out of 1 gramme of hydrogen by its combination with oxygen. I do not say that in practice we do not utilise more of the power by previous compression; but whether we utilise it or not, that amount is developed.

Again, with regard to the explosion of chloride of nitrogen, this could not be calculated by the ordinary methods of combustion, since it is due to the decomposition of the compound into its elements, not to the combination with fresh elements.

It seems to me, however, though perhaps I am mistaken, that it is possible to calculate the power developed by the explosion of nitrogen chloride, in the following manner:

Suppose we take its composition to be NCl_3, though this is not certain, the atomic weight of $N = 14$, $Cl = 35\cdot5$; therefore, $NCl_3 = 14 + (35\cdot5 \times 3) = 120\cdot5$.

Taking grammes, 14 grammes nitrogen occupy 11·2 litres, and 35·5 grammes Cl occupy 11·2 litres; therefore, if we convert 120·5 grammes NCl_3 into its elements, nitrogen and chlorine, we get $4 \times 11\cdot2 = 44\cdot8$ litres, at normal pressure and temperature.

$44\cdot8$ litres $= \frac{(44\cdot8 \times 61\cdot02)}{1728} = 1\cdot58$ c. ft. Suppose the nitrogen chloride to have been in a cylinder having a frictionless piston 1 sq. ft. area, and neglecting the volume occupied by the nitrogen chloride as a solid or liquid when it decomposes, it will lift the piston 1·58 ft. high; that is, till its pressure equals that of the atmosphere. Now, in doing this, the work done is to lift the piston against the pressure of the air, which is $15 \times 144 = 2160$lb. on the piston of 1ft. area (since 15lb. = pressure of air on square inch, and 144 is the number of square inches), through a distance of 1·58ft., the work in foot-lb. is 2160 × 1·58 = 3434ft.-lb. This is done by 120·5 grammes, so 1 gramme will do $\frac{3434}{120\cdot5} =$ 27, about, foot-pounds of work.

This seems very little considering the tremendous violence of the explosion; but we must remember that gunpowder, which in small grains would burst a gun, in large cubes can be used safely, owing to its having time to communicate motion to the projectile, the only difference being the rapidity of combustion. So also it may be with the chloride.

I shall like to hear the opinions of other correspondents on these points, which are of great interest, and I am glad that J. H. Huxley has started the subject. **Ll.B.A.**

THE FOREGROUND IN SKETCHING—SCIENCE FOR ARTISTS.

[20275.]—In landscape paintings I have frequently been struck with the singular treatment not only of the immediate foreground, but of what is supposed to lie beyond it. Some artists would seem to forget that the laws of perspective apply to distinctness as well as to mere size; for I have seen pictures representing views which only a man with telescopically adaptable eyes could possibly see—a flowery hedgerow, perhaps, with a whole field intervening, painted in true proportion, but in as perfect detail as if it were only distant a couple of feet. The difficulty of your correspondent (query 47282) is a natural enough one, but he answers his own question when he says, "No one sketching a (distant) scene sees the detailed leafage at his feet." No one looking at the sketch is supposed to see it either. It is there merely to indicate, what could not otherwise be known, that the scene *is* distant. Suppose I sketched a castle, standing on a knoll, distant, say, a mile, and put in the knoll only, without any of the intervening ground. My picture would represent a knoll without detailed herbage, and an equally indistinct castle on it; and every person who saw it would consider it a very bad attempt to sketch a *near* view. It is only the presence of the foreground, and the unconscious comparison between it and what is beyond that leads us to the perception of distance in a picture at all. There is no reason, to be sure, why a sketch with the immediate foreground wanting could not be made: but the effect of it would only be that of a complete picture with a piece at the foot cut off.

I believe I am right in saying that too many artists affect to despise the aid of science in their work. Perspective is, of course, a *sine quâ non* of success in landscape painting; but physical science is also a great help. I have seen a preposterous sky put into a picture for the sake of an "effect" of colouring. The clouds certainly can assume a great many shades and tints under certain known conditions; but some tints they can't assume, even to please artists. Distant hills, again, are often given the most remarkable tints in sheer defiance of nature. Rainbows are turned outside in, moons put in impossible attitudes, and so on, all through ignorance, or the most culpable carelessness. Surely there is enough variety of scene in nature as she is to satisfy artists. When she is exhausted it will be time enough to begin making variations in her.

As no branch of science is of greater importance to landscape painters than meteorology, I hope by and by (and with the Editor's permission) to have something to say on "Meteorology for Artists."

J. A. Westwood Oliver.

Belle Vue, Springburn, Glasgow, July 1.

COLOUR.

[20276.]—It may, probably, be of little use to explain to your correspondent, S. Calton, where his mistake lies, since it appears from his letter that the explanation has already been given to him—Sir John Lubbock having most courteously replied to his letters asking for information to be found in any scientific treatise on optics. But a word or two of explanation may not be wasted in case any of your readers who have not paid attention to the subject should be misled by the statements of your correspondent.

Although Sir John Lubbock had explained that two differently-coloured lights—blue and yellow, for example—could not be compounded by superposing blue and yellow glass, your correspondent, treating Sir John's explanations with the same contempt with which he seems to regard all scientific conclusions, straightway places his coloured glasses together, since he "contends that two colours must give invariably the same result, however compounded."

It is a popular belief that blue and yellow, when mixed together, produce green. This is, no doubt, true in many cases of mixing blue and yellow pigments, or of superposing blue and yellow glass: it is altogether untrue of mixing blue and yellow light. If anyone doubts this, let him make the following simple experiment. Choose blue (not cobalt blue) and yellow glass, which, when superposed, give a fine green. Construct a wooden wheel, having a rim connected to the centre by six spokes (as narrow as possible), and have the wheel so mounted that it can be put in rapid rotation by winding a piece of string round it, and then spinning it after the fashion of a top. Now fill up the six spaces between the radii alternately with the blue and yellow glass. Let a strong beam of light fall through a small round hole through one of the coloured glass divisions of the wheel on to a white screen, and set the wheel slowly rotating. The spot on the screen will be seen to be alternately blue and yellow. Now set the wheel revolving rapidly, so that the eye no longer perceives the separate colours, but receives the impression of the single tint, due to the mixture of blue and yellow light. It will be found that this compound colour is not green, and has no tinge of green about it.

I need not offer instructions to your correspondent, who is an artist, on the methods of experimenting with mixtures of coloured pigments; but if he wishes to experiment on the effect of mixing variously-coloured light, he must adopt some other mode than that explained in his letter. There are plenty of books which give instructions on this point. One of the easiest is Mayer's "Light" in "Nature" series. **X. N. X.**

THE APERTOMETER—LANTERN OBJECTIVES.

[20277.]—It may perhaps lend additional interest to the reply of "Akakai," p. 309, June 2nd, as to a difficulty raised, p. 262, May 26, in my paper on Microscope Power, if I detail the result of the experiment which he suggested. His explanation seems to me the most concise and intelligible as regards the basis of this aperture question, which has yet appeared in your paper, or any other, and deserves the best thanks of all "brass and glass" men, like myself.

I have had the opportunity of trying the measurement of one of Powell and Lealand's wide-angled oil immersion eighths, and the process confirmed "Akakia's" prediction to a nicety. (1.) Focussed *dry* on the central silver ring of the apertometer, the reading of the pointers was just 1·00 N.A.; I could not make it less. (2). Then, on the interposition of a drop of water, the field brightened amazingly, and the pointers had to be widened to precisely the 1·25 N.A. he mentions. (3.) Lastly, oil being substituted for water, the pointers had to be removed further than the glass semi-disc of the apertometer could accommodate them; it is only graduated to 1·4 N.A., and the numerical aperture of this lens certainly exceeds that quantity.

On the other hand, trying the same experiment with an immersion one-sixth by another maker, the *dry* reading was 1·00 as before; but with *water*, the pointers stood at 1·20 only; and with *oil at the same point*. The full aperture of which the lens is capable, having already, as demonstrated by "Akakia," been measured in water.

Does this indicate that it is useless to make oil immersion lenses unless their N.A. is greater than can be obtained with lenses constructed for water immersion? It would be of assistance to many of us if "Akakia" would kindly say a little more on the subject, and especially give some instructions as to the use of the apertometer, which is comparatively a new instrument. Its description is to be found in the volume for 1878 of the R.M.S. *Journal*, but it does not seem to have yet been honoured by a place in your pages.

By examination with a Browning's table spectroscope, I find the refractive index of the glass of the apertometer used for this measurement is 1·527 for the "D" line, and 1·533 for "F." Perhaps "Akakia" will say which of these should be taken. Also, I find that the refractive index of cedar-wood oil is 1·51 (not more) for the "D" line, and the sulph. carb. zinc in glycerine is 1·50. But the calculations for N.A. homogeneous immersion given on the cover of the R.M.S. *Journal* are based on 1·52, as there stated. This makes some difference, though not much. For instance, a balsam angle of 117° 31′ comes out 1·29 N.A., with refractive index of 1·51, instead of 1·30 exactly, with index 1·52, as tabulated.

There is another way of estimating "aperture"—viz., by measuring the diameter of the apparent field of light transmitted by the objective, as viewed by placing the auxiliary lens between the objective and an eyepiece carrying a Jackson's eyepiece micrometer. But by this method my results were not so accordant as they should be. Taking the same o.g. brought to focus upon a slide, with the several interposing media in turn, the apparent diameters of field were:—The one-eighth, with air, 60 divisions of e.p. micr.; one-eighth, with water, 78 divisions of e.p. micr.; one-eighth, with oil, 89 divisions of e.p. micr.; one-sixth, with air, 63 divisions of e.p. micr.; one-sixth, with water, 71·5 divisions of e.p. micr.; one-sixth, with oil, 71·5.

The one-sixth gave the same reading with both water and oil, as it should do from what precedes; but why it should read more when "dry" than the one-eighth does under similar circumstances is not clear. The measurement was confirmed by another microscope, which gave diameters in the same proportion as the above.

By the way, May I ask Mr. Shrubsole (page 284, Vol. XXXIV.) if he found my description of lantern objectives (pages 236, 308, same vol.) of any service? **Antares.**

IS GOLD AN ELEMENTARY SUBSTANCE?

[20278.]—The interesting article in your issue of the 7th inst., on "Artificial Forms of Silica resembling Agate," reminds me of a letter I recently read in the *Mining Review*, an American journal, by Dr. D. P. Kayner, in which the writer states that while experimenting in California upon the sands and quartz for the separation of gold, he came to the conclusion that gold was not an elementary substance.

Acting upon this conclusion, he made a metal resembling gold in every respect. His *modus operandi* was as follows, in his own words: "Experiment we did; and taking certain proportions of the three baser metals, combining them with such other substances as would represent as near as possible nature's alchemy, luting the whole together in a French clay crucible and encasing that in a black-lead crucible all closely covered and luted to represent the confined state of minerals and gases in the earth. The whole was placed in a Chilton furnace and kept at its highest heat for several hours, when the contents of the crucible were poured out, resulting in a nugget of metal having all the characteristics of pure gold—viz., colour, malleability, and resistance to acids." Dr. Kayner further states that what is true of gold he has no doubt is also true of some of the other metals.

The discovery has little commercial value, as it appears to cost three times as much to make as pure gold; but as a chemical problem it is of the deepest interest, if we could only ascertain for certain that which Dr. Kayner states is absolutely true. Judging from his letter above, no doubt whatever could be raised on that score.

Worthing, July 10th. **C. H. Romanes.**

THE EXPANSION OF IRON IN THEORY AND PRACTICE.

[20279.]—In letter (20259), the writer mentions as an example a stretched cord expanding when moistened. I should have thought it was generally known that the reverse would happen. It seems a pity that such a slight mistake should have been made, and I should be sorry to see it left uncorrected.

Edward F. Carter.

Temple-Balsall, Warwickshire.

FULLER'S MERCURY BICHROMATE BATTERY.

[20280.]—The sulphate form of battery, after twenty-three years' use, has been partially—I might say almost entirely—superseded by the battery about which I write. Inquiries from time to time, made in one corner and another, have induced me to compile this letter. The makers write:—

"This battery possesses the most valuable essentials of a telegraph battery—economy of maintenance with constancy, and a potential double that of the sulphate form. Its internal resistance is very low—a valuable condition for working open lines, on which the insulation varies with every shower of rain. For instance, twenty-four cells give unvarying good signals on circuits, where, with 70 ordinary cells, the signals are either weak or strong, according to the weather. An examination of the conditions of the two forms of battery will explain this. The ordinary sulphate battery has an internal resistance of 10 units per cell, or, say, 700 units for the 70 cells; consequently, the quantitative force is very low, and the potential high. The 24 mercury-bichromate cells, having a resistance of only 48 units, yield a large volume of quantity, and consequently are capable of putting into motion a force of sufficient capacity to supply the leakage occurring at the insulators, and at the same time give an unvarying force to the instrument.

"The conduction of an exposed line wire in cold and wet weather becomes more complete, and the necessity for increasing the battery power, as it is usually done, is not in any way needed; but the maintenance of quantitative force is absolutely necessary."

Quantitative force is maintained by Fuller's battery to a marked degree, and its maintenance is cheaper than many other forms of battery. They are used by nearly all railway companies in England, and by the P. O. Telegraphs, &c.

The battery consists of an outer glass or porcelain jar, and an inner porous cell. Zinc is element in porous pot, and the carbon is placed in the glass jar. Bichromate of potass crystals (3oz.) must be put in outer jar. Mercury is put in with zinc, also sulphuric acid; a little acid also goes in outer jar. Fill with water, and battery is ready for use. Further particulars to any querists.

H. Stooke.

HOW TO MAKE A FLAT FOR A NEWTONIAN REFLECTOR.

(*Continued from p.* 351.)

[20281.]—It would be well before commencing to smooth the surface, especially if the disc has been "shanked" round, to grind the edge to a clean circle. This is easily managed if the screw bosses of tools are of the same size and thread as the lathe mandril. The tool on which the disc is cemented may be screwed on the lathe, and a piece of thin sheet-iron or ordinary tinned iron is bent to fit loosely half the circle; No. 90 hole emery mixed with water must be used with this grinder—the latter needs holding up to the edge of glass with the hand only, if the disc is chipped nicely round. If this has not been accomplished, a "jigger," on the construction described in my letters on Specula Working, will bring a most unshapely disc to a circle. I may here state that the surface should be ground down as fine as it is possible in the last smoothing emery. This is of more importance in flat work than in specula working, for in the latter case the surface must be altered in figuring from the nearest approach to spherical that is obtained in the smoothing to a parabolic form. With the flat all processes must tend to keep up the one form. The amateur worker will I have no doubt get, when he has smoothed his flat, our old enemy the depressed ring due to capillary attraction. If he has had no practice in polishing on paper, the method I now describe will serve him better. I cannot think that pitch is a good substance to use for *flat* polishing, the elastic property, so useful in parabolising, in my experience causing a lot of trouble in flat work. Rigidity, not elasticity, seems to be wanted in producing a plane; I have, however, used pitch for large speculum metal flats on account of its *polishing* properties for metal. The polisher should be made of lead ½in. thick and 3in. diameter. If our operator can turn up in one piece a leaden holder as sketched (Fig. 1) it is best, but a wooden handle can be substituted for the leaden knob. In that case a male-thread must be cut on the leaden plate, as shown at A, Fig 1. The face may be roughened with a sharp point, so that the mixture forming the polishing-face will hold well—melt and strain through cambric a mixture of 1 part rosin to 12 parts good bees-wax, incorporate with this mixture, when in a fluid state, as much fine putty-powder as will bring it to the consistency of treacle, while heated—a very little of this mixture is needed, as the depth of 3-16in. is enough for this surface. Paste a rim of note-paper round the edge of holder ½in. deep, warm the holder, set it level, and pour the mixture in to a depth of ⅜in., taking care to stir the mixture well, the putty-powder, being of such weight, will instantly sink if this is not carefully done, the result being a mottled or patchy surface. When the mixture has set, cool down well in cold water, and strip off the notepaper ring; chuck the holder in the lathe and take a cut across the face of the mixture, and trim the edge true, then turn in V-shaped grooves ¼in. wide, and leaving a ¼in. surface, a groove and surface ring alternately, as shown at Fig. 2. Turn a conical hole in centre ⅜in. at top, and with a pen-knife cut across gutters, taking care that all grooves and gutters intercommunicate. Now rub the polisher on tool No. 3, and note where it fits. It is very likely that a raised burr will be found at the edges of each surface-ring; these must be lightly trimmed down, as the tool will show, by discolouring the surface of the mixture, where it touches. The discoloured parts must be lightly scraped down until a general system of patches, very close together, are seen to cover the whole of the surface-rings. Have ready a paste of putty-powder and water, and "work in" the polisher by rubbing with elliptic strokes, first on No. 3 tool; then cleanse by washing, screw down on the bench-screw the tool No. 1, with disc attached, and feeding the polisher again with the putty-powder paste, work with elliptic short strokes for 10 minutes. It is well at this point to see how "we take," i.e., how the polish is starting: a good "take" would show at least 1½in. in the centre affected by the polisher, and say ⅛in. at the edge. This would tell us that our old enemy, which I will in the future call the *c. a* ring, has been fairly attacked.

FIG. 1.

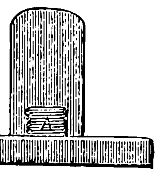


FIG. 2

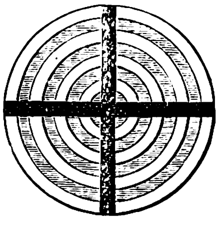
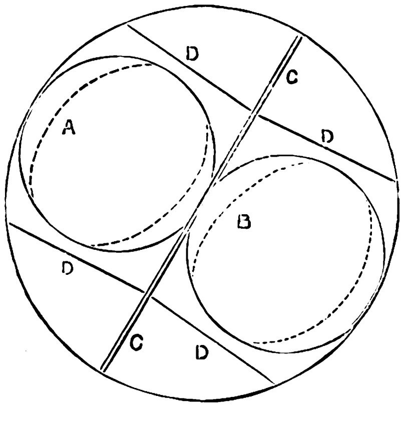


It is well in polishing to alternate elliptic strokes with straight ones across the centre. As our amateur worker is not supposed to have a perfect test-plate by him, to test his working as he proceeds, in the manner described by our clever and generous friend Mr. Brashear, which test, by the way, is an old friend put to finer uses, I have thought how well our amateur may make his surface-test itself: this is the old way. Take one part of a flat surface to test another by the "colour test." I have never, however, seen the colour test depended upon finally, and rather think I should like to try my flat in front of a telescope o.g. afterwards to make sure. As I, perhaps, do not know the *refinement* of the colour test, perhaps Mr. Brashear will step in with a few hints to help us all, should this meet his eye. I will give my experience. Polishing should not take more than three hours: if a satisfactory polish is got in one hour it is better, as the "roll back" on marginal error increases with polishing. When sufficiently polished, hold a spirit-lamp under the tool No. 1, warming evenly all round, push off the disc, stand on edge till cold, then soak off the cement by placing it in a saucer of spirit of turpentine. It is best to mark the back surface with a diamond, or scratch it with a three-square scraper, so that we are not mistaken in the sides. Then make a cardboard circle 2in. diameter, and mark off with soap two circles, A and B, Fig. 3. Mark off the major axis of each ellipse in the direction of the dotted lines on the back surface. This will insure the cutting away of marginal error. Now cut the disc in halves, down the line CC, with a diamond. after dividing the disc, cut off each end as marked at DDDD, and "shank" out the two circles, leaving the soap-marked rings inside the chipped edge.

FIG. 3.



I hope to conclude in my next on this subject with colour-testing, and finally edging up the flats correctly.

Prismatique.

(*To be continued.*)

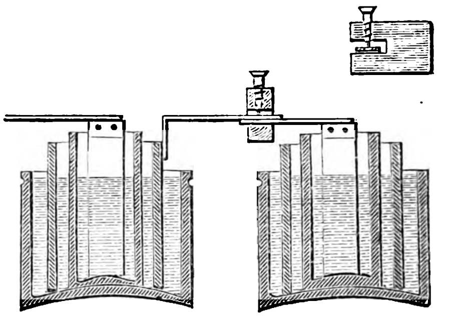
CONNECTION OF BATTERY CARBON.

[20282.]—Referring to letter 20234, the method of carbon connection suggested is faulty—the saving of ½oz. of lead at 2d. per lb., is false economy. The correspondent himself indicates the faultiness of his arrangement, as he states the lead contracts and loosens in the hole when cold. What can be worse than loose connections, allowing room for dirt, &c.? Now, by the Silvertown Co.'s plan of casting lead *outside* the plate of carbon, it tightens in cooling, and forms the best of connections—beating all your electro-depositing or platinum clip binding screws.

Electra.

CHEAP BUNSEN BATTERY—COPPERING CARBONS.

[20283.]—We have been making a Bunsen battery lately, and have found the following plan a good one for connecting the carbons. Prepare a depositing solution of 3 pints saturated solution of copper sulphate to 1 part dilute sulphuric acid (1 part acid to 10 parts water.) Place this solution in a jam-pot, with a piece of sheet-copper dipping into it. Attach a wire to this copper, and lead it to the copper of a Daniell cell. Place three of your carbons in a wooden clamp, with a thin strip of copper between the carbons and the wood. From this strip lead a wire to the zinc of your battery. Before placing the carbons in the depositing solution, paint a band of paraffin round the carbon, ¾in. wide and ½in. from the end, to prevent the copper from depositing too high up. Now place the ends of the carbons in the depositing solution, and attach the battery and leave for two hours and a half. Unclamp the carbons and wash the coppered ends; dry, and drill two holes through the coppered end of the carbon; pour hot water through these holes, to dissolve out any sulphate of copper which may have soaked in; dry thoroughly in the oven; now place in the vice, and with a soldering-iron tin the top. Attach a copper strip ⅜in. wide, by soldering. When this is completed, stand the coppered end of the carbon in melted paraffin, deep enough to just cover the holes. Allow to stand until the paraffin has soaked up the carbon about an inch. Take out and allow to set. Paint over the copper and copper strip with melted paraffin. This paraffin prevents the nitric acid from creeping up the carbons and attacking the copper and spoiling the connections. A simple form of clamp is shown in the sketch, which we found perfectly efficient and very inexpensive. Oak is a very good wood to make them of.



Holmes Bros.

MEDICAL REPLIES.

[20284.]—Taking Cold (47297).—Refer back to a former reply of mine on this subject. Otherwise your query is ineligible for answer, and you must get some local medical man to examine and advise you.

Contracted Fingers (47302).—Querist suffers from a contraction of the fingers, which is sometimes due to contraction of the tendons—sometimes to contraction of the fascia around the tendons. The diagnosis on this point can only be settled by personal examination. In either case the remedy is subcutaneous division of the contracted fibres.

Inflamed Throat (47308).—Not eligible for useful reply.

Deafness (47239).—The advice given by Mr. Dalby is excellent. But Mr. Ollard will discover, on again perusing my note, that his case is one of perforation or absence of the *membrana tympani*, Otherwise fluids or air could not be forced through the ear from the mouth and nose. The cases for which I wrote do not include such as his, all of which need discriminating diagnosis and personal advice. As to ear-trumpets, &c., they merely act by collecting large areas of sound-waves and concentrating them upon the ear. Practical trial of the various contrivances is the only guide which I can here indicate, and that which one hears most comfortably with will be the best.

Abscess in Groin (47322).—Probably glandular, and to be treated like other glandular abscesses, for which refer back to a former reply of mine. Poultice when inflamed or tender. Rest. Improve general health by careful diet and regimen, such as previously described.

Drowsiness (47333).—Not eligible for useful reply.

Stiffness in Foot (47334); Lameness (47339); and Rheumatism (47343).—Not eligible for useful reply; must have personal examination.

Excessive Perspiration (47355).—I have seen similar cases, but they are very rare. Probably due to some disease of the sympathetic nerves. Treatment would be conjectural, and not even conjecturable except upon personal examination.

Stammering (47366).—This is due to a want of due co-ordination of the complicated muscles by which speech is produced. It is easily acquired when young by nervous children who are with nurses, servants, and other persons who stutter. The habit when established is very difficult to cure. Drugs have no effect upon the habit, but it becomes worse if the health deteriorates or the child is worried and made nervous. With such children, keep up the general health by careful feeding, early going to bed, and avoid noticing or hurrying the child when it hesitates in its speech. The more the child is noticed or hurried the worse it will stutter. Let everyone about the child speak slowly and distinctly, and make the child read aloud with extreme slowness and distinctness for a quarter of an hour four hours a day to some one who is very gentle, and with whom it is quite at home. Such reading is the only method of cure, and this, if adopted early, and duly persevered with, will re-establish deliberate well co-ordinated action of the muscles, and after that is established, speed should come gradually.

James Edmunds, M D., &c.

Grafton-street, Bond-street.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[46635.]—**Imitation Marble (U.Q.)**—Probably, this can be made with Portland cement, but the colour would be decidedly objectionable. The usual process is with plaster, which should be of the finest description. This is gauged with lukewarm water, in which is dissolved size, isinglass, or gum-arabic to fill up the pores, and render the composition of a texture capable of being polished. If various tints are required, the colours are dissolved in the size-water. (Scagliola is formed with a great number of splinters [*scagliole*] of marble in the plaster.) The different colours are produced by metallic oxides: as blue, oxide or carbonate of copper; red, litharge; yellow, the yellow oxide of lead; or for green, by green enamel; grey, by ashes; brown, ashes and cement mixed; and black, by forge ashes. In best works, it is usual to mix with the plaster pounded Carrara marble. The mixture is worked together, in the form of a very damp paste, until the whole is homogeneous. When perfectly dry, the surface is rubbed with a very fine-grained grit-stone, washing and cleaning it with a sponge in the same way as marble is polished; it is then rubbed, with a linen rubber, with moistened tripoli powder and chalk: it is finished with a felt rubber, charged with oil, and very fine tripoli powder; and, finally, a rubber with oil only. The above is extracted from Burnell's "Treatise on Limes, Cements, &c.," published in Weale's rudimentary series.—DITTON.

[46744.]—**Marble (U.Q.)**—Bethersden and Purbeck marble, both from the same (Wealden) formation, are very dark green, almost black, and filled with small shells, the general effect being a very dark grey. I know of no work specially devoted to the marbles of the United Kingdom; but the following list, taken from the "National Cyclopædia," will probably satisfy "Murano." No doubt, further information could be readily obtained from any marble or stone-merchant. **Black marbles**: Ashford in Derbyshire; Dent (Yorks), Crickhowell; Tenby; Kilkenny, &c. **White**: Skye, Inverary, Assynt, Blair Athol, &c. **Ash and Grey Marble**: Orleton, in Shropshire. **Brown and red**: Buxton and Betham Fell, near Milnthorpe. **Green**: Irish green. **Black, variegated with other colours**: Ashburton and Torbay, Devon. **White, variegated with other colours**: Near Plymouth, at Killarney, &c. **Green, variegated with other colours**: Mona, Anglesey. **Marbles containing shells, corals, &c.**: Plymouth, Ashburton, and other Devonian limestones; the Crinoidal marbles of Flint, Derby, and Garsdale (Yorks); the shell marbles of Buckingham, Whichwood Forest, Stamford, and Yeovil, from the Oolite; and Purbeck and Petwork (similar to Bethersden), from the Wealden.—DITTON.

[46859.]—**Indigo Blue Dyeing.**—S. J. Simpson, on p. 383, gives a brief description of indigo dyeing by Holliday and Sons' process, and asserts that the only difference from the old woad vats is simply that Holliday's is worked with bisulphate of soda, zinc dust, and lime. The writer displays ignorance of the two methods of indigo dyeing, or he would have been able to have given a fuller and more correct description than he has done. In the first place, lime is used in both cases: in fact, it is the lime that keeps the old woad vat, and it is more essential to use it than in Holliday's process, and the indigo by their process is specially prepared known only to, or at least done so by, the patentee), whereas with the woad vats it is the pure indigo that is used. I may add that the process of indigo dyeing by Holliday's process is far superior to any yet discovered, and will ultimately supersede all other methods of blue dyeing. It is a superior colour, it is less expensive in cleaning, and is equally as durable. It will stand washing and the atmosphere better than other systems, and will dye double the quantity of wool, yarn, or cloth, in any given time. Having worked both systems for a number of years, I can testify to the above, and would recommend any party beginning indigo dyeing, to adopt Holliday's process.—J. ORMISTON.

[47039.]—**Clock Query.**—Set the "fly" so that it revolves slower; perhaps it is loose on its spindle.—ST. LUKE.

[47043.]—**Camera.**—To MR. LANCASTER.—In reply to yours on p. 359, my objective has:—1st, an achromatic lens, 31 mill., with shutter; 2nd, a conical piece, with a set of two lenses (double convex and meniscus, separated by a ring), 38 mill. and diaphragm, 5 mill.; 3rd, a separate piece, with convex lens, 21 mill., a diaphragm 8 mill., and shutter. 2 and 3 can be screwed on 1.—A DUTCH SUBSCRIBER.

[47045.]—**Wire Harness for Weaving.**—I believe the machine for making wire heddles is an American invention; but are they much used in this country?—C. K. J.

[47048.]—**Greenhouse.**—The vine would, of course, cover the roof, and so exclude much of the light the flowers would require; but if you do not intend to "force," you may have a vine and flowers too. It would be better to utilise the wall for, say, peaches and nectarines; but the best thing to do would be to call in a practical gardener to see the place, and ask his advice.—ESSAR.

[47049.]—**Gilding Book-Edges.**—As the "receipts" referred to were, in all probability, taken from this paper, they are no doubt correct. At any rate, the method of applying gold-leaf to book-edges has been frequently described. Look in p. 550, Vol. XXXIV., for instance. "J. K. B." has, probably, allowed the glair to get thoroughly dry, or has attempted to burnish before the gold was fixed. If he tries again, he will, no doubt, succeed.—E. G. M.

[47052.]—**Paint on Mowing-Machines.**—Is it possible that "Daylight" means he has seen some galvanised iron? Try it with a knife.—T. P.

[47057.]—**Glaze or Enamel on Iron.**—Would the querist say what temperature will suit?—then, possibly, he may get a reply. As it is, his reference is incorrect, and it is impossible to know what recipes he refers to. He will obtain nothing more fusible then a common glass having a large percentage of lead, and perhaps that won't adhere to the iron. There are many recipes in the back volumes, including the present one, for the enamelled iron tablets.—VIDEO.

[47059.]—**Iron Chimney Rusting.**—Cover it well with Brunswick black when it is thoroughly cleaned. Of course, you mean it is the outside that rusts.—G. T.

[47060.]—**Atmospheric Nitrogen.**—See Angus Smith's "Air and Rain." The quantity of nitric acid found in rain varies with the locality. In parts per million he gives Runcorn ·278, Liverpool ·582, Manchester 1·179, Glasgow 2·436.—S. R.

[47066.]—**Scissors and Razor-Grinding Machine.**—Surely, you can take a hint from one of the ordinary travelling grinder's wheels. Many of them have only one treadle, which works direct to a flywheel, and that has a band driving a pulley on the grinding spindle.—E. H.

[47081.]—**Polishing Granite.**—Is it granite or concrete that has to be polished? At any rate, it is done by taking a lump of granite, some sharp sand and water, and then with plenty of elbow-grease you will get a surface. Finer qualities of sand are used until the polish is brought up.—E. G. M.

[47081.]—**Polishing Granite.**—After the surface is tooled as truly as possible, rub down with an iron or wood muller and wet sand, and then with a lead muller and emery; next rub with hard pumice-stone, keep constantly wet with water only, then with rouge under a linen pad. To finish, well wash the surface, and when perfectly dry, polish with a linen pad, moist with water, and powder of calcined tin of the finest sort, and finally with a pad of dry rags, carefully removing first any grit that might scratch the surface; the above is from Spon's "Workshop Receipts."—DITTON.

[47082.]—**Hardening Leather.**—Choose good pieces, bark-tanned, soak in water until thoroughly mellow, and then hammer thoroughly. If you can get the use of a hydraulic press, by all means get a die and a plunger, and compress the leathers as much as you can.—E. C.

[47143.]—**Aluminium.**—"Zelia Naien" will find it very difficult to separate the Zn from the Al economically and perfectly. On the other hand, the alloy will probably have advantages, as it will most likely take solder, hitherto a matter of the greatest difficulty with pure aluminium. If "Zelia Naien" will send me his address, I think I can help him.—C. WOODHEAD, The Woodlands, Hitchin.

[47143.]—**Aluminium.**—In the production of aluminium, "Zelia Naien" asks for a method of separating the zinc from an alloy he has obtained. He has received in reply a very "deserved snub" from Mr. Grey (page 361), as Mr. Allen calls it (page 404). I concur in the same opinion. Nevertheless, I will give "Zelia Naien" some useful information about his research. I have extracted also very easily an impure alloy from a mineral ore sent to me from Spain; its technical name is "Ghanite," a proper aluminate of zinc, whose chemical formula is Al_2O_3ZnO. How to purify the extracted alloy? I will not say my own experiments—they were a failure. But I will kindly tell "Zelia Naien" that, in the factory of Nanterre, near Paris, erected in 1858, by M. Deville and M. Morin, they have employed every means of scientific purification. When the alloy is melted at the temperature of volatilisation of zinc, a portion of the zinc burns up and vanishes away as a vaporous oxide in the form of a flocculent powder—the "pompholix" of the ancient chemists. In trying to increase again the temperature in a crucible of plumbago, the volatilisation of zinc goes on, but the aluminium oxidises in the atmosphere of carbonic oxide produced by the carbon of the crucible. The quantity of metallic aluminium left is quite insignificant. The process is very wasteful. A crucible of wrought iron, instead of plumbago, sets up a triple alloy—aluminium, zinc, and iron. M. Morin has tried many other methods of purification. In spite of his long practical experience, every new process for the production of aluminium has proved a failure.—SPANIARD.

[47145.]—**Oil.**—Into a tin pan, 3ft. square and 1ft. deep, set on ground, pour three or four gallons of linseed-oil, to which throw in a quarter of a pound of coarse litharge to each gallon; stir this every day for a fortnight, and take care to agitate it well. At the expiration of the term the oil will have acquired a good drying quality—will be equal to boiled oil—and will have suffered no loss, as heat was not employed in the process. The resultant oil is also white and limpid.—H. STOOKE.

[47160.]—**Recovery of Silver.**—I think you are wandering under a delusion. Because lead has favourably replaced the silver plate in your battery, it must not be assumed that the lead contains silver. Any two metals in the following table will give off a current; and the farther they are apart in the order given the greater will be the power given off. The deduction, therefore, is that you have formed a couple which is as much to your satisfaction as the one previously in use. You do not say what metal you used with the silver and lead. Table of metals evolving voltaic electricity:—

1. Aluminium
2. Manganese
3. Zinc
4. Iron
5. Nickel
6. Lead
7. Tin
8. Copper
9. Mercury
10. Silver
11. Platinum
12. Carbon

These might be added to.—H. STOOKE.

[47168.]—**Trimming Copper Sheets.**—Many thanks to "Mide" for his answer on the above. Perhaps he will have the kindness to inform me how to keep one side of the burnished sheets bright whilst the other side is being trimmed, or how best to restore it to its brightness again?—and oblige—COPPERY.

[47174.]—**Pedal Reeds.**—From the description you give of your intended instrument, I should consider it wise to leave out the reeds of 32ft. pitch, and add one of 16ft. pitch, which will make in all two rows of 16ft. and one of 8ft. pitch. Let one of the 16ft. rows be voiced soft, and the other 16ft. row a little more reedy. This will be far better than having a 32ft. set, which is not required in an instrument of the size you describe. Any further advice if asked for.—G. FRYER.

[47174.]—**32ft. Pedal Reeds.**—"Ariel" can procure 16ft. sets of pedal reeds from any of the warehouses where those things are kept. They are known in trade as "small Bourdons." As to 32ft. reeds giving the actual 32ft. tone, I suspect he will have to give an order for them. The lowest reed will be from 8in. to 10in. long, according to scale adopted. If "Ariel" wants addresses he must look in the "Musical Directory," as makers and sellers rarely advertise, being well known in the trade. There will be a difficulty about the speech, but the patient workman will remedy that. It is simply impossible to give any directions, or even to show how it is done, for it depends almost entirely on the setting of the reed—the vibrator. You may have a reed that speaks slowly, and you press the vibrator further into the block only to find that it won't speak at all, say; then you lift the vibrator higher so that it stands well above the block—then perhaps you find it stutters and splutters. You try again, and lo, it speaks the instant the key is depressed. You may defy anyone to tell you why, or to explain what there is in the last position of the vibrator which makes the difference. Mr. Huxley, on page 385, recommends an old and abandoned dodge, which he will find, I believe, in a patent of Debain's, taken out in 1870. Debain also (see p. 61, No. 315) patented curving the reed, filing a hollow across the block, &c., all of which allow the wind to pass, and induce the reed to go with it. That was for his aspirophone, which was built on the plan of the American organ. Mr. Huxley should have stated that what he calls the "American twist" did not improve the speech because it was done by somebody who did not understand it. A reed properly set and twisted, speaks directly without any filing of the block, which is ruination in parts of the scale.—S. MAYER.

[47196.]—**Electricity v. Gas.**—I should not intrude further but that the question is important, and is bound to come to an issue some day. When we ask a question, it is to know the reason why, or why not, a thing can be done, not to be told to go and find out ourselves, as though the thing was impossible. When I saw an installation of the electric light the engine was a 20-h.p., working up to 50-h.p. to supply 16 lamps; also a 4-h.p. engine up to 7-h.p., to supply 3 lamps, the cost of small engine £100. I saw at once that the process was not economical. Considering this, I am glad to read of available small dynamo machines (p. 405) as these, if effective, are a step towards universal adoption. But Mr. Lancaster has been persistent in condemning such small machinery and also small batteries, presuming that from nothing, or next to nothing, nothing will come. But when we see hydrogen, an invisible and almost imponderable substance, possessing such enormous powers, it makes us think with the ancient Paul, "that things which are seen were not made of things that do appear." I am aware that we have to do with facts, but we do not know what remains to be found out. I cannot experiment myself, as my violin and "cello" takes up all my spare time; but "N. Z." has advanced the subject one stage by declaring the hydrogen incandescent gas lamp (with electrical action) to be a fact. So we have two ways of making an incandescent light with almost the same materials—the gas lamp with one jar, the electric lamp with many jars. With the object of reducing the number of elements, I wish to ask another question,—Cannot hydrogen gas be burnt with the electric light? Forgive me for supposing that hydrogen gas is a large component of electricity; this is only my idea, electricity has yet to be analysed. If it is a part, then the escape of hydrogen should be prevented or made use of.—FIDDLER.

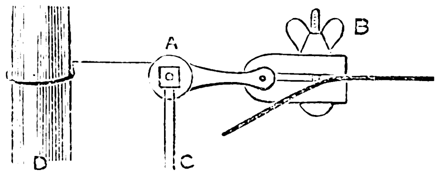
[47226.]—**Picture-Frame Making.**—Frame-making, especially when using the cheap foreign article, requires considerable practice to make a good job of it, and therefore I will give a few more "wrinkles," which are the result of my experience. I don't approve of "Cotswold's" plan (see page 409), because he leaves the glue to soak in first, which will bring out the end grain, and thus prevent the plaster edges from coming together. Then he does not give any method of holding the two pieces together until the glue is dried sufficiently to stand the nailing. The first requisite is to have the plane "flat" on its cutting edge (and this is not very easy for an amateur to accomplish), and, of course, very sharp. The next important memo. is, that you must not alter the set of the plane-iron whilst doing the eight mitres of any frame, or you will require to do them "all" over again. Then, bear in mind that, by shooting, say, the end of a long piece, with the gilt side uppermost, and the corresponding end of the short piece, with the gilt side downwards, that any slight errors will be compensated. Grip the largest piece in the vice, with the gilt facing your left hand; hold the companion piece so that your forefinger is feeling that the mitred edges are together. Now raise it up ⅛in., and bore with sprig-bit through the top one ½in. into the other (have your sprig-bit very sharp, and don't use it as a turnscrew, &c.); procure nice delicate sprigs, not the horrid rough and blunt articles commonly sold as cut nails. Have your glue thick, and just put one "dab" towards the back of the mitre, in with your sprig, and tap gently down, as "O. J. L." recommends, being guided by the feel, in conjunction with the eyes, and if not quite right, a sprig in the opposite side will probably make matters right. I have not tried any of the cramps, but am certain that, with anyone used to the job, the whole frame could be done ere one corner could be accurately cramped up for nailing. Memo: these cheap mouldings are often very crooked, and in driving the sprigs to keep the back-boards in place, don't use a hammer, or your glass will often come to grief; but use the edge of, say, an 8in. flat file.—J. J. A., Liverpool.

[47228.]—**Telephone.**—A hundred yards.—H. STOOKE.

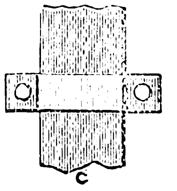
[47238.] — **Astronomical Telescope.** — To "ALDEBARAN."—Artificial tests for definition, such as small print, &c., are never to be depended upon. It often happens that a telescope, perfectly useless for stellar work, will define such objects remarkably well. A simple and, at the same time, a very certain test for both object-glasses and specula, is to remove the eye-tube, and to place a white screen at the focus of some bright object, such as a gas-flame or an artificial star, obtained by placing around the flame a sheet of bent tin, with a ⅛in. hole just in front. A piece of cardboard about 6in. square, with a similar hole punched in the middle should then be held close to the outside of, we will say, the object-glass, and the hole moved across its surface in every direction. There should be one particular position where the image should be perfectly steady, whatever may be the movement of the perforated card. If there is no such position, the figure of the object-glass is imperfect, and a blurring or nebulosity (not to be confounded with the effects of irradiation) would be present at the edges of any bright image. This blurring would not, perhaps, affect the definition of terrestrial objects, or even lunar detail; but it would render the telescope utterly useless for separating close doubles, or for showing planetary markings. Its definition may, however, be much improved, and sometimes rendered perfect, by stopping off the faulty portions of the object-glass. This may be determined by noting at which zone of the object-glass the hole was opposite when the motion of the image was most distinct. It will not be necessary to give tests for achromatism, because any shortcomings in that direction will be sufficiently obvious, and I do not suppose "J. L." will, in such a case, be curious to know whether his lenses are too much or too little corrected. A "rough-and-ready" way of estimating the magnifying power is to divide the focus (in inches) of the object-glass by one-half that of the field-lens, supposing it to be a Huyghenian eyepiece. Thus, if the former be 36in. and latter 1in., the power would be 72 diameters. For hints on eyepieces, see page 337 of the current volume. I may also mention that I have received some very excellent and cheap secondhand eyepieces from Mr. Caplatzi.—ALDEBARAN.

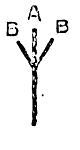
[47245.]—**Electric Bells.**—Dust in switch perhaps.—H. STOOKE.

[47246.]—**Private Telegraph Wires.**—The wires are strained by a "draw-vice," and when sufficiently tight are placed into the groove of the insulator, and bound in with No. 16 *g. i.* wire. The nearness to wall of outdoor wires affects them not, if they do not actually touch it; but only their insulators. However, if they are just within 4 inches of wall accidents occur, for when the wind blows contacts occur, and spiders in fine weather spin their webs between the wire and wall, which after a shower, open up a path for a considerable amount of leakage. I must apologise for my rough sketch of the "draw-vice." D is a pole, and A drum of vice, which works on an axle governed by the key C. The jaw B clips wire to be strained. On turning C, the wire fixed to D is wound on to A, and the distance between vice and pole shortened, and, therefore, B is strained in proportion thereto.—H. STOOKE.



[47264.] — **Lightning Conductors.** — These generally consist of a stranded copper rope, from ¼in. up to ½in. diameter, which is fastened down to the wall of the chimney, &c., by means of staples. Formerly the conductor was insulated from the wall, but as the efficiency thereof depends upon its capability for opening up a ready path for the charge, this course was beneficially abolished. When the conductor is not insulated from the stack, the chimney itself assists the discharge to earth. The copper wire is fixed to a platinum-tipped iron or copper rod at the top of the chimney, and at the bottom must be appended to a good earth plate, or some other good earth connection. The rods are often forked, as shown in the figures, but BB are certainly superfluous, as if the "flash" approaches and strikes the chimney, it is a natural circumstance that the current will find the path of least resistance—the main conductor — without these expense-increasing platinum points. The earth-plate, formerly mentioned, may be 2ft. square, and should consist of galvanised iron or of copper. If the soil is dry, a few bushels of coke around it will improve the earth. Any old iron, &c., may be beneficially buried around the earth-plate. A very good conductor may be made of a half-inch wide strip of ⅛in. copper fitted to wall, as shown at C. It is simpler and cheaper than a stranded construction. The brackets (if they may be so termed) which hold the copper strip down to the wall, are easily cut out and bent into shape from thin sheet copper, and after the holes have been punched are fixed down by clout nails. Thus we see that the conductor should leak all the way down, and the more it leaks at every point, the more efficient it will prove, because, as before stated, that efficiency depends on its earth-conducting power. Conductors should be frequently examined, as they corrode, and connection from top to bottom gets impaired. If you have a galvanometer, get a battery cell, and connect to top of conductor through galvanometer; the result should then be a full deflection, say 90°. Now try for deflection at bottom. Say you get 80°. The conclusion can then be drawn that 10° of the current are carried off to earth through the brickwork and 80° through the conductor. When the weather is wet more current will go through the damp chimney; tests should, therefore, be made in dry weather for comparative results. Should the deflection from the top fall off, you may depend something is wrong, and that the wire wants looking to. Of course, the deflection at the bottom of the conductor will also be reduced by deterioration; but it must be remembered that the weather must, for testing these uninsulated lines, be fine, as dampness affects the lower deflection.—H. STOOKE.



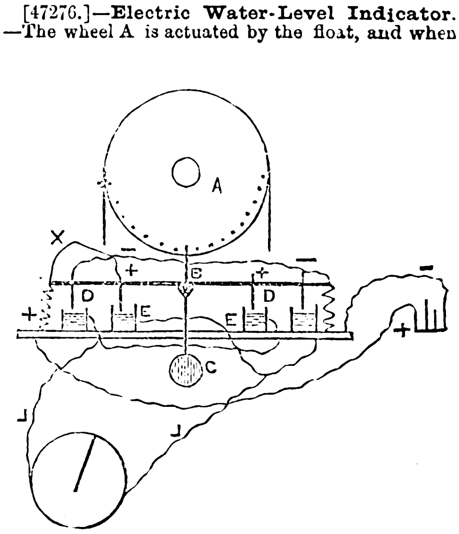


[47274.] — **Illuminating Clock.** — Paint the dial with the new luminous paint, saving gas, &c. A piece of wood, painted two coats, was found to yield sufficient light to get gunpowder out of a dark magazine. See "Scientific News" column of this journal a week or so ago.—ELECTRA.

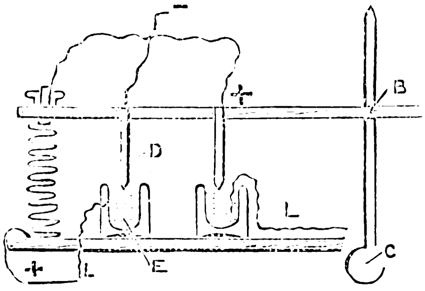
[47274.]—**Illuminating Clock.**—You can have the source of illumination in the room, and have mirrors to reflect it on to the face of clock, but you would lose about one-third of the light at each reflection. The better way is to have the light below the face of the clock, and just in front, then looking-glasses on each side, and in the front, would help to illuminate the clock. I have often thought that a good clock might be made for night use, having two rotating discs with a hole in each, long and narrow, the one disc serving the purpose of minute-hand, the other hour hand; then a circle of round discs outside in place of figures, the light to be at the back of the dial. Such a clock could be seen ten times further away than now, and would be most valuable at night. The light, of course, would illuminate the whole of the figure spaces, and the holes in minute and hour discs, which would rotate. This would be a novelty worth the making.—W. J. LANCASTER.

[47275.]—**Electrical Indicator.**—I do not see how you can arrange this without going in for a very expensive contrivance. The company under which I serve have to pay £15 to £20 for an apparatus simply to show when tank is full, which I will describe if you wish for it. The apparatus might be modified to show when the tank was empty also; but to show intermediate positions would, I should say, be useless. Write again.—H. STOOKE.

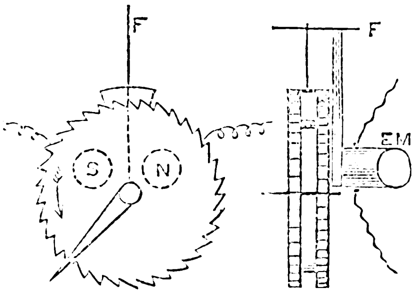
[47276.]—**Electric Water-Level Indicator.**—The wheel A is actuated by the float, and when revolving causes the bar carrying the contact-pins to rock on its centre B, and so producing a circuit on one side or the other by immersing the pins D in the mercury C, the pendulum C bringing the bar into its normal position. I have shown pins in a line for the sake of clearness, but they can be placed anyhow so long as they dip together. By using mercury I think you will make a great deal better contact than you can with solid metals, but the pins on the bar and the connections must be well insulated. For the recording instrument you will require a couple of ratchet wheels of equal



size, but fastened together a little apart, and mounted on a common centre. You must have as many teeth on them as your float-wheel has pins, and the teeth must be cut in an opposite direction



to one another, so that when the electro-magnet attracts the armature, and escapement F toward the pole marked S, the wheel at the back revolves



in the direction of the arrow (and with it the wheel and index that are shown), the reverse action takes place when armature, &c., is drawn toward N; there are several disadvantages in this plan—viz., the necessity of having the batteries at the reservoir, the liability of instrument to get out of step, and the continuous action if the pins on float-wheel should happen to hold the bar down; but all I have seen are not free from these defects. If this does not suit write again.—Wallington.

[47279.]—**Spoilt Glass Shelves**.—I presume that no acid is about the place where you stored them, as that occasionally injures glass.—H. Stooke.

[47279.]—**Spoilt Glass Shelves.**—The easiest way to remove the stains is to repolish the glass. Make a pad with thick cloth on a flat piece of wood, with a handle on the other side; then get some of the finest putty-powder, and commence to polish with the powder and a little water, and work until all the stains are removed, then finish polishing with dry powder. Take care you do not get any grit on the glass.—W. J. Lancaster.

[47281.]—**Tricycles**.—The power obtained by the lever and rotary motions is about equal, provided the stroke is of the same length. The reason why the rotary motion is so much used, is that most people consider the motion more pleasant and less tiring. It also has the advantages of enabling the wheels to run faster or slower than the pedals, according as the lower cogwheel is larger or smaller than the upper one, and it admits of the use of "balance gear," for double driving. This, I consider a great point, for I consider "balance-gear" very much superior to any ratchets or clutches, and the enormous number of "balanced-geared" machines which have appeared this season shows that the makers think so too. Levers are easier to construct, for chains entail a very great deal of work. There are, however, several patented methods of communicating the rotary motion to the wheels, some of which are rather superior to chains.—G. R. T.

[47281.]—**Tricycles.**—I have used almost every kind of tricycle, and can find nothing superior to the chain. The lever machines I would not use. I can with the chain climb any hill, although it is not always well to attempt to climb a steep hill; more energy is used up than would be required to push the machine up the same hill. I have no preference for a double-driver; can do quite as much with a single geared well, and can turn corners much more easily and quickly with single-driver. I have seen some nasty spills with double-drivers in turning corners at all sharp. I should most decidedly recommend a back-steerer single-geared machine, of not more than 44in. diameter. With such a machine you can go 12 miles an hour, and if you will, can keep your seat all day. I rode 19 miles in an hour and three-quarters the other day on a Swallow without the least fatigue, and after eight o'clock at night, several long hills being on the road. This is, I think, as much as one would care to do on any machine. There is one part of the tricycle that needs a lot of improvement, and that is the saddle, or seat. I should like to see a dished saddle, very much like the half of a washing-bowl, and fitted on springs working only in a forward vertical motion. Such a seat would be most valuable.—W. J. Lancaster.

[47287.]—**Magneto-Electric Machine.**—Put the bobbin in a lathe and guide the wire with your hand. The change of polarity must be made at the point where the poles stand (or rather just before they stand) NN, SS, as no motion would be the result if a continual NS NS condition was not kept up.—H. Stooke.

[47287.]—**Magneto-Electric Machine.**—Leave out 2in. of wire in commencing to wind your spool, fill up each, connect the two bottom wires (cleaned) together, have shaft between spools bright, wind four folds of finishing end round, braze fast to shaft (from one spool only). Observe, should your shaft have a broken connection, and the pinion working in the step between magnets be inserted with guttapercha, then fasten the other end of spool wire to the pinion, apart from the shaft. The other question is of no use. In putting the machine together, do not let spools bear upon magnet, and if tin spring bears upon framework, you throw back the current, gently bear your spool spring upon flats not too stiff. Notice your pole wire connection has a drop of oil, and I think it will work.—Tom B.

[47288].—**Drying-Racks for Dry-Plates.**—According to my experience, there is not much to choose between the vertical and horizontal positions. In the former case a space of at least half an inch should be left between the plates; and in the latter they should not be laid flat upon any cold material, such as glass; but supported on strips of cardboard or wood, so as to allow the air to circulate underneath.—W. Robinson, Junr.

[47288.]—**Drying-Racks for Dry-Plates.**—The racks are bad because there is not a sufficient current of air between them. You could easily make a circular drying frame to hold, say, a dozen quarter-plates, the outer edge of each to be 2in. apart, then they would dry much more rapidly than in the usual rack. The drying circle could be made of tin directly; have a tube in the centre, say 2in. in diameter, then around this have the one series of tin grooves soldered; then for the outer circle a tin band with another series of grooves would be all that would be required.—W. J. Lancaster.

[47292.]—**Bunsen Battery Connections.**—See my letter elsewhere, in reply to "Beetle Crushers," letter 20234, on carbon connections.—Electra.

[47292.]—**Bunsen Battery Connections.**—Read letter 20234, from "Beetle Crushers." You can deposit copper by placing the end of carbon in sulphate solution of that metal and passing an electric current through it. The carbon is connected to the — pole and the plate of copper (which must be put in solution opposite the plate of carbon) is connected to the positive pole of the battery. The little spirits necessary for the soldering may be entirely overlooked. I may say that it is very convenient to have all carbons provided with terminals, as in case of removals, renewals, or when cleansing the batteries, they can be easily removed.—H. Stooke.

[47298.]—**Examination of Malt.**—Infusion of malt cannot be filtered through filter-paper without pressure, but a piece of clean calico answers very well. The heat at which the infusion has been prepared makes a good deal of difference to the filtration. An extract of suitable strength may be prepared by adding 50 grammes of ground malt to 250 cubic centimetres of water at 145°, raising the infusion to this point, and keeping it there for 1½ hour, afterwards heating it to 180° for half an hour, filtering as above, and rinsing with enough hot water to make up to 500 cubic centimetres. This will give a proportion of 10 to 1, from which the results for acidity, &c., can be easily calculated. If the heat of the infusion is too high to begin with, the "goods will set," as a brewer would say, and it will be very difficult to get the extract off. Further particulars if wished.—E. S. Beaven.

[47298.]—**Examination of Malt.**—I have found the best way to get a clear and rapid filtration is to allow mash to stand in beaker long enough to allow grains to settle to bottom, leaving wort at top, and then to carefully pour, without disturbing grains, on to a sponge, or loose plug of cotton wool inserted lightly in a funnel, returning first drainings on to filter if not clear. Have found this the best way of very many practical trials through filter papers.—J. W. East, Louth, Lincolnshire.

[47299.]—**Lantern Optics.**—You can get a true disc when the light is either within, at, or beyond the equivalent focus of condenser, by using discs of varying aperture over the opposite side of condenser, just cutting off the marginal rays. The equivalent focus of the condenser will be a point nearer to the condenser than you have evidently taken, but even if the light is at this exact spot you must cut off at least one-tenth of the diameter of outer lens to get a clear-edged disc. With a single lens condenser the effect will be different.—W. J. Lancaster.

[47301.]—**Vacuum Tubes and Coil.**—You have a leakage somewhere, most probably a soldered connection broken. Go carefully over every connection, and then get the spark between the two points of a discharger, and notice whether there is a continuous run of sparks, or if there is a spark only, and then a rest; then a succession of sparks, and another rest; if so, then if connections are right, the insulation is wrong. Let me know the size of coil when you write again.—W. J. Lancaster.

[47303.]—**Rusty Water-Pipes.**—I see no alternative for "Puzzled" but to replace the iron water-pipes by lead, as the water passing through the iron pipes affects the same so much as would, no doubt, in time prevent any water passing at all by reason of the amount of rust in the pipes.—Ditton.

[47305.]—**Photography.**—To Mr. Parkinson.—No doubt the white spots are caused by air-bubbles in the developer. Remedy: To each pint of oxalate solution add 2oz. of lump sugar; this has a double advantage, as it greatly improves the tone of the enlargement. If this should not be a perfect remedy, send specimen, showing defect, and I will do my utmost to assist you. Spot out with Indian ink cooled down with indigo. Of course you must match the tone with that of your enlargement. Spot silver prints with sepia. I find the glycerine developer suitable for all kinds of plates, if you give long exposures and slow development; but if rapid exposures are necessary, use any of the standard formulas, or that supplied with the plates.—James Parkinson.

[47309.]—**Clarionet.**—The position of the holes in this instrument is a compromise between the theoretical correct position and the most convenient for human fingers. Obtain an organ pipe scale, and compare it with your clarionet, and you will see at once what I mean. Do not make the bore any larger because you wish to have the instrument flatter, as if you do the upper notes will be difficult to obtain. I should like to assist "Old Blow-hard," if possible, and perhaps "Vulcanite" or Edwin Morgan will help him.—Hampstead.

[47313.]—**Tests for Bicarbonate of Soda and Tartaric Acid.**—Commercial bicarbonate of soda generally contains a proportion of carbonate. To a clear solution of the bicarbonate in cold water in a wine-glass, add a few drops of solution of sulphate of magnesia (Epsom salts); if carbonate of soda be present a precipitate will be formed. Tartaric acid sometimes contains lime and potash as impurities. On heating a little of the acid in a spoon over a flame, it should melt, carbonise, give a smell of burnt sugar, and on stronger heating, burn off without leaving any residue. Does "Novillo" mix the two salts together before they are actually wanted to be used? If so, there is sure to be some loss of carbon dioxide. On the other hand, when they are used, they should be thoroughly mixed together in the flour, and in the right proportions—viz., 13 by weight of acid to 16 of bicarbonate. If "Novillo" will send small samples by post (in wooden pill-boxes), I will test them, and let him know the amount of impurities they contain.—E. S. Beaven, Warminster.

[47315.]—**Harmonium Pan.**—Anyone capable of handling tools in a workmanlike manner, and possessed of the requisite appliances, can make a pan for a harmonium, whether it is for one or seven rows of reeds, which shall be quite as good as the majority of those that can be purchased. Whether, considering the time necessary, it is worth while to make is another matter, and one that must be left to the discretion of the individual. It need only be mentioned, then, that the price for a really good 2½ row pan is about 25s. (not more), before proceeding to tell "Gotha" how he may make one. It will simplify matters if the making of a one row is fully described, because many of the operations have to be simply repeated in constructing larger affairs. It would be easier to refer the querist to back numbers, where full details have been given more than once; but as I take the insertion of the query to mean that those numbers are out of print, and I happily possess every number of the English Mechanic, it may be of service if I make a réchauffé, guided to some extent by my own experience. First, we require to make a channel frame having 60 pieces of thin wood across it, so as to make 61 divisions, each of which must be blocked off into suitable lengths for the different reeds. To make this take a piece of ¼in. yellow pine, 34in. long by 1¼in. broad; make a mark ¾in. from each end, and then space off the remaining 32½in. into 61 equal divisions. The easiest way to do this is to have the keyboard you intend to use, and mark the centres of each key on a strip of wood; then placing the strip against the piece of pine, mark off the channels, taking care that the centres of the keys will fall directly over the centres of the channels. Thus you will have 60 pencil marks, at which you cut a groove ⅛in. deep by the same width. Now draw a line diagonally along the strip, starting just about ¼in, from the edge, and cut through; then you have two pieces 1⅜in. deep at one end, and ⅛in. at the other, and the next thing is to fit them with ends; these should be of ¾in. pine, and 5½in. long: then if the side pieces with the grooves are tongued into them, we have an oblong frame 32½in. long, 4½in. wide, 1⅜in. deep at one end, and ⅛in. at the other, all inside measurements. The depth is not exact, because the saw has taken a bit of the 1½in., but no matter. One end piece will be 1⅜in. deep, the other ⅛in. Now take some stuff just thick enough, when planed up, to fit into the grooves, and cut it up into lengths of bare 4¾in., the width, or depth, decreasing as you go from the thick to the thin end of the frame. As you are a workman all those little channels (rabbets) you cut are perfectly square one with another, and you now glue in the pieces of thin stuff so as to make a channel-frame, having 61 divisions. For the lowest bass-note, 8ft. C, you require the channel to be the full 4½in. long; but as you proceed towards the treble the length must shorten gradually. So you put in little blocks of wood with glue, and you put them in so that there will be no difficulty in planing the thing on both sides to as perfect a level as your skill will enable you to do. The lengths will be as follows:—Bottom C (i.e. first channel) 4½in., 2nd C (i.e. 13th channel) 4in., 3rd C, 3½in., 4th C, 2½in., 5th C, 1¼in., and 6th C, ⅝in. These lengths will indicate the line of the blocks, which need not commence till about the 9th channel from the bass or deep end. You will understand that the square side of the channel-frame is the pallet-side, and you will consequently arrange your blocks so that the pallet-holes will be on the further side from you as you hold the frame in proper position—consequently, the blocks are to be put in by commencing at the nearest end of the channel. Having blocked off the channels to your satisfaction, procure some beech ⅛in. thick when planed, or if you can't get that, use sycamore, and cut out two pieces 34in. long by 5½in. wide. Invert the channel-frame on one of these, and keeping all edges flush (pin the pieces), mark the width of the channels and the end close up against the side-pieces. That's for the pallet veneer. Fair in the centre of the marks, and just within the mark that indicates the end of the channel, cut the pallet-holes 1⅛in. long at bass-end, and 9-16in. at treble-end—bare quarter wide at bass, and bare 3-16in. at treble. The frame is then reversed on to the other or reed veneer, and the widths again marked just inside the blocks. The reed apertures must then be cut so that the tongue of the reed shall play as closely as possible to the block—the bass-end being 1½in. long, and the top C ⅝in.—the width being full-quarter at bass and bare at treble—but, *sub rosâ*, it won't matter if you make all the same width; however, if broad-reeds are to be used, give plenty of room. The two veneers being ready, plane up the square side (pallet) of the channel-frame; get the glue ready; a couple of pieces of thick wood, one of which you should make as hot as you can; glue veneer all over, and with the pin holes as guides put in place; clap on the hot piece of wood, the other underneath, and put on the cramps; then dry. Serve the other side ditto (but plane the treble end down until you nearly touch the veneer), and the pan is complete so far. To make it suitable for an instrument, you mount it in a frame of ¾ stuff 2½in. deep. The only reason for using beech as veneer is because the reed screws hold better. Possibly, however, you would prefer to cut a pan out of solid beech; if so, make channels with drills to the dimensions above given, and put on a pallet veneer to cover them. To make a two-row you clap a 16ft. scale pan alongside, the two pallet-holes being brought close together, and when you draw that out on a piece of paper you will see that by shifting the dead space where the blocking cuts off the channels there is room for more than a half-row of reeds extra in the treble part of the instrument; but you will then have three pallet holes to cover. The scale for 16ft. may be ⅛in. longer than that of the 8ft. in all octaves, but the channels must also be deeper, say 1 3-8in. at the bass end, and ½in. at top end, whereas in the 8ft. the depth at top C is practically nothing more than the thickness of the two veneers. I have given you a scale which answers well, but if you will keep the proportions in view, you may alter it to the extent of ⅛in. in length either way, and goodness knows how much in depth, bearing this in mind that, other things being equal, the shallower the pan the reedier the reeds; and the deeper, the rounder the tone, and also the sluggisher the speech. If the querist or anybody else wants to know more, or to have something explained, if he will indicate the difficulty in these columns I will endeavour to help him over—especially if he will put his difficulties in clear and unmistakable language. Sketches are, I think, unnecessary, for they would occupy space, and as any one who intends making will of course draw the parts to the measurements given, those interested will be able to make their own sketches.—S. MAYER.

[47319.]—**Ordnance Datum.**—The Ordnance Datum is the approximate mean water level at Liverpool, and is the Datum line from which all levels on the maps issued by the Ordnance Office are calculated; this has nothing whatever to do with the level of water in water-bearing strata, which varies within the widest limit, according to the nature of the various geological formations of any particular district—DITTON.

[47319.]—**Ordnance Datum.**—The datum for Great Britain is the level of mean tide at Liverpool, as determined by the Royal Engineers of the Ordnance Department, and from this all levels throughout the survey are measured. On many of the Ordnance maps the elevations of salient points are marked; but the "sea level" of any broad arrow bench-mark can be ascertained by proper application to headquarters at Southampton.—ANTARES.

[47324.]—**Sketching Stool.**—The legs of the stool are joined at their middle points with a triangular bolt; the section of each leg being the sector of a circle, angle 120°, with the inside corner sufficiently rounded off to allow of the stool opening.—GAMMA.

[47324.]—**Sketching Stool.**—The legs are held by a three-armed iron joint. As all the legs move at once they make room for each other, but unless they are left rather slack on their respective pins they will have to be notched near the middle to allow them to open sufficiently. It is not a very strong kind of stool, but if a piece of brass curved to fit is screwed on each leg at the joint and with the iron pin of the joint coming through it in the middle, it will strengthen it considerably. If the bottom ends of the legs are fastened with string at a little less than the right width when open it will add to its strength.—E. F. C.

[47325.]—**Street Medical Coil.**—To MR. LANCASTER.—I shall be very pleased to give you the information. Let me know whether you want to make only the coil, or the coil rotator, bells, &c., usually on the base board in street coils; also let me know whether you want to make the battery as well, and I will give you all the necessary instruction.—W. J. LANCASTER.

[47326.]—**Traction-Engine.**—First, see that the bearings from the crosshead to the crank, also the two bearings of the shaft, do not shake, because that will often cause a noise at both ends of the stroke apparently proceeding from the cylinder. Should this not be the case, the fault lies with the slide-valve. First take off valve-box cover, and put reversing-lever over to one end of stroke; then try round for lead, which should, in an ordinary-sized engine, be 1-16in.; try both ends of stroke with each end of reversing-quadrant. Should the lead be right, there may be too much outside lap, which you can try by marking a wooden slip by the ports on cylinder slide-face, and comparing them with slide-valve edges, for, probably, there is too little inside lap. Allowing for no cushioning at end of stroke, this does not so much matter for engines running at an ordinary speed if there is sufficient lead. The remedy for insufficient lead is to advance both eccentrics until the required amount is given at one end of the stroke; then try round and equalise. If too much outside lap, file off until the required lead and cut-off is obtained. If too little inside lap, pin a brass or iron slip upon the inner edges of valve, and file off until sufficient cushioning is obtained.—FRED. WALKER.

[47329.]—**Boat-Building.**—I am afraid £20 would go a very little way indeed towards carrying out "A Would-be Jack Salt's" ideas in fitting out such a boat with the conveniences required for living on board. Six times that amount (at a moderate estimate) would hardly cover it, and this without allowing for rigging and canvas, both very expensive items. As to steam power, even if you could spare the room, a 4-horse engine would be of no use. "A Would-be Jack Salt" does not say if he has had any practical experience in the art of sailing. If he has not, he may take my word for it that he will find himself in a very dangerous position if he relies upon himself to navigate a boat (however small) at sea. Why not go to some seaport town with a good tidal harbour well sheltered from wind and wave (there are plenty such on the South Coast), where you can live cheaply and get a boat suitable for your purpose for a very moderate sum? I shall be happy to send any further hints which may be useful.—ARIEL.

[47335.]—**Packing.**—I have tried the packing you mention, and, indeed, nearly every kind of self-lubricating packing extant, for piston-rods and slide-rods, and find that, although they do not cut the rods, it conduces to the life of the packing to oil the rods while in motion occasionally. I have also remarked that in cases where water has dropped upon the rods while working, they have remained bright and surfaced for many years, irrespective of packing—old hemp and patent wove being tried with equal success.—F. WALKER.

[47337.]—**G.E.R. Loco.**—Eight-wheel tank engines on G E.R., built about 1866, were of following dimensions:—Cylinders, 15in. diam., 22in. stroke; leading and trailing-wheels, 3ft. 7in.; coupled-wheels, 5ft. 9in.; boiler barrel, 3ft. 11in. diam., and 13ft. 6in. long; tubes 143 in number, 1⅞in. diam., and 13ft. 9¼in. long; heating surface, 977 5 sq. ft.; Firebox, 64·6 sq. ft.; total heating surface, 1,042·1 sq. ft.; weight, 38 tons; ditto on coupled-wheels, 21 tons; working pressure, 130lb. per sq. inch. Is not L.B. and S.C. "Beaconsfield" same as "Richmond," "Hartington," "Devonshire," &c., with leading and driving-wheels, 6ft. 6in. diam., and trailing-wheels 4ft. 6in., cylinders 17¼in. by 26in.? "Caen," "Genoa," and "Naples" seem to be similar build, with the difference that the wheels are not so large—only about 5ft. 6in.—CARSTAIRS, London, S.E.

[47338.]—**Leclanche Battery.**—You have four of Grenet's cells; however, no doubt they will require a thorough clean; take them to pieces, clean out all the small particles and dust out of bags, then put in again with a few extra pieces of manganese; get new zinc rods. You should use porous cells if the canvas bags are too much worn.—W. J. LANCASTER.

[47348.]—**Bending Copper Tubes.**—Has "Salop" tried filling his tubes with melted lead or rosin where he wants to bend them. Of course he must wait till the lead or rosin is cold.—G. I. C. E.

[47348.]—**Bending Copper Pipes.**—Fill the pipe with lead, and you will bend it without a buckle; fill it with rosin, and you will do the same when you have acquired a little skill. The rosin is more easily melted out.—T. P.

[47348.]—**Bending Copper Tubes.**—The method we adopt, and I think it is almost universally adopted, is to fill the tubes with solder, then turn a groove in a chuck, same radius as required bend; then bend tube round this, and melt out the solder. You can make a perfect bend in this way.—W. J. LANCASTER.

[47348.]—**Bending Copper Tubes.**—"Salop" cannot bend copper tube (unless stout), without ribbing inside. With a sharp radius it is best to fill with lead or rosin. If he has to make a coil similar in shape to a hairspring of watch, he had best use rosin, being easier to employ. I have been making one last week of one-inch copper tube, ten ounces per foot, and was obliged to hammer out ribs with round-face hammer when charged.—T. W. G.

[47349.]—**Dry-Plate Queries.**—(*a*) If the object of the querist is to be able to compound a developer which will answer under all circumstances, I am afraid he will be disappointed, as the character of an emulsion and the quality of the plates prepared with it depend upon many conditions. As a rule, a slow plate requires a stronger developer, with more ammonia than a quick one; but a good deal depends upon the exposure. If that were relatively increased, it is quite possible that a weak developer, such as would be right for a quick plate, would answer equally well for the slow. (*b*) Potassic oxalate is required in excess in order to dissolve and keep in solution the ferrous oxalate, which would otherwise be precipitated as a fine yellow powder on the surface of the plate. The principal effect of dilution is to render the development slower.—W. ROBINSON, JUNR.

[47351.]—**Mathematical.**—The following solution is extracted from Todhunter's "Key to Algebra," p. 124:—"These results are easily established by induction. For simplicity, it is well to take a particular value of r; it would be found that the reasoning would apply to any other value of r. We may show, then, by actual multiplication that the laws which are stated hold when $n = 2$, or when $n = 3$. Assume that they hold for any assigned value of n. Let $r = 3$, and suppose that $(1 + x + x^2 + x^3)^n = a_0 + a_1x + a_2x^2$

$$+ \ldots\ldots a_{3r-1}x^{3r-1} + a_{3r}x^{3r}.$$

Multiply both sides by $1 + x + x^2 + x^3$; then $(1 + x + x^2 + x^3)^{n+1} = a_0 + (a_1 + a_0)x + (a_2 + a_1 + a_0)x^2 + (a_3 + a_2 + a_1 + a_0)x^3 + (a_4 + a_3 + a_2 + a_1)x^4 + \ldots\ldots$ Then we see that the coefficient of x^4 is greater than that of x^3, if a_4 is greater than a_0; and this is the case by supposition, and so on."—J. H. M. JACOBY.

[47351.]—**Mathematical.**—Write the explanation as follows:—$(1 - x^{r+1})^n (1 - x)^{-n}$. Put in the first factor, $x^{r+1} = y$. Now we may disregard the latter factor, as every term in the first must be multiplied by every term in the latter. We have only to consider $(1 - y)^n$. In Todhunter, Art. 508, the first part is proved. By Art. 510 the greatest coefficient is $\frac{\underline{|n}}{\left\{\underline{|\frac{n}{2}}\right\}^2}$ or

$$\frac{\underline{|n}}{\underline{|\frac{n-1}{2}}\;\underline{|\frac{n+1}{2}}}$$ according as n is even or odd.

By the formula the coefficient middle term, or of two middle terms, according as n is even or odd, are $\frac{\underline{|n}}{\left\{\underline{|\frac{n}{2}}\right\}^r}$ or $\frac{\underline{|n}}{\underline{|\frac{n-1}{2}}\;\underline{|\frac{n+1}{2}}}$ hence is seen the second part. Obviously, by the binomial theorem, the third part holds. I must request "A. B." to carefully consider the remarks in the beginning. Does he consider them legal?—AN ENGINEER'S SON.

[47353.] — **Gelatine Plates.** — Use a little greater excess of soluble bromide, and do not cook the emulsion quite so much.—W. ROBINSON, JUN.

[47353.]—**Gelatine Plates.**—I believe that damp, after the plates are dried, will cause green fog. I think the gelatine has a lot to do with it as well, as the first lot of emulsion I made had green fog so bad that I could not use it, and thinking it might be bad gelatine I got some of Nelson's No.1, and have had no trouble since with either fog or frilling. I use about half a grain of chrome alum in five or six ounces of emulsion, which may have something to do with absence of frilling. I think making the emulsion is the easiest part of the process, coating the plates being my greatest difficulty.—E. F. C.

[47354.]—**Green Stains for Deal and Other Woods.**—Any respectable chemist could supply you with what you require. Verdigris and water is quite unsuitable, and does not constitute a stain. There is too much pigment in it.—G. FRYER.

[47355.]—**Excessive Perspiration.**—I should advise "Sudor" to try the following: Put 10 drops of dilute phosphoric acid in half a tumblerful of water, and take one dessert-spoonful every 4 hours. If not better in a month, I shall be happy to make further inquiries into his case.—DOCTOR.

[47357.]— **Malleable Castings.** — Put 2oz. fluoric acid, 1oz. nitric acid, and 1oz. of saltpetre to 10lb. of metal. When the metal is melted, add the solution. It can be made in a brass furnace. When you have cast off patterns, the castings want keeping at a red-heat for three or four days in iron boxes in a furnace.—T. S. H.

[47358.]—**Shocking Coil.**—Let the core be ¾in. diameter, then well insulate it, and use for primary 6oz. of No. 18—this will give you two layers; then well insulate, and put on as secondary ½lb. No. 30, this will give as much current as any ordinary person will care to take. The secondary will give you about 10 layers, and of course you must insulate each of the layers from the others.—W. J. LANCASTER.

[47361.]—**Watch - Construction.**—When a watch loses time, the balance-spring requires taking up or shortening. Unpin the spring at the outer coil, and remove the balance from the watch. Then, with a pointed tool, turn the brass collet, to which the spring is attached, in the required direction, and replace in watch, taking care to set the spring so that the watch is in beat. The spring must be set flat, and perfectly free throughout its length, except, of course, where it passes the curb-pins in regulator. Between these it should have just perceptible freedom. I would warn Mr. Fryer that this is a rather delicate operation for anyone with such a limited acquaintance with watchwork as his queries would indicate he possesses.—J. E. FLOYD.

[47361.]—**Watch Construction.**—To make the watch go faster, you must "take up" the hairspring if it is not a lever watch. You must first make the wheels secure, then remove the cock-plate, or bar; next prise out the little pin which holds the hairspring; turn the balance round until the hairspring is free; then remove the balance; next put the point of a small drill, or something similar, into the opening of the brass collet which holds the inner coil of the hairspring, and prise open the collet. Now you will be able to turn the collet the same way as the outside end of the hairspring is pointing. If you want it to go slower, you turn the reverse; now replace balance and put watch in beat. If you had stated what kind of watch you have, it would have been much easier to answer the query.—A FELLOW-WORKMAN.

[47361-2.]—**Watch Construction.—Watch-Dials.**—If your watch loses time, you must take up the spring a little by unpinning it at the cock-stud, and drawing it through; a very little may suffice. This has the effect of shortening the action of the spring, and so making the watch to go faster. The reverse alteration makes it go slower. If the spring plays freely between the regulating-pin and curb, you may make the watch gain several minutes a day by simply bending the hairspring nearer the pin of the regulator, thus lessening the "play." If you take the spring up you will have to reset the watch on beat. This is done by easing the collet round until the hairspring-stud rests exactly over a small drill-mark upon the cylinder-wheel. If it is a Geneve watch that you are altering, it can invariably be got on beat correctly in this way. Occasionally, when a new cylinder has been put, the position of the drill-mark is altered, so it would not in every case be a correct guide to a correct beat. In, I may say, 90 cases out of a 100, you would be right in doing so. If the watch is a verge follow the instructions given in a recent letter of mine. Enamelled watch-dials are fixed in a variety of ways. In most English watches, the dials have two or more feet soldered to them, and are pierced with small holes at their ends to receive pins, which are inserted after the dials have been placed on the plates or frames. Geneve dials are generally secured by "crescent" screws and slotted dial-feet, or drilled feet and pins, as in the English work. I do not speak of metal dials, which are attached differently in many cases. American dials are sometimes secured with pins like the English, and in many instances with screws, which are set on the edges of the plates, and are screwed up against the dial-feet. If you intend to replace the cream-coloured dial with a white one, send the present one as a pattern to the material dealer for the size and shape of the new one, at the same time sending the bottom or pillar-plate, or the frame, if fitted with one.—ALFOJOE.

[47362.]—**Watch - Dials.**—English dials are usually secured by pins passing through feet attached to the dial. The ends of these feet and the pins may easily be seen near the edge of the bottom or pillar-plate. To get a new dial, take the watch to pieces, and send pillar-plate, together with dial-rim, if there is one, to a dial maker, who will make one with feet, holes, &c., in proper position. It then only remains to drill pin-holes in feet, and enlarge holes in dial to free hands.—J. E. FLOYD.

[47362.]—**Watch-Dials.**—Remove the movements from the case; next the hands; you will find the dial pinned to the inside of the pillar-plate; remove these pins, and send the old dial to J. Stockall, 6 and 8, Clerkenwell-road, London, with 8d. in stamps, and instructions; when you get new dial, fit it in its place; mark the stumps, and drill little holes for pins, same as old dial.—A FELLOW WORKMAN.

[47363.]—**Watch Cylinder.**—File up a plug which will go two-thirds up the inside of the cylinder; now fit a rose on the end of the plug, so that about two-thirds of the plug protrudes beyond the rose; file this two-thirds down, to about half the size of the plug; now cut off the plug, put it into the cylinder, and file up your pivot. I shall give full instructions in a week or two, with drawings.—A FELLOW-WORKMAN.

[47364.] — **Silver Filagree Brooches.** — A simple and effective method to clean silver brooches is to wash them carefully with clean soap and water.—G. FRYER.

[47364-5.]—**Silver Filagree Brooches—Gold Coins.**—Should it prove, on examination, that the filagree work has not been soft-soldered in any way, you may impart to them a beautiful frosted appearance by thoroughly washing them in hot soda-water (weak), to remove dirt or grease, and then, after making almost a red heat by the flame of a spirit-lamp or gas, with a blowpipe, laying the articles in a solution of vitriol—water two parts, vitriol one. The water must be pure rain or distilled. Let the articles remain in the solution for a couple of hours or so, then swill in clear water and dry. Do not use any cleaning powders, leathers, or brushes. The articles should come out a pure dead white. Cyanide of potassium is equally efficacious for the work, but is rather more dangerous in its nature, if you unwittingly get it on your person. If you are going to solder good-quality wires to the coins, say 18 carat, you may use a little common gold in lieu of solder, say 9 carat. If you use 9-carat wires, you must have solder specially prepared to run at a low heat, and to be obtained of any material dealer. These remarks apply also to rings. The articles may be freed from discoloration by immersing them in diluted aquafortis, or even in the vitriol solution, swilling them in water afterwards. If iron wire is used for binding, all traces of it must be removed previously. 9-carat gold can seldom be got up to a good colour, owing to the base metal forming the alloy. Polishing by rouge, &c., is the only plan you can adopt. Re-colouring is seldom or never done to any lower quality of gold than 12 carat. 9-carat gold, when of a rich yellow colour, would be gilt only. It is not necessary to gild the rings after soldering, if you polish them up well, unless you wish for the rich effect of "parcel gilding," as the partly gilt, partly bright work is called.—ALFOJOE.

[47367.]—**Heating Apparatus for Greenhouses.**—There is a mistake in this query. Instead of 20ft. of 2in. pipes it should be 60ft. of 2in. pipes.—R. H.

[47371.]—**Photographic.**—For cause and cure of "oystershell" markings, see my reply to query 46574, p. 137. The free iodine liberated from iodide of lithium could probably be driven off by heat, or absorbed from solution by a strip of clean zinc; but, in either case, I do not think the result would be as satisfactory as using fresh iodide.—W. ROBINSON, JUN.

[47372.]—**Lens.**—Assuming that your lens is a biconvex, or its two radii are 1½in. by 1½in., then grind a concave 1½in. by 4in.; this will give you a lens, when the two 1½in. surfaces are cemented, of 5in. focus, within a very small amount. The crossed concave should be made out of flint.—W. J. LANCASTER.

[47373.]—**Removing Old Varnish.**—The best thing to use to remove old varnish from globes will depend on the nature of the varnish; but the two commonest solvents are turpentine and alcohol (methylated free from gum will do). Try the alcohol by wetting the surface of the globe and applying a piece of blotting-paper when the varnish appears to be attacked.—T. P.

[47375.] — **Lightning Conductors.** — Undoubtedly the arrangement given by W. Clark is dangerous: — the conductor should be taken straight down, and connected with earth, as given by "Derbyshire" in reply to 47264—page 409.—DITTON.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

Since our last "Ditton" has replied to 46635, 46741.

USEFUL AND SCIENTIFIC NOTES.

The Quickest Railway Run.—According to the *Engineer*, a Great Northern train, with an 8ft. single driver outside cylinder engine, which recently took the Duke of Edinburgh from Leeds to London on the Great Northern Railway, did the journey, 186¾ miles, in exactly three hours. One stop was made at Grantham. The actual speed, therefore, was over 62 miles per hour. This is, we fancy, the quickest run of the stated length on record.

THE largest sailing vessel afloat was launched last week from the shipbuilding yard of Messrs. Harland, Wolff, and Company, of Belfast. She is named the Walter H. Wilson, after one of the partners of the firm of builders, and is for Mr. Samuel Lawther, J.P., Belfast. Her measurement is 300ft. by 42½ft., by 25ft. She will be classed 100 A 1 at Lloyd's. She is built of iron, has four masts, three of which are square rigged, and is capable of carrying 4,000 tons dead weight.

QUERIES.

[47376.]—**Bone Calcination.**—Will some reader of "ours" favour me with a few hints on the calcination of bones? A description of furnace and title of a good book on the subject will be very acceptable.—BONE.

[47377.]—**Casting Small Articles in White Metal.**—Will some correspondent inform me how best to succeed in casting small articles in white or Britannia metal, such as valves for dry gasmeters, valves and valve-boxes of wet meters, and various other non-corrosive fittings?—METAL.

[47378.]—**Legal.**—To MR. WETHERFIELD.—I am saddled with a wife who constantly gets drunk, assaults me, and damages my furniture. Will you say what I can do? I am a professional man, and do not want an exposure.—M. B.

[47379.]—**Model.**—Would some fellow-reader give the exact proportions of port-ways, crank-shaft, working-gear, &c., for a cylinder 1in. bore and 2in. stroke?—MECHANIC.

[47380.]—**Clark's Process for Softening Water.**—To "NUN DOR."—Kindly give particulars of the above (referred to in your reply to 46929, p. 381), especially as to quantity of lime required, say, per gallon of water?—H. J. NOLAN, 3, Clifton Villas, W.

[47381.]—**Wildbad and Its Cures.**—Perhaps Dr. Royston Pigott would supplement his interesting account of the above spa. Kindly give invalids some information as to the best, or rather easiest way to travel to the Black Forest, and what the probable expense of the journey, and a sojourn there for a month would be for persons of but moderate means?—H. J. NOLAN, 3, Clifton Villas, N.

[47382.]—**Engine Query.**—Will some of "ours" say what lead the valves of a pair of condensing engines should have of the following descriptions?—Diam. of cyls. 20in., length of stroke 4ft., and running at 33 revs. per min., boiler-pressure 75lb. Also, say what part of stroke steam should be cut off at? I should mention that the load, or one-half of load, is knocked off every five minutes.—YOUNG BEGINNER.

[47383.]—**Hardening.**—Will some of our practical turners or forgers kindly give a proper method of hardening a carriage-axle? I have tried, but failed. I put one handful of charred bones and one handful of charred leather in a piece of 3in. hot-water pipe, and put in the axle, and sealed up both ends with clay, and heated 2½ hours in a smith's fire, then knocked box off and immersed in salt water, but it did not harden a bit; so I hardened with prussiate of potash, which makes a cankered mess of it after being got up smooth in lathe. A practical amateur will greatly oblige a—NOVICE.

[47384.]—**Coil.**—To MR. FRED. WALKER.—I have made a medical coil, the same as you described in the "E. M." on June 9th, 1882, only I have made mine ¾lb. of wire, and the shock is weak. Also the contact-breaker works but very little. I think that there is something wrong in the contact-breaker that prevents me from getting a better shock. I have a Bunsen battery and a wire core. If you will kindly assist me I shall be obliged.—G. TOPS.

[47385.]—**Spectacles.**—To MR. LANCASTER OR OTHER OPTICIAN.—I am near-sighted—the furthest distance for reading ordinary print being about 6in. I find this a great impediment in music, and the best spectacles I seem able to get do not make me see like other people. What I want to know is, if it is possible to buy, or have made, glasses that would enable me to read music comfortably at 2 or 3ft. from a music-stand, and which would not have any tendency to injure the sight?—KURZSICHT.

[47386.]—**Riveting Ship's Kelsons.**—I should be much obliged for a sketch of the best riveting machine for riveting ship's kelsons. There is 3in. by 3in. between flange of frame and kelson lug. What kind of a jaw would be required to get on the rivet between frame and kelson? Any hints on shipyard rieveting machines and what they are qualified to do, and how to fix them for different jobs, will be very thankfully received. I think deck stringers might be done with them.—A. RUTT.

[47387.]—**To "Aldebaran."**—I have bought a second-hand telescope, 3½in. in diam., and fear I have been taken in. Shows small stars very distinctly, but they seem to have rays or wings, whereas I am told that in a good telescope they ought to show a small disc. It answers very well for sunspots, and shows the lunar mountains very clearly. I have not tried it on the planets. I have taken out the o.g., and notice that the glasses are not cemented together. Should they be? and if so, which would be the best way to set about it.—GEORGE TOWNSON.

[47388.]—**Cold-Water Soap.**—There is now extensively sold a yellowish hard soap, with the words "Cold water soap," and "Sinclair, London," stamped on each of the bars. As it has a rather peculiar appearance, I should like to know more about it. Could Mr. Allen indicate the composition of that soap?—A TEN YEARS' SUBSCRIBER.

[47389.]—**Engine and Carriage-spring Furnace.**—Can any of your reader inform me what is the best form for economy of an engine and carriage-spring furnace? My longest spring is 5ft. long. Is there any economy gained by the arrangement of bringing the smoke over furnace-hearth before getting away to chimney? I saw one worked some time ago by wind from blast fanner, but with what results I cannot say. Please describe construction of furnace, with sizes, and also height of chimney.—HOMBRE.

[47390.]—**Foundry.**—Could "Foundry," "Cast-Iron," or some other of your correspondents, give me some particulars as to how the mixtures of cast-iron and steel are made? And if cupola is of the same construction as is used for ordinary iron-founding? I, myself, have made a trial of mixing cast-iron and steel in an open cupola, but sorry to say, got nothing out better than common iron after all my trouble in getting the different classes of iron and weighing of the old steel rails, &c., &c. What I want to get at is a chilled wheel for a narrow gauge railway that could be depended on without breaking, as the common cast-iron ones generally do. The Americans put very good wheels, and all chilled, under their railway plant.—HOMBRE.

[47391.]—**Portable Lounge Chair.**—Would some reader kindly give dimensions, with sketch, of one of those hammock or lounge-chairs, something on the plan of the Yankee hammock-chair, or one like those used on board of the Trans-Atlantic steamers, the frame to be of oak, and to fold up when not in use?—AN AMATEUR M.

[47392.]—**Perfumed Pastilles.**—Would some reader tell me how to make them?—AN AMATEUR M.

[47393.]—**Cocoanut Oil.**—We have a large cocoanut plantation in Singapore. The price of oil at present being very low, it hardly pays us to make it. Can anyone suggest some profitable manufacture from the oil, so as to make it pay? Our oil is very clear and sweet, as it is not pressed.—SINGAPORE.

[47394.]—**Combustion of Coal.**—Having followed the replies to the queries on the "Combustion of Coal" with considerable interest, I shall feel extremely obliged if Mr. Kanthack would tell me how to calculate (as simple as possible) the weight of air required for complete combustion into cubic feet.—IGNORANT.

[47395.]—**Large Tank.**—I have just taken down a tank 15ft. long, 5ft. wide, 4ft deep, flanged, and put together with bolts and nuts. I find the joints were made with iron borings, each joint being about ½in. apart. Will some of "ours" kindly tell me the proper way to put the same together—whether I am to put all the bolts in, and then make the joints, or how, and how much sulphur and sal-ammoniac to one lot of borings?—J. T. H.

[47396.]—**Simple Rotary Engine.**—Will some kind reader kindly tell me the best form of the above for steam at, say, 30lb. of steam, to drive a 3in. Britannia lathe at the ordinary speed for wood-turning: this to be made by myself, so ease of making is one object in view? Please to give all particulars available, with dimensioned sketch, and oblige—ROTHER.

[47397.]—**Engraving Machine.**—I read description of engraving machine with considerable interest, but failed to understand how the drill was moved backwards and forwards, so as to form the letters or figures. Would it be asking too much of you to explain more fully the movements of machine in question to me? I could only see that the drill has the usual rotary motion; but how it is made to follow the lines of any design, I fail to see either from the woodcuts or description. This is a thing that would interest great numbers of our readers I should imagine. I thought engraving could not be touched by machinery; but I find I am mistaken. Your correspondent, N. S. Heinecken, speaks of the "elaborate and effective engraving machines of various makers being known to your readers" I should be very glad to see an account in the columns of "E. M." of these machines.—SCRATCHER.

[47398.]—**Lewis' Incandescent Gas-lamp.**—To "SIGMA."—Will you kindly say whether this lamp can compare in economy with the gas-burner at present in use, say Sugg's or Silber's, using the gas now supplied?—PAUGUL.

[47399.]—**Condensing Exhaust Steam.**—What is the most efficient method, consistent with economy, of condensing the exhaust steam of 12-i.h.p. engine, so as to reduce back-pressure, water to be afterwards injected into boiler? Kindly state cooling surface of condenser, and quantity of water per hour required. Would a circulation of water through condenser and double pipes to an open tank on roof be sufficient, and what should be the size of roof-tank? Water is very expensive.—P.

[47400.]—**Electric Light for Workshop.**—Will some correspondent kindly say which would be the best system to employ for lighting workshops where 200ft. of gas per hour are now burnt in common burners, and approximate power necessary for same? At least, six lamps would be required. Kindly give a hint of the cost of apparatus, and of the comparative economy in working the gas and electricity, neglecting the power.—P.

[47401.]—**Coil.**—To T. N. ANDREWS, Plymouth.—In your description of coil in the MECHANIC, March 10th, 1882, p. 15, you say nothing about the ends of the paper tube being fixed into the reel ends, and you also seem to have put the paper tube between the primary and secondary wire instead of being round the wire bundle and inside of the primary, as surely it ought to be. More information will oblige.—W. R. C.

[47402.]—**Summer-House.**—Will any of our subscribers help me? I wish to make a summerhouse 7ft. wide and about the usual height. What size and quantity of materials shall I require, as I wish to buy all at once? The shape I wish is hexagonal, with cone roof.—SECONDS.

[47403.]—**Lawn Tennis Court.**—I wish to make a lawn tennis court (not turf), in as effective and cheap a manner as possible. Can you tell me the best way to proceed—asphalte, cement, cinders, or what? The ground at present is ordinary garden ground.—G. T. S. GILL.

[47404.]—**Railway-Carriage Lamps.**—Can any reader interested in carriage lighting tell me how it is that there are so many lamps on our line all with about 1lb. of oil run over into bottom of glass globes? There is certainly a fault somewhere. Is it in the construction of lamps, or in trimming of same?—HOMBRE.

[47405.]—**Locomotive.**—Will some fellow-reader kindly help me out of the following difficulty?—In taking out a copper firebox to put in a new tube-plate, I find in the outside casing plates all round about the taper holes where the copper stays pass through, more than half the thickness of plate eaten away: all the rest of plate in good condition. Is there a galvanic action formed between the iron plates and the copper stays, or is it bad copper with too much arsenic? Having discussed the matter over with several parties, but all seem to have different opinions. I should like to hear the opinion of some of our readers. What is the opinion of W. J. Lancaster?—HOMBRE.

[47406.]—**Dew-caps.**—Can any of your readers kindly inform me of an easy and effectual method of constructing for oneself a dew-cap for a 3in. refracting telescope?—TYRO.

[47407.]—**Concave Lenses.**—Will Mr. Lancaster, or some other gentleman, kindly instruct me how to cut and finish the grooves on the edge of oval concave-lenses for spectacles with the invisible frames?—C. R. D.

[47408.]—**Fish Glue.**—Is glue manufactured from fish-skins—not bladders—anywhere in Europe?—where? And can the process be given in a general way?—AMERICA.

[47409.]—**Circular Bead-cutter.**—I have large quantities of small round beads to make, exactly same size as an ordinary lead pencil. I use thousands of feet of this beading, but should like to know if it is possible to cut them with a revolving cutter at once running through. My idea was to fix a cutter in some manner to a short revolving hollow shaft, pass a piece of square yellow pine just cut from the circular saw through a square aperture to keep it from turning round with motion of cutter, then through hollow shaft containing cutter, and come out finished at the opposite side. It would require to be quite smooth, even if two cutters had to be used. It would be driven from a gas-engine, with small pulley on the hollow shaft. What number of revolutions ought the cutter to have per minute to work efficiently? It would be required to cut any lengths, from 2ft. to 20ft.—BEAD.

[47410.]—**Dry-Plate Intensifier.**—What is the chemical reaction on the addition of a haloid salt, such as ammonium chloride or bromide, or potassium bromide or iodide, to mercuric chloride solution? Some photographers recommend a solution of mercuric chloride alone. Does the addition of one of the above-mentioned salts increase or modify the action of the mercury? If so, in what way? Have any of your readers tried copper bromide, followed by silver nitrate, as a dry-plate intensifier? I have, with good effect. It is recommended by Abney for wet plates, but I have never read of its being used with dry plates.—W. H. S. W.

[47411.]—**Throwing the Hammer.**—In the exercise of throwing the hammer I have broken half a dozen shafts. Hammer is sixteen pounds weight, shaft 4ft. long, regulation length. Is there any mode of seasoning the handles? The break occurs from just at the ball to about a foot from it, and takes place when the hammer lands on the ground. My shafts have been pretty thick, and of ash and hickory. Perhaps some one of your correspondents could help me out of my difficulty?—SCOTTICE.

[47412.]—**Coulomb's Law of Electro-Statics.**—At line 5, on p. 191, of Prof. Thompson's "Elementary Lessons on Electricity," the force exerted between two charges of electricity is said to be inversely proportional to the distance between them. But the formula given lower down in the same page makes the proportion inversely as the square of the distance. Which is correct?—H. E. A.

[47413.]—**Marble.**—A month ago I brought home a Carrara marble figure from Pisa. I now find that spots or blotches of a very pale buff colour are appearing all over it. I am told that this is a common fault with white marble. I have tried plastering on a coat of thin stucco, leaving 24 hours and then washing off; but this does not seem to be effectual. Can any correspondent give advice, or help me to the best method of cure?—VULCANITE.

[47414.]—**Substitute for Leather Disc.**—I have a small machine in which I use a metal disc to turn a leather disc instead of a pair of bevel-wheels: but I find that the leather wears very soon. Could any reader inform me of a paste or composition with which to coat the leather so as to protect it?—A DOWN MECHANIC.

[47415.]—**Organ Stops.**—Will Mr. Dresser or other of our organ correspondents kindly give me a few hints how to voice the pipes of a clarabella stop? Several pipes I have tried have always a chiffing, and in others a quivering whenever they speak. How can this be overcome? I should also like to know if the inside of the cap ought to be hollowed as in Fig. 25, No. 8 of Mr. Dresser's articles, or like Fig. 22? Also, the nicking: ought it to be straight, or should it run obliquely across the block? I may say that the pressure is 2in., and the pipes are cut 2-7, and the lips left thin. Any information will oblige.—L. G.

[47416.]—**Aluminium—Mellogen.**—I thank Mr. E. Sellon and will communicate with him. I am obliged to Mr. Alfred H. Allen for his wish to disabuse my mind: but had he carefully read my communications, he would have learnt that it was no "hopeful method," but a thing actually accomplished. As he is so interested in aluminium, he may extend his interest to other like apparently difficultly reducible metals, and will be pleased to hear that I find no difficulty in reducing magnesium and other metals by a process of my own, and without the aid of sodium. Thanks for the answer to my query "Mellogen." I really wished for the chemical formula of action. Given C and H_2O, how does the electric current produce $C_{11}H_2O_4$? I have a theory, but at present only a theory, and I should be glad to learn from one who knows.—ZELIA NAIEN.

[47417.]—**Varnishes.**—1. What is the best work on the making and properties of the various painter's and coachmaker's varnishes, and who are the publishers? 2. Does copal gum possess any special properties for making varnishes not to be found in other gums, and what are they? 3. What is "prepared painters' copal"?—T. MACKENZIE.

[47418.]—**Refrigerator.**—Would it be possible to construct one on the compressed-air principle, of moderate cost, and to be worked by hand, so as to be available for domestic use?—ARIEL.

[47419.]—**Riveting China, &c.**—Can any reader of the "E. M." inform me as to the process in riveting broken china, &c., or if there is any published work giving such information?—JOBBER.

[47420.]—**Steinheil's Eyepieces (page 397, "E. M."**—How are they constructed? Will some correspondent kindly give diagram?—ZETA.

[47421.]—**Transparent Gum.**—Can any of "ours" tell me how to increase the transparency of dissolved gum? I have had the best gum-Arabic, which, although white, is not transparent, and when dissolved has a slightly starchy appearance. Can it not be made in its liquid state to appear almost as transparent as pure water?—SOLUTION.

[47422.]—**Stamping Notepaper.**—Having some notepaper to stamp with in white colour, I find the colour I use (flake white and stamping varnish) turns a grey colour. Would any of your numerous correspondents kindly inform me if there is any other varnish or compound to be used with a steel die that would keep the colour pure white?—ONE IN A FIX.

[47423.]—**Diabetes.**—Will Dr. Edmunds kindly give a simple test for sugar in urine? A friend of mine who has lost two children through this disease (although attended by good doctors) wishes to keep a check on it, and to know of its presence before it is so far gone. Is there any diet to be recommended to anyone who is supposed to be diabetic, and what would be the best thing to do if sugar were detected by the test? Local doctors seem to know very little about this disease.—E. F. C.

[47424.]—**Crystallising Vessels for Epsom and Glauber's Salts.**—Can any of your readers practically acquainted with making the above salts say what is the best kind of vessel for cooling and crystallising them? I am much troubled with some iron ones, each time emptying of the salts, those lying close to the iron bring away a dirty brown discolouration, causing much loss, having to be separated from the rest and worked over again. What could I coat the pans with to remedy this? Ordinary paint seems to have no effect.—ANXIOUS.

[47425.]—**Electrical Measurement.**—Would someone give me information respecting the following?—Equal deflections on the same galvanometer always equal the same "current." Does the same deflection on the same galvanometer always equal the same "electromotive force," and the same with "resistance"?—STUDENT.

[47426.]—**Reynard Incandescent Light.**—I have endeavoured to obtain this light by following the directions given in *Nature* of June 1st: with petroleum I obtained no light at all; with benzoline I get a blue flame, but fail after repeated attempts to make the platinum gauze incandescent. No doubt there are many readers of the "E. M." who have tried the light. Will some of them suggest any cause for my failure?—S.

[47427.]—**Calculating Strains in Boiler.**—Will "M.I.C.E." tell me why the following sum should be multiplied by 2?—A boiler 6ft. diam., 50lb. pressure and ⅜in. plates. First, 6 × 50 × 3 ÷ 8 = 112·5 for strain on circumferential seams; secondly, 6 × 50 × 3 × 2 ÷ 8 = 225 for strain on longitudinal seams. Why multiply by 2 in second case? What is resisting strain of same? Will "M.I.C.E." also notice query 47291, p. 387?—JOHN.

[47428.]—**Etching.**—To "R. B."—I am much obliged to "R. B." for his answer to my former query, and for kindly offering further assistance, of which I now wish to take advantage. Not understanding anything about chemists' weights, &c., I find rather a difficulty in finding the right proportions for mordant. Will "R. B." tell me whether the following are right?—I have troy weights, decimal system; taking ·032151 troy oz. to = 1 gramme, then taking three figures of the decimal to be near enough, gives for the mordant, hydrochloric acid 3·215, chlorate of potash ·643, water 28·292, or for smaller quantity take one-eighth of each. Is there a simpler method than weighing for getting proportions? What proportion of beeswax to turps is best? Is Japan varnish the same as Japan black sold at 1s. per bottle? I purchased the "Handbook" and other necessary articles. They give every satisfaction, but the ground seems too thick with two coats for the point to get through easily. What is the advantage of smoking? This ground seems to be a different mixture, smelling of ether.—ROGATOR.

[47429.]—**Electro-gilding.**—In gold-plating brooches I never can get the plating to cover the solder. How can it be done?—A AMATURE.

[47430.]—**Instantaneous Photography.**—To MR. W. ROBINSON, JUN.—I am much obliged for your reply. I have since used some other plates, and the results are better, but not quite satisfactory. The centre of the picture is very good, but at the ends of the plate there is scarcely anything to be seen, and then in developing they become so very thin, and the hypo. clears it nearly all off the glass; in fact, if I left them in the fixing as long as the many books I have read recommend, there would be nothing but clear glass. With regard to the lens I use, there is only one stop, which is described as an f_8 stop.—TYRO.

[47431.]—**Speed.**—Would some one kindly work out the following:—Two trains approaching each other, one is 30 yards long, running at 50 miles per hour; the other is 36 yards long, running at 40 miles per hour. What time elapses from when the engines meet until the brake-vans are clear?—S. W. J.

[47432.]—**Locomotive Boiler.**—To "E. L. P.," OR OTHERS.—Shall be obliged to any reader for answer. I wish to know if coppersmiths understand the making of model boilers fitted with tubes, and having a proper-made firebox to burn coal or charcoal? Also, how is the starting valve made that turns steam on or off inside of boiler? Should the dome be placed over the joint of valve, and how is it possible to get at it to repair if the dome is riveted on to boiler? Should the supply-pipe in boiler be placed high up, so that it is clear of water? Would a boiler 19in. long by 5in. diam. supply steam to a pair of cylinders of 1¼in. long?—W. RICHARDS.

[47433.]—**Portland Cement Floors in India.**—In India the floors of houses are usually made of either brick and mortar concrete well rammed, and then plastered with lime plaster of a more or less fine quality, or else of brick set on edge in mortar and then plastered as above. It has lately been found a great improvement to lay on this a fine layer of about ¼in. thickness of Portland cement, as the cement sets much harder than the chunam (lime). My difficulty is, that the Portland cement almost invariably cracks all over the floor after being down for a short time, and in some instances separates from the floor beneath and shells off. Is this the fault of the cement, and is there any means of remedying this defect? The cement is usually mixed 1 to 1 of fine sharp sand, and the floor kept under water for sometimes a month to properly harden it.—A MELTING MECHANIC.

CHESS.

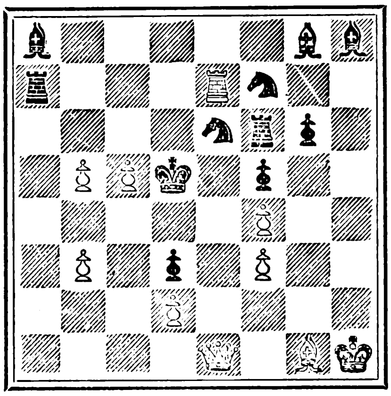
ALL Communications for this department must be addressed to the Chess Editor, at the office of the ENGLISH MECHANIC, 31, Tavistock-street, Covent-garden, W.C.

PROBLEM DCCLXIII.—By J. W. ABBOTT.

Black.



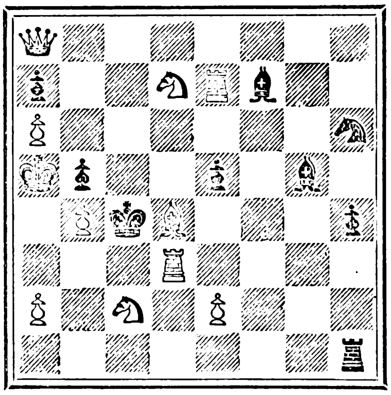
White.

White to play and mate in three moves.

PROBLEM DCCLXIV.—By C. A. GILBERG.

From *Brentano*.

Black.



White.

White to play and sui-mate in three moves.

SOLUTION TO 759.

White.	*Black.*
1. Q to Q R 7	1. Kt to K Kt 3
2. Q to K Kt sq	2. Anything
	(a) 1. Kt to K B 2 (b)
2. K takes Kt	2. Anything
3. Mates	
	(b) 1. Kt at K B 8 moves
2. Q to Q 4 (ch)	2. K takes Q
3. Mates	

SOLUTION TO 760.

White	*Black.*
1. R to K R 2	1. P takes P (a)
2. R to Q Kt 3 (ch)	2. P takes R
3. B to K B 2	3. P mates
	(a) 1. P moves
2. Q R to K Kt 2	2. P moves
3. B to K B 2	3. P mates

NOTICES TO CORRESPONDENTS.

IN problem 757 the Kt at K Kt 3 should be at K B 2, and a P should be placed at K Kt 4, in order to avoid a second solution.

SCHMUCKE.—You have hit 760, but have missed the point of 759; there is no mate if $1.\ \frac{\quad}{\text{Kt to K Kt 3}}$ $2.\ \frac{\text{Q to Q 4 (ch)}}{\text{K takes Q}}$ $3.\ \frac{\text{B to K B 6 (ch)}}{\text{Kt covers}}$.

"CHESS STRATEGY," BY S. LOYD.

AT last the long-looked for volume by Mr. S. Loyd has appeared, and we think that in interest and value it must far exceed any one's expectations, though no doubt they were high, owing to the great reputation of the author. In fact, it is not too much to say that no collection of problems hitherto published comes anything near the present one, and that because we not only have 500 of the writer's best compositions, but (what is perhaps of equal value) his own views on the various subjects in connection with the art. These views are not laid down in any precise or formal way, but in a delightful, gossiping style which makes the book as attractive as a good novel. The fault or weakness of previous collections (if we may except Klett's and Kohtz and Kocklehorn's) is that the problems have been published simply in order of moves, without note or comment: so that there was no connection between them, and nothing to interest except their own intrinsic merits; but here, if the author does not take us into his workshop, he does what is better: goes thoroughly into every point (to use his own words) "upon the defects as well as the beauties of the art, showing his way of composing and solving, how to get new ideas, and how to judge of their relative merits." Accordingly, we have pregnant remarks, with illustrations, on such subjects as "crowded positions," "economy of force," "end games," "key moves," "neatness," "old style problems," "problem solving," "surprise moves," "suggestive problems," "two movers," "problem building," "sacrifices." Thus, every page is interesting; and although we expect a good deal that the author lays down will be questioned (especially with regard to his definition of "problem" and his views about two movers), it is none the less valuable on that account. We intend shortly to give a few problems extracted from the work. Copies may be obtained from J. Watkinson, Esq., Fairfield, Huddersfield, at 12s. each, post free.

ANSWERS TO CORRESPONDENTS.

◆

⁂ *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6 Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

⁂ Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, July 12, and unacknowledged elsewhere:—

THURSO MECHANICS' INSTITUTE.—Starley Bros.—J. Hagger.—G. Hudson.—J. Francis.—F. A. Millar.—R. Murray.—A. M. Read.—J. Gillott, Jun.—W. F. Stanley.—G. Calver.—G. Plant and Son.—Cunliffe and Croom.—A. MacNab.—G. J. Hewson.—E. Bryce.—W. R. Hicks.—Etna.—W. B.—B. B.—W. M. Gardner.—C. J. Little.—Miner.—J. Smith.—W. R. H. R.—Rigel.—New Querist.—Spelter.—E. B. Fenessey.—Tourist.—A Mongeril.—E. M.—G. Tolman.—Deh.—H. B. C., Lambeth.

FIXUS LECTOR. (What sort of a book do you want? "Marine Engineering" applies to many branches. If the "Marine Steam Engine," see Sennett's work with that title, published by Longmans.)—CORNUBIA. (Native alum is found in the shape of a potash alum on alum-slate in a few parts of Britain. The alum of commerce is manufactured from alum-schists, or clay, and is, we should say, a profitable undertaking.)—C. ADAMES. (If you refer, you will see that the article is quoted. The Fig. is a diagram, and the part that has puzzled you is merely to show how the supply-pipe is attached. It need not taper smaller, and you can use either steam or air.)—DRAUGHTSMAN. (You will find the rule in p. 259, No. 812, or with diagram in p. 457, No. 851; also p. 599, No. 883.)—G. I. C. E. (Yes, it will do. Run it through some melted paraffin wax, if you like.)—M. OLLINER. (1. Nothing serious. 2. It is a very useful book, if that is what you mean. 3. It does not treat of personal health, but of sanitary arrangements.)—JAS. CALVESBERT. (Dissolve shellac in pure methylated alcohol; add lampblack and, if you wish for a jet black, a little prussian blue.)—ONE ANXIOUS. (We do not know; it is a trade secret. There are, however, several processes.)—E. H. (For boomerang see p. 124, No. 313.)—H. H. (It acts as an indicator of a change in the weight of the atmosphere in its locality, but is scarcely a barometer. It is, however, a useful prognosticator of the weather, and is not more often adopted because the water evaporates and becomes dusty and dirty. If some coloured solution made with boiled water is used, and the apparatus is protected from dust, it will be found useful as a weather-glass, but it can never take the place of a barometer.)—H. S. T. BISCOE. (Your idea is quite correct.)—A. FRASER. (See p. 100, No. 836. You must serve an apprenticeship or work in the engine-room.)—R. H. S. (Many recipes in back numbers—p. 111, No. 863, for instance.)—A SAILOR G. H. (Clock-springs will do, but we believe they are to be bought ready cut. File the tip to sharpen; near the screw to flatten.)—D. J. (You mean the "agglomerate." Peroxide of manganese, gas-carbon, and rosin, moulded under great pressure.)—PAINFUL. (Bunions, apparently; but examination necessary.)—G. W. (Both recipes have been given several times, but the colour of the last is a trade secret.

Brunswick black is made by dissolving asphaltum in boiling oil, and thinning with turpentine. A common kind is made from pitch.)—R. W. (We doubt if there is such a book.)—J. TEMPLAR. (Too much of such a drink would not be beneficial; a tablespoonful of oatmeal to a pint of cold water, makes a wholesome and satisfying drink, and weak cold tea, with a slice or two of lemon squeezed into it, is palatable and thirst-quenching.)—SEMPER FIDELIS. (Diluted nitric acid will remove it: use carefully.)—SY. SMITH. (The filtering medium is choked up, and the water is really not filtered at all. You will have to send it to the maker to be refitted, but the best advice we can give is to discard it altogether, and buy a filter with a removable top, so that you can clean the charcoal block once a week, and substitute a fresh one when worn out.)—PAUGUL. (Received; but in this instance we had not room for reproduction.)—ONE IN A FIX. (You can obtain a copy at Somerset House, for a small charge.)—R. F. (You had better give up smoking; it does probably induce dyspepsia in some men, and you seem one of them.)—NOVICE. (They do not require any artificial heat at all now. You will find a recipe for making them into wine in No. 345, p. 179; but such grapes are wasted in wine. To make a preserve, treat in same way as other fruit. Grapes ripened in a house should, however, be eaten as they are. You can preserve by cutting the bunches with long stems and putting them in bottles of water.)—DE'RING. (We have given many recipes for graphs. Use more glue if it is too soft. Good clear glue—not Nelson's gelatine, which is wasted on such things. Dissolve aniline violet in alcohol, and dilute with water.)—A AMATURE. (It is lacquer, which you must clean off, and pickle the metal in nitric acid; then relacquer. It is an art requiring much skill, to be acquired only by practice.)—WATER-GLASS. (1. Answered directly or indirectly in every volume—see pp. 9, 80, 172, present volume, for instance. For the other question see some of the text-books and the *Nautical Almanac.*)—VIOLINIST. (Spohr's book is considered one of the best; but lessons from a teacher are more necessary with the violin than any other instrument. There are some useful hints on p. 94, No. 784.)—ONE UNSETTLED. (See p. 47, No. 652. For particulars apply to Mr. W. C. Burnet, 10, Blomfield-street, Finsbury-circus, E.C.)—GEO. SMITH. (In type.)

Every Workman connected with the Building Trades requiring a situation should advertise in "THE BUILDING NEWS," published every FRIDAY, price Fourpence, at 31, Tavistock-street, Covent-garden London, W.C.

"THE BUILDING NEWS" is the Principal Journal, representing Architects and Builders, and has the largest circulation of any Professional Journal in the kingdom.

Every Workman should insist on seeing "THE BUILDING NEWS" every week at his Club or Coffee House. He will find more "Lists of Tenders" for new work in it every week than in any similar paper, and can thus judge where work is likely to be had. He is also specially invited to make use of "Intercommunication" if he wants to know anything about his trade; to write to the Editor if he has any suggestions to make and to advertise in the paper when he wants work.

The charge for Advertisements for Situations is One Shilling or Twenty Words, and Sixpence for every Eight Words after.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post-free to any part of the United Kingdom. For the United States, 13s., or 3 dols. 25c. gold, to France or Belgium 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 3d. each to cover extra postage.

Messrs. JAMES W. QUEEN and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post-free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. XXIV., XXVI., XXVII., XXVIII., XXIX., XXX., XXXI., XXXII., and XXXIII., bound in cloth, 7s. each.
[Vol. XXXIV. Now ready.]

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in March and September, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d each, through any bookseller or newsagent, or 2½d. each, post-free from the office (except index numbers, which are 3d. each, or post-free, 3½d.)

Indexes for each half-yearly volume up to Vol. X. (except Vols II., III., IV., V., and X.) inclusive, 2d. each Post free 2½d. each Indexes to subsequent vols., 3d. each, or post-free, 3½d. Cases for binding, 1s. 6d. each

⁂ Subscribers are requested to order Cases and Vols. through their booksellers, and not to send direct. The regulations of the post-office prevent their transmission through the Post.

CHARGES FOR ADVERTISING.

	s.	d.
Thirty Words	2	6
Every additional eight words..	0	6

Front Page Advertisements Five Shillings for the first 40 words afterwards 9d. per line. Paragraph Advertisements One Shilling per line. No front page or paragraph advertisement inserted for less than Five Shillings Reduced terms for series of more than 6 insertions may be ascertained on application to the Publisher.

ADVERTISEMENTS in EXCHANGE COLUMN—for

	s.	d

For every succeeding Eight words..	0	3

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen Words	0	6
For every succeeding Eight Words	0	6

⁂ It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions; and in cases where the amount sent exceeds One Shilling the publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement and charged for.

Advertisements *must* reach the office by 3 p.m on Wednesday to insure insertion in the following Friday's number.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a PINK Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

Holloway's Pills—Weakness and Debility.—Unless the blood be kept in a pure state, the strongest constitution will fail and disease supervene. These truly wonderful Pills possess the power of neutralising and removing all contaminations of the blood. They quietly but certainly overcome all obstructions tending to produce ill-health.

OUR EXCHANGE COLUMN.

◆◆◆

The charge for Exchange Notices is 3d. for the first 24 words, and 3d. for every succeeding 8 words.

◆◆◆

Horizontal **Engine and Boiler,** all fittings complete, 4 horse-power boiler, 9ft by 2ft. 7in. Exchange for larger. D. SCREEN, Wolverhampton.

Drilling Stand. made of 2in, iron, 4ft. 6in. high, with jib 1ft. long, swing brace with 36 best steel drills, with screw for feed. Offers of anything useful invited.—219, Walton-road, Liverpool. ½cwt. of slide-rest tools, all best cast steel. Offers as above.

Thirty-four Vols. "**English Mechanic,**" bound, complete and clean. Wanted cottage piano, or offers.—J. WOOD, 189, West-terrace, Burley-Wharfedale, near Leeds.

76 **Microscope Slides** for Exchange. Also Microscope Turn-table —LINTIN, 170, Freedom-road, Sheffield.

Good Norwich yellow cock **Canary.** Exchange.—WILLIAM RIGBY, Walmer Bridge, near Preston.

¼ dry-plate **Tourist's Camera,** complete; for Lantern Slides.—SHEERMAN, 147, Clarence-road, Lower Clapton.

Two **Lathe Heads,** 6½in. centre, 4 chucks, socket, and two T-rests. Exchange.—C BLANCHARD, 4A, Little Church-street, Edgware-road.

Clarionet Stop of Organ Pipes, 42 notes, from tenor C, spotted metal, London made and voiced, nearly new. Offers wanted.—HAVARD and STEVENSON, 103, Byrdsley Park-road, Birmingham.

Seventeen 2s. numbers of "**Cassell's History of** ENGLAND," unsoiled. Also quarter-plate Camera. with dark slide, focussing lens, and instructions, cost 33s. 6d. Wanted, Slide-rest, or other engineer's tools, in exchange.—HARDY. Newtown, Yeovil, Somerset.

Photographic Apparatus (complete) wanted for Halse's ten guinea Galvanic Machine, in good working order, for curing rheumatism.—WILLIAM ANDERSON, 3, Brookdale avenue, Ilfracombe.

What offers for Gem **Sewing-Machine** on beautiful stand, oscillating treadle motion. Photographic Dark Tent, Quarter Dry Plate Camera and Lens?—E. SCOTT, Patrington, Hull.

Wanted to exchange, Watchmaker's **Balance** WHEEL-CUTTING ENGINE 6 cutters, 35s, or other goods; for good Telescope, with day and night eyepieces.—E. SCOTT.

"**English Mechanic,**" Vols. XXIV., XXV., XXVI., XXXIV unbound. What offers. Also box of Marquois' Scales. Offers—L JACOB, 41, Grosvenor, Bath.

To Amateur Mechanics.—Small **Steam Engine,** 1in. bore, 3in. stroke, vertical. Wants slides for crosshead fixing up. Also Vol. XXI., XXII., XXIII, ENGLISH MECHANIC, clean, unbound. What offers? Small bench lathe or bicycle parts.—FRANK DYSON, Delph, Saddleworth, near Manchester.

Tricycles, one or two good wanted. Exchange for House Painting, Graining, &c.; experienced workmen. Contract or otherwise.—MATTHEWS, 31, Neville road, South Hornsey.

THE SIXPENNY SALE COLUMN.

For Sale.

Collographic **Photographs** for Machinery and Trade Patterns. Sample and list for 2d.—PUMPHREY and DAY, Birmingham.

"**The Night-light Clock.**" Illustrated and described on page 370, No. 848. Price, carriage free, 5s. 6d.—F ROBERTSON, 13, Greek street, Soho, W.

Lathes, Lathes, cheap good screw-cutting, from £10. Easy payments. Hire system First-class tools.—MAKIN, Cupola, Sheffield.

Electric Machines, Indicators, Bells, Batteries, Wires, Switches, Terminals, Carbons, &c.—KING and Co., Electricians, Bristol (List Twopence.)

Beautiful **Cloth Dress,** in all colours, price 8s., or 8d yard. Patterns, one stamp.—FIRTH, Kirkgate, Wakefield.

Stammering speedily and effectually Cured, personally or by correspondence Testimonials from all classes.—VOX. M., Ward's Library, Grosvenor-road, Highbury, London.

Oval Frames.—CAPELL, Oval Turner, 79, Milton-street, Dorset square, N.W., London.

Bench Drilling Machine. very strong, invaluable to amateurs. Securely packed for 30s.—BEECHING and GOOSE, Mareham-le-fen, Boston.

Gutta-percha Tissue, best, quite new, free 1s. 4d. per square yard.—W., Brewery House, Nenagh, Ireland.

The Cuttriss **Electro-motor,** 30s., the cheapest and most powerful for size, guaranteed to drive any domestic sewing machine.—CUTTRISS, Electricians, 85, New Briggate, Leeds.

Launch Engines, different sizes, good and cheap. State requirements—JOHN MIDDLETON, 16, Hope-street, Glasgow.

J. J. Allingham, Mechanical Engineer, 91, White Rock-street, Liverpool, makes and repairs model machinery, etc., and is open to undertake agencies for sewing machines, bicycles, tricycles, fretcutters, wringers, etc., etc.

Dynamo Castings and Wire for Machine for six 10 candle incandescent, or one arc, 30s.—PATRICK.

Incandescent Lamps, Batteries, Wire. All Electrical Apparatus and parts.—PATRICK, 15A, White Lion-street, Chelsea, S.W.

Foreign Stamps, 1,000 well-assorted, 1s. 2d. free, 50 varieties, 6d. Sheets on approbation. Good discount.—SYLVESTER HEDRON, 14, Guilford street, Russell-square, W.C.

Engineer's Spring Steel **Tape.** nickel case, French (2 metres) and English (6 feet) measure. Post free 3s. 6d.—R. BURNS and Co., 10 Castle-place, Belfast.

Twenty-horse, Seven, Four, Two, and one-horse **Engines.**—JAMES SUTCLIFFE, Princess street, Granby-row, Manchester.

Blecnum Spicant and Parsley **Ferns.** 1s. per dozen, free.—JAMES DOVE, Low Fold, Ambleside, Westmoreland.

Silver-on-Glass **Mirror,** simply mounted (equatorial), with screw motions. Very good definition, £7—REV. S. MILLS, Droylsden Rectory, Manchester.

Numerous and Instructive **Illustrations** of modern steam engines and boilers, 24 stamps.—234, Swan-road, West Bromwich.

Hop Tonics, **Ingredients** for preparing, post free, 8 or 14 stamps.—JONES, Chemist, Westminster-road, Liverpool.

Selenium. — What offers for 1½oz. in broken cylinders. Perfectly pure, good sample.—D. WILLIAMS, 60, Kellett-road, Brixton, London, S.W.

Musical Box. in excellent condition, 3 tunes, very cheap, price 12s. 6d.—BIRCHALL, Junior, 5, Mark-lane, London.

Transit Instrument, 2½in. O.G., by Worthington, £15; 7¼in. o.g. by Dollond, no cell £20. Air gun by Phipps, £3. Quantity of astronomical books. Send for list—MRS. ALMOND, Westgate, Dewsbury.

10,000 Fine Art **Photos,** Actresses, Celebrities Paintings, Statuary, &c, from 2s per 13. Unrivalled collection.—WILLIAMS.

Send for **Packet** on approval. Superior Copying, Enlarging, Painting, &c. Lists free.—T. WILLIAMS and Co. (P. 12) Bridgnorth. Agents wanted.

Wheel-cutting. Fluting, Grooving, and Spiral-cutting Apparatus (new), spindles of steel hardened, frame and pulleys of gun metal. Cheap, 40s.—J., Rio Cottage, St. Thomas, Exeter.

Parker and Weston's "small" direct-acting **Steam** PUMP (nearly new, and perfect), cost £16 10s., cash £7.—As below

"**Engineer,**" from May, 1880, to July, 1882, 113 clean copies, 25s.—R., 36, High-street, Welshpool.

Lathe.—Bar Bench **Lathe,** 3in. centre, 3ft. bar, four chucks, tap for tapping wood chucks to mandril nose. Offers invited, or cash, 35s.—W., 39, Tasman-road, S.W.

Photographic.—Quarter-plate Camera with Portrait lens, tripod. Two dark slides, dipping bath, and printing press. Offers invited, or cash, 30s.—W., 39, Tasman road, S.W.

Patents.—Share in a Patent for which there is a prospect of extensive sale on easy terms.

Patents.—Inventors wishing to perfect, protect, and sell, or work practical inventions connected with electrical or other matters, may communicate with F. M. ROGERS, 21, Finsbury pavement.

100 coloured **Stencil Designs** (full working sizes), with patent tool and copyright instructions for cutting stencils by new process, 10s. Carriage free.—CHARLES LEWIS, Decorator. Welshpool

2¾in. back-geared **Lathe,** planed iron bed, 30s.—TURNER, 72, James Turner-street, Winson-green, Birmingham.

Micro Photos—List of 350 one penny stamp.—E. and A. DANCER, 436, Stockport road, Manchester.

Telephone Transmitters and Receivers. The loudest and cheapest made.—NEWTON and Co, 13, Hill-street, Birmingham.

Foreign Stamps, 120.—Sierra-Leone, Barbados, Newfoundland, Brazil, Japan, Guiana, Orange states, Finland, 7d.—KILLINGLEY, Upper Fox-street Leicester.

Bicycles, Bicycle Fittings, Anvils, Bellows, Stocks and Dies, Tueirons, Vices.—Repairs done.—PATTEN, "Onward" Works, Wolverhampton.

Diamond Pencils, for writing and sketching on glass, stone, &c., 3s. Real diamond guaranteed.—GEORGE TEMPEST, 3, Canova-street, Liverpool.

Lathe, 4in. back gear; bargain. Tools, chucks carpenter's bench and tools. Complete list on application.—Address, LATHE, 1, Addington crescent, York-road, Lambeth, S.E.

Volvox Globator, tube 9d:; small tube 4d.—M. C. P., Bisham Vicarage, Gt Marlow.

Iron Indiarubber **Stamp-making Press,** cost 16s., used twice, 10s.—M. C. P., Bisham Vicarage, Marlow.

Metallic "A" and "E" **Violin Strings,** Acknowledged success. Six, post free, 1s—JOHN ELARCO, 36, Kelvin-grove, Liverpool.

Air-Cane (breechloading), shot and bullet barrels, perfect, price £3 10s.—R. STIRLING, 14, S. Hamilton-street, Kilmarnock.

Excelsior **Model Engines.** Cheapest in the world. Send for list—SKINNER and Co., Park Works, Alexandra-road, Manchester.

Excelsior **Model Engines.** Cheapest in the world. Send for list.—SKINNER and Co., Park Works, Alexandra-road, Manchester.

Remington **Type Writer,** nearly new, cost £20, £9 —FRANCIS, Rochford, Essex.

Pedal Organ Pipes, CC to B, metal, fine tone, £5. —FRANCIS, Rochford, Essex.

Astronomical Telescopes.—3in. Tulley, £8. 4½in. Browning, £8. 5¼in. Gregorian £6. Second hand. Property of an amateur.—Onvah House, Stodart-road, Anerley.

Pair of **Telephones.** Switches, and Bells, cheap. Send for particulars.—E. A, 20, Malden-road, Kentish Town.

A pair **Engines, Boiler, and Tanks,** suitable for yacht Good as new. Cheap—JENKINS, Waterson, Milford.

An **Invention** that will realise a large capital.—Apply, W. T. BRAHAM, 392, Stretford road, Manchester.

A perfectly constructed **Ten-cell Grove's.** with special ebonite cells, grooved to steady the power cells. Platinum points to all the binding screws.—F. HARVEY, Bushey Heath, Herts.

A delicate **Balance and Weights,** Griffin make. F. HARVEY, Bushey Heath, Herts.

Patterns of Weston's Pulley Blocks, all ready fit up, complete, new, cheap.—W., 19, Atkinson-street, Stockton-on-Tees.

Sewing Machine, the Improved Perfection Shuttle Lock-stitch, 60s.—BROWN, 93, Leyton-road, Stratford, E.

Microscopic Objects, prepared ready for use, 12 packets, 1s. 1d, post free—W. WHITE, Warden-place, Nottingham.

Fret Machinery, parts for fitting to wood framing for steam power, cuts 4in.

Bicycle, 52in, by Hillman and Herbert, only used twice, £8 10s. Painted—J. HERBERT, Engineer, 8, Southampton-street, Fitzroy-square, W.

The English Mechanic

AND

WORLD OF SCIENCE AND ART.

FRIDAY, JULY 21, 1882.

EXPERIMENTS WITH THE ELECTRIC ARC.

A FEW weeks ago MM. Jamin and Maneuvrier, in the Paris Academy, described some instructive experiments in which the electric arc was maintained between various "electropyres" (to use a recently-coined word), by action of a Gramme machine with alternating currents. With two quite similar carbons as electropyres, there is no deflection of a galvanometer in the circuit, the two rapidly-successive contrary currents neutralising each other. But, with one carbon thick, the other thin, there is permanent deflection (as though a battery were inserted in the circuit); the current from the large carbon to the small dominating over the other, and giving a differential current. There is also a differential current where the electropyres are a mass of metal and a carbon point. With lead a deflection of 29° was had; with iron 30°; with carbon 31°; with copper 60°; with mercury 70°. In the case of zinc, the current, at first as strong as with copper, falls off, probably owing to formation of oxide.

The electromotive force of the differential current is small, and about the same, for lead, iron, and carbon. For copper it is equivalent to 50 Bunsens, for zinc (at first) to 66, while mercury shows 103·7. It is proved that the first three substances offer the greatest resistance, while copper and mercury offer the least.

The differential current can only be explained in two ways: by a difference in the resistance, or by an inequality in the inverse reactions of the arc in one direction or the other. As no difference of resistance was observed with change of direction, it is concluded that the current in question is due to a particular property of alternating currents.

Whatever the explanation, it is clear that, the arc once produced with mercury, the differential current quite alters the action of the machine. One system of currents is, if not extinguished, considerably weakened, and the other constituted by excessive currents of greater intensity and duration. The commutator by which alternating-current machines, like those of Nollet and Meritens, are rendered available for chemical operations, might be replaced automatically by one or several arcs formed between a bath of mercury and a carbon point. It remains to ascertain the economic conditions of this transformation.

The effects obtained from the Gramme machine, with alternating currents in the electric egg, are remarkable. The two currents contribute equally (say the authors) to the phenomenon, which is that of Geissler tubes, but which assumes incomparable brilliancy, owing to the considerable quantity of electricity which passes and rapidly modifies the appearances observed. The carbons get heated, redden, and reach a pale white, not only at their extremity, but throughout their length; then they are rapidly volatilised by the combined effect of heating and of the currents. Whatever the cause of this volatilisation, it is certain that a carbonaceous matter spreads in the state of vapour. The globe gets filled with a blue gas, like vapour of iodine, deepening in hue to indigo. The vapour is abundantly condensed on the glass, rendering it opaque. The authors avoided this termination by using instead of single carbons two bundles of crayons, diverging from the rheophores, conewise, towards each other. Here the currents are divided into a large number of effluves, less intense than the single effluve; all the carbons are illuminated at once, and less the more numerous they are. The volatilisation is nearly *nil*. A still brighter effect was obtained with copper rods.

In a more recent paper, MM. Jamin and Maneuvrier have described some striking modifications of the arc when sulphide of carbon vapour is introduced into the vacuous space. The carbons in these experiments were parallel—fixed at the base, and separable at the top by a simple mechanism. With a vacuum as complete as possible in the receiver, the arc, of course, does not form; there is the Geissler tube phenomenon: but when a few drops of sulphide of carbon are introduced, increasing the pressure about 0·05m. or 0·06m., one sees the arc between the points, and it persists as they are separated. At this moment there is, as it were, an explosion of light, so bright as to be unbearable, incomparably superior to the usual brilliancy of the arc. Looking through coloured glass, one observes the arc to be of horseshoe form, or like a large Omega, resting with its two ends on the carbon points, and about 0·05m. in height. A long flame rises vertically from it. The points of the carbons seem red and very brilliant, but the arc is pale-green, and, as this colour dominates, the whole room is as if illuminated by a Bengal flame with copper in it. The brilliancy increases with increase of tension of the vapour; but, the resistance also increasing, the arc may go out and have to be started again and again.

The spectrum of the light is formed of four channelled spaces in the red, the yellow, the green, and the violet, very similar in appearance, though the green is the most luminous. They probably obey the same harmonic law, which remains to be discovered.

While these appearances are in progress, a chemical action takes place. If air have remained in the receiver, the sulphide of carbon burns incompletely; a cloud of sulphur fills the space, and is deposited on the glass; the carbon burns alone. If the air have been well removed these clouds do not form; a brown deposit is produced on the glass, and becomes black. This deposit is volatile. Its odour recalls that of sulphur. "It is evidently a compound of sulphide and carbon; perhaps a protosulphide corresponding to carbonic oxide, perhaps an isomeric combination of ordinary sulphur. One finds, indeed, neither a deposit of sulphur nor one of carbon, and the crayons have neither lost nor gained. It is probable that the sulphide of carbon is dissociated, the sulphur volatilised, the carbon in vapour disseminated in the arc, and that this carbon and this sulphur recombine in the flame to reconstitute a combination under different conditions; but this is merely a conjecture, no analysis having yet been made. *En résumé*, this experiment is remarkable for the extraordinary quantity of light produced, for the size of the arc, for its colour, for the composition of its spectrum, and for the chemical actions which take place. It is not probable that it could ever be turned to advantage for illumination, on account of the colour, unless for lighthouses and signalling at a distance."

CONTINUOUS RAILWAY BRAKES.*

IN the preface to this work, Mr. Michael Reynolds tells us he has endeavoured to explain what, according to his experience, a continuous brake should be capable of doing, and when it is found most useful. The key-note of his remarks may be found in his statement that even the worst continuous brake is a marvel of improvement on the old system of separate and independent brakes under the control of driver and guards, and worked by the primitive mode of "turning handles." By turning handles, the author obviously means the gymnastic feats which can still be witnessed on too many of our lines, when the stoker and the guards, in order to bring a train up to a station, are compelled to revolve a lever many times in order to screw down the brakes. The question of continuous brakes was first brought prominently into public notice by the celebrated Newark trials, which were made in 1875, just seven years ago; and the competition which has gone on since then amongst the rival brakes has left the railway companies in much the same condition: that is, they have found nothing better than the brake that was then offered for their acceptance, and shown to be an efficient train stopper and a valuable safety appliance. Readers of these columns must be well acquainted with the recent history of the question: they are aware that while some companies have taken every advantage of modern inventions, others have pursued a policy of "shilly-shallying," apparently waiting for something to turn up, while at least one boldly declared that continuous brakes should be used only in emergencies, and that the brake in use on their particular line was the best in the world—an opinion which has since been unconditionally surrendered. As the whole question is not unlikely to come before the Legislature, —it would probably have been brought forward before now, but for a press of other more important matters—this work, in which Mr. Reynolds has given a popular explanation of the different brakes, will be of great assistance in forming public opinion, and it might be studied with benefit by those who took upon themselves to burk the Bill that was introduced this session in the House of Lords. The brake question may be considered as a difference of opinion concerning the relative merits of two principles—viz., compressed air and exhaust,—the latter utilising a portion of the pressure due to the atmosphere. One ingenious and, under certain conditions, efficient system, utilises the hydraulic principle; but the fact that the conditions necessary for its proper working are not always present will prevent its general adoption in this country. Amongst the brakes described by Mr. Reynolds are the Steel McInnes and Westinghouse, both of which employ compressed air, and the Aspinall, the Eames, the Hardy, the Sanders, and the Smith, all of which utilise the atmospheric pressure, and some of which are automatic in action. Barker's hydraulic brake, as it deserves, has a chapter devoted to it, but no description of the Heberlein is given, the scope of the work covering only those brakes which are in use in the United Kingdom. In his introduction, Mr. Reynolds has some rather scathing remarks, which may go home to those who "manage" railways; for, speaking of the old-time practice, when the driver was supposed to be gifted with prevision, and was always to shut off steam in time, it was only reasonable, he says, to expect that the efficient heads of his company would likewise possess foresight, and would place all the brake-power in the hands of the individual who could, in almost all cases, see the danger in front of him, or would be first to find out that he had kept steam on too long. Even at the present day there are railway authorities who object to providing drivers with the means of quickly stopping, and when the means is provided, they object to the driver having full control over it. It is only fair, however, to say that the great majority of railway authorities have recognised the importance of placing all the available brake power within reach of the driver, and not a few have gone further and adopted arrangements which place the control of the brakes primarily in the hands of the man who is responsible for the safe piloting of the train. It will form one of the most remarkable pages in the history of railways (says Mr. Reynolds) that the whole, or nearly the whole, of the improvements which have been made are the fruit of human sacrifices, and not the result of man's long-sightedness. So far as some companies are concerned, that remark will be applicable to their present conduct when the history of the battle of the brakes comes to be written. Years ago, when the companies found that accidents continued to happen through the simple but dangerous fault of over-running stations, instead of increasing the brake power in the hands of the driver, the distant signals were put further out, so that there should be a greater distance in which to pull up the trains; but since it became evident that signals of themselves would not arrest a train the engine of which, for instance, had left the metals, the importance of brake power has been generally recognised, and since 1875 the battle of the brakes has been waged without the companies determining upon the united action which would obviously be for their benefit as much as for that of the public.

---

*Continuous Railway Brakes. By MICHAEL REYNOLDS. London: Crosby Lockwood and Co.

The inventor of the first brake used upon vehicles running on rails appears to have been Le Caan, of Llanelly, who applied a heavy cast-iron block resting on nearly half the perimeter of the wheel, but it was employed only for carts. The inventor of the first steam brake was undoubtedly Robert Stephenson, for in a patent dated October 7, 1833, he describes a method of applying steam to raise a small piston, which, attached by a rod to a small walking beam, lifted a connecting-rod, which straightened a toggle-joint and pressed a couple of blocks against the tires of adjoining wheels. That brake was so far a failure that it was not adopted, and the reason, as given by Mr. Reynolds, is a very simple one; for Stephenson applied it only on one side of the engine. The little cylinder was mounted on the framing by the side of the firebox, and if Stephenson thought of connecting it to both sides of the locomotive, he doubtless found considerable difficulty in carrying out the arrangement, which was, however, abandoned for the familiar screw brake applied by hand. The coupling arrangements in those days were, as may be surmised, of the crudest; but the shaking-up of the passengers at every stop led, in 1835, to the adoption of the screw coupling, an invention of Mr. Booth's, the secretary of the Liverpool and Manchester Railway, which, with sundry modifications, is in use to the present day. Mr. Booth also patented a contrivance for checking the speed of a train by throttling the exhaust, so that a heavy back pressure was brought to bear upon the pistons. In this connection Mr. Reynolds has some remarks which are not very clear, for he says, "The steam brake should have been applied to both sides of the engine, and it should have been put in the power of the driver to have locked the wheel with it. In fact, it is a mistake to place a brake in the driver's hands that can lock the wheels." Probably it is only a printer's error, the meaning being that it should have been "out of the power of the driver to have locked the wheel," but we put that forward merely as a suggested explanation, for we learn from a note that the text has been "revised" by Mr. D. K. Clark. In his chapter on the "conditions of a perfect brake," Mr. Reynolds enforces, by recounting several accidents, the importance of placing the brake-power within reach of the driver, and also of rendering the brakes automatic, so that in the event of the train separating, each coach contains within itself its own stopper, so to speak. A thoroughly good continuous brake will also act as its own tell-tale, for it is of as much importance to have a brake always in good order as to have a brake at all; in fact it is safer to be without one than to have a contrivance liable to get out of order, and to be useless just when it is most required. Besides that, simplicity of working, as distinguished from simplicity of construction, is an essential feature of a good brake, for a second lost when danger is discerned may make all the difference between disaster and safety. The familiar screw-brake with which the majority of locomotives are fitted was, at the time of its invention, a great improvement, but the gymnastics necessary to put it on, and even the labour that is required to take it off, are out of place in these days of mechanical invention. It seems absurd that, with the power of a thousand giants at his elbow, a stoker should have to waste precious seconds and exert his comparatively feeble strength in turning a lever handle round, in order to bring blocks against the wheels which could be applied much more quickly and more forcibly by a modification of even the simple arrangement which Robert Stephenson patented nearly half a century ago. Well may Mr. Reynolds say that the operation is barbarous and out of place in these advanced times, when an ounce of steam can do the same thing, and do it better. The cardinal error made by the early managers of railways was in dividing the responsibility for the safe conduct of the train between the driver and the guards. At one time, the head guard was perched up on the top of his brake, or carriage, immediately behind the engine, with the idea that he was to see along the road in front, and warn the driver; but the guard in that position was in worse state than the driver, even when the latter had no protecting-plate or cab, for his eyes were blinded by the sparks and fragments of coke from the engine, and in winter he was pierced through and through by the biting blasts of the icy wind. Nowadays, the guard is at least protected from the weather, and the driver has a spectacle-plate, or a sort of half-cab, which, we believe, is preferred by the men themselves to the more elaborate arrangement generally adopted in America. The divided responsibility for the brakes still, however, remains on many lines, but there are signs that at last the boards of directors are beginning to see that the position is illogical and not conducive to safety. That change in opinion has been mainly brought about by the introduction of continuous brakes; but the continuous screw brake and the chain brake are comparatively old inventions, which are now rapidly passing into the limbo of history with the advent of the new views that the driver should have full control of the braking as he has of the motive power, and that the system of brakes throughout a train should be automatic in action if any accident should happen to either the apparatus or the train. In Mr. Reynolds' book we have all the best-known brakes fully explained with the aid of numerous large plates, while smaller diagrams serve to illustrate the details; and the attentive reader who carefully follows the explanations will have little difficulty in deciding which is the better of the two principles we have mentioned above. For some reason, several of our largest railway companies have adopted systems which are radically wrong, as they work on the exhaust principle, the extreme pressure in which must of necessity be something less than 14lb. on the square inch. To obtain the requisite amount of brake-power with these systems, it is necessary to have the collapsing sacks of large surface, or, to put it another way, the portions actuating the brakes must have a large area simply because they cannot have high pressures, and the consequence is that they are slow in action, and waste a great deal of steam. The weak points of the vacuum-brakes have, however, been so ably pointed out in our columns by Mr. Stretton, that we need do no more here than say that Mr. Reynolds, who speaks from practical experience on the foot-plate, condemns them, and ventures to say he is convinced that if the Midland abolished the use of the steam-brake on the engine, they would have a "serious accident in less than a week." As appendices to the work, we have Mr. Harrison's famous report, Captain Galton's experiments, and a description of the Westinghouse speed indicator. The celebrated Newark trials are embodied in the text, so that the reader will find in this book a clear exposition of the brake question as it relates to the rival systems; if, after reading it, he can understand the action of certain railway companies, he will comprehend why the best appliances are not always adopted, and will also speak tenderly of the want of foresight exhibited by the managers of railways in the early stages of their existence.

THE ACHROMATIC OBJECT-GLASS.—VI.

By W. BRADBURY.

(*Continued from page* 419.)

WE have previously seen that the uncorrected equation for spherical error in a double object-glass is $A = a\,\delta\,.\,\eta$. But as F, one of the values from which δ is found, is in this case double its former amount, instead of δ we shall have 2δ: and introducing the correcting factor as before, $A = a\,.\,2\,\delta\,.\,\eta^2\sqrt{\eta}$.

By this equation, we can make the aberration of each convex equal to that of the concave lens. In a triplet, it is more convenient to assume the curves of the flint lens; and, for the sake of simplicity, we will take it as an equi-concave.

In the previous example, the correcting factor was ·578; in this case, it will be double the amount, or 1·156. Also, focus of the convex was 8·64: therefore, each convex will now be 17·28. Focus flint, as before, is 12·13. Computing the curves by the formula before given, we find each is 13·91. The value of q is 1, which, being introduced in the equation, gives 5-3 as the value of a. Multiplying this by 1·156, we get 1·927 as the value of A. The root of the equation which satisfies this value is 1·34; so that $R : r :: 1·34 : 1$ in each convex lens.

$$R = 17·28 \times ·528 \times 2·34 = 21·34. \quad r = 21·34 \div 1·34 = 15·93.$$

Here we have:—

First lens ..	21·34	Second lens	13·91
Bi-convex..	15·93	Equi-concave..	13·91
Third lens	15·93		
Bi-convex	21·34		
Compound focus	30.		

The first and third lenses are thus arranged in opposing positions, and to some extent correct each other.*

I have not met with an account of the curves used in any triplet of Tulley's make. If they were based on the foregoing process of selection, their arrangement was very different from that of Dollond. Instead of making the two convexes of equal foci and similar in form, Dollond appears to have preferred the second convex of shorter focus than the first, and generally equi-convex. The proportionate curvature of the first and second lenses seems to be not far from equal, varying from about 4 : 5 to 7 : 10. If the correction could be satisfactorily carried out in the manner indicated by Tulley, a great practical point in favour of his system is the small number of tools required; for, as there are only three different radii in the triplet, three pairs of tools would be sufficient.

---

* Boscovitch's formula appears also to be adapted for triplet computations. An example by Robison is quoted by Rees from Brewster's Table V., Appendix to Ferguson's Lectures, Vol. II., page 418.

The firm established by Tulley, unlike that of Dollond, does not appear to have had a very lengthened existence. A member of the family seems to have entered the service of another London optician. Of him and his practice with triplet combinations, "Prismatique" says:—"Although Ross, Dallmeyer, and Browning still make small object-glasses triple, the double form is in general use for large work. Originally, the nearest approach to achromatism was supposed to be gained by the triple form. Tulley made triple object-glasses with two shades of inherent colour—viz., Dutch plate, of a perfect pink, and green English crown. He made use of these inherent colours, really, to correct the secondary spectrum."

Dollond and Tulley are justly looked upon as the fathers of English optical art. Genuine instruments of their make, like paintings by the old masters, still retain their values. When we remember the improvements that have since been made in the qualities of optical glass, and in the methods of working and polishing it, the fact that their telescopes still hold a place amongst the best work of the present day is no slight monument to their skill, industry, and perseverance. When the character of the glass was so uncertain, and good discs very difficult to meet with, the production of a fine object-glass must have been a task of immense labour. No one but an artist, having a higher object than that of mere gain, would have been content to expend the amount of time and patience such a production would necessitate. That Dollond and Tulley worked upon a correct model is evident from the fact that the general features of their construction are still retained in the best English work. The changes in curvature are chiefly matters of detail, due to the difference in the character of the glass, rather than to any rearrangement of the proportionate curvature of the lenses.

Sir John Herschel appears to have made a complete systematic analysis of the theory of the object-glass. His essay is probably the first correct and convenient account that was ever published in the English language. Possessed of high mathematical abilities, and an intimate knowledge of the laws of optics, his researches extended over the methods of most of the celebrated European geometers; and the results of these investigations were embodied in an elaborate paper, printed in the "Philosophical Transactions" for 1821. It is to be regretted that this account, from the pen of the highest authority on the subject that ever lived, is not procurable in a more accessible form.

Herschel advocated a different arrangement of curvatures. Whether he was the first to do so I cannot say; but it is an essential departure from the orthodox practice of the representative English opticians. Instead of using two positive and two negative curves, he made the outer surface of the flint also positive, thus having three convex surfaces opposed by one concave inner surface. I do not think this form has been largely used in English work, but French opticians have extensively adopted it. Dr. Kitchiner, I believe, states that Tulley made a fine objective on this principle, expressly in accordance with Herschel's formula. When lenses are combined in this manner; the longer convex radius is placed outwards, thus increasing the spherical error; but as there is only one negative surface, slight alterations of it must have a powerful effect on the balance of aberrations.

Herschel has drawn up a numerical table, for computing the radii required by different refractive and dispersive powers. It is simple and concise, and needs the rule of simple proportion only to find any desired results; but it is always advisable, as a check upon the numbers, to try whether they satisfy the foci which the dispersive ratio requires. Most likely some slight alterations will be found necessary. Herschel proceeds on the plan of making the inner curves constant for the same dispersive value, while the outer ones vary jointly with the refractive indices. In using this table, if the given dispersive ratio lies between any of the tabular numbers, it is necessary, first, to find the whole horizontal line of numbers due to it, by taking the proportional difference from the numbers immediately above and below the given value. Then the radii may be rectified separately for the refractive indices by taking the proportional difference, due to the difference in refraction.

Herschel's Radii for an Aplanatic Object-Glass.

Crown refractive index, 1·524: Flint index, 1·585. Compound focus, 1,000.

	First Surface—Convex.			Second Surface. Convex.	Third Surface. Concave	Fourth Surface—Convex.				
Dispersive ratio or value of δ.	Radius R, for above refraction.	Variation in R, for a change of + 0·01 in crown index.	Variation in R, for a change of + 0·01 in flint index.	Radius *r*, for above refraction.	Radius R^1, for above refraction.	Radius r^1, for above refraction.	Variation in r^1 for a change of + 0·01 in crown index.	Variation in r^1 for a change of + 0·01 in flint index.	Focus of Crown-Positive.	Focus of Flint, Negative.
0·50	674·85	+ 5·00	− 0·36	428·27	415·75	1436·97	+ 99·21	− 39·62	500	1000·00
0·55	671·84	+ 7·40	− 0·11	363·32	360·06	1453·53	+ 100·80	− 50·33	450	818·18
0·60	670·69	+ 6·76	+ 0·37	304·88	306·40	1429·37	+ 100·49	− 56·59	400	666·67
0·65	673·16	+ 5·63	+ 1·25	252·08	255·66	1357·09	+ 116·14	− 63·23	350	538·46
0·70	682·79	+ 3·35	+ 3·12	204·22	208·31	1231·54	+ 116·13	− 75·70	300	428·58
0·75	708·16	− 1·74	+ 5·68	160·73	164·50	1051·86	+ 108·47	− 72·07	250	333·33

Herschel's standard refractive indices are not likely to occur very often in modern combinations. As a rule, the crown index will be lower, and the flint higher than those he uses, unless Chance's light flint be used, which has a refraction slightly lower. An approximate rule for finding a tolerably correct proportion of curves for ordinary indices may be formed in the following way:—Taking the compound focus as 1000, assume the outside crown radius as 672, the outside flint radius as 1420; then, from these conditions and the refractive and dispersive powers, the inner radii may be found*.

It may not be inappropriate to illustrate the use of the foregoing table by means of an example. Suppose we take Chance's hard-crown, refractive index 1·51, and Chance's dense-flint, refractive index 1·62, to find the curvatures from the table.

The most difficult matter is to get the accurate value of the dispersive ratio; I believe it will be found equal to 0·6 as near as possible. As this agrees with one of the tabulated values, no alterations are needed for dispersion; the horizontal line of numbers is:—

Radius of first surface = 670·69
Variations for 0·01 in crown, 6·76; in flint 0·37
Radius of second surface = 304·88
Radius of third surface = 306·40
Radius of fourth surface = 1429·37
Variations for 0·01 in crown, 100·49: in flint − 56·59

These are for indices 1·524 and 1·585. In the example they are 1·51 and 1·62; hence, the crown difference is —0·014 and the flint + 0·035. Multiplying 6·76 by — 1·4, and 0·37 by + 3·5, we have 9·46 to be subtracted, and 1·29 to be added to 670·69, making it 662·52. This is the corrected crown curve. Next for the back flint curve; multiplying 100·49 by — 1·4 and — 56·59 by + 3·5, we get 140·68 and 198·06, both to be subtracted from 1429·37, making it 1231·31. Hence the corrected radii are:—

$$\text{Crown lens}\ \left.\begin{matrix}662{\cdot}52\\304{\cdot}88\end{matrix}\right\}\ \text{both convex.}$$

$$\text{Flint lens}\ \begin{matrix}306{\cdot}40\\1231{\cdot}31\end{matrix}\ \begin{matrix}\}\ \text{concave.}\\\}\ \text{convex.}\end{matrix}$$

These radii are for a compound focus of 1,000 inches. If the objective in the example be desired to have, say, 50in. focus, we must divide each of the numbers by 20; thus obtaining:—

$$\text{Crown lens}\ \left.\begin{matrix}33{\cdot}13\\15{\cdot}24\end{matrix}\right\}\ \text{Flint lens}\ \left\{\begin{matrix}15{\cdot}32\\61{\cdot}57\end{matrix}\right.$$

I do not think that this form is one which would be liked by practical men, as it is of the "rider" pattern. It will be noticed that the inner convex radius is deeper than the adjacent concave, so that the lenses would "ride" or touch in the middle, unless prevented by a brass ring used in centring. An examination of Herschel's table will reveal the fact that between the dispersive values 0·55 and 0·60, a gradual change in the inner conditions occurs. For the former and all preceding values, the concave curve is the deeper; but a gradual tendency to approach to equality exists, and for some intermediate number the two will be in contact; after which, for 0·6 and all succeeding values, the convex is the shorter radius.

An explanation of this matter may readily be found. When the value of δ is low, the difference in dispersive power is great; consequently, a short focus convex is combined with a long focus concave. Sufficient aberration in the former can then be obtained, without an abnormally deep posterior curve. But with an increase in the value of δ comes a decrease in both crown and flint foci, more so with the second than with the first lens. Hence, shorter curves are needed in each case, but especially so with the flint lens. This reduces the concave surface so much, that sufficient positive aberration cannot be got without throwing more convexity into the adjacent surface—thus reversing the condition of the inner radii, and making the glasses to touch in the centre, instead of round the margin.

Therefore, it may be taken as a general rule, that:—

For all values of the dispersive ratio, greater than 0·575, Herschel's form of object-glass has the convex inner radius shorter than the adjacent concave flint radius.

I am far from thinking that such an arrangement of lenses is in any respect inferior to the more common forms. With regard to spherical and chromatic correction, theory would seem to indicate that where a large amount of influence is exercised by the inner radii, the convex should be the deeper. For as the action of flint-glass is much stronger than that of crown, to produce an equal effect it will need only a much less angle of incidence, or, which is the same thing, the ray should fall on a flatter surface of flint than the crown from which it emerges. Practical men, however, have an objection to the "rider" form of object-glass; though, I believe, it is occasionally adopted in the best class of work; but if substantially equal results can be obtained from a more convenient practical arrangement, it is natural that they should prefer the form, which occasions least trouble in finishing.

If, then, we are determined to make the lenses conform to the common condition of marginal contact, though this condition is by no means essential, we must put a limit on the applicability of Herschel's formula, and say that these rules are only suitable for glasses having a very great difference in their dispersive powers.

(*To be continued.*)

A TORPEDO DETECTOR AND A SCIENTIFIC DIVINING ROD.

TWO inventions which are based on the principle discovered by Prof. Hughes and illustrated in his induction balance, claim some little attention, as being probably very useful appliances. These are Capt. M'Evoy's torpedo detector and Mr. C. F. Varley's "divining rod," a simple arrangement, by means of which it is believed that it will be possible to discover the existence and position of metallic lodes without the practical test of sinking costly shafts. M'Evoy's apparatus will probably be found of use as an indicator of the position of lost anchors, cables, &c., as well as of torpedoes, and the following will give an idea of its construction. It consists of a small mahogany box, containing a pair of coils or bobbins, a vibrator similar to that employed in electric bells for making and breaking contact, and a telephone. To this box is attached a given length of flexible cable, with four conducting wires in it. To the other end of this cable is attached a flat wooden case, in which there are two coils. This case is weighted so that it will readily sink when placed in the water. There are also terminals on the box for attaching battery wires, and an arrangement for putting on and cutting off the current is provided. There are two complete circuits through the box, cable, and wooden case, the one primary and the other secondary. The battery, the vibrator, one coil in the box and one coil in the wooden case are in the primary circuit, while the telephone, one coil in the box, and one coil in the wooden case are in the secondary circuit. When the battery is on, the coils in the box are adjusted so that little or no noise from the make-and-break action of the vibrator is heard in the telephone. When thus adjusted the instrument is ready for work, and if the wooden case is then brought near a metallic body a loud noise is heard in the telephone, thus indicating the proximity and locality of such a body.

---

* Herschel gives references to several foreign works treating on the destruction of spherical aberration. Perhaps those who can obtain access to them may be able to extract useful theoretical or practical details, and will send them to these pages. Such researches are valuable, especially if the subject embraces correction by means of other curves than spherical, and touches upon chromatic correction also. Mention is made of Euler, *Dioptrica*, Petersburg, 1769; Clairaut, *Mem. del. Acad. Sci*, 1757; D'Alembert, *Opusc.*, Vol. III.; Lagrange, *Miscell.*, III., II., I., 152; *Mem. Acad.*, *Berlin*, 1778; Schmidt, *Lehrbuch der Analyhschen Optik*; Santini, *Teorica. degli. Stromenti Ottici*. Also *Phil. Trans. R.S.*, 1821 and 1827; Littrow's Memoir, Vol. III., *Mem. R.A.S.*, *Lond.*, Sir J. Lubbock, *Lond. and Edin. Phil. Magz.*, 3rd series, Vol. VII., Sept., 1833.

Mr. Varley's instrument, which has been patented (No. 5353, 1881), consists of a rod of one metre to two or three in length, pivoted in a frame. At each end it carries two helices of 20 to 30 centimetres in diameter, the planes of the rings being parallel with the axis, and the centres of the two helices placed about one metre apart, more or less. These helices are connected together by two wires passing along the rod so as to form one circuit, but broken at a convenient part of the axis and attached to two insulated semi-cylindrical pieces of metal mounted upon the axis and against which two springs press. This arrangement forms a commutator, and the contacts change during the rotation as the planes of the rings or helices become vertical. The axis is connected by means of a pulley and cord with a large wheel carried on the frame, which supports the pivots, or is otherwise geared so as to permit of its being rapidly rotated. The two springs of the commutator are connected to a delicate astatic galvanometer at a convenient distance, or to a movable coil placed in a magnetic field. At right angles to the plane of the rod projects a pointer. This pointer is attached to the frame carrying the rod. The frame is mounted on pivots so as to turn in any direction; the stand carrying the frame having two axes, one horizontal, the other vertical as in the altazimuth mounting of a telescope. If there be an electric current passing in a straight line of indefinite length underneath the axle it will produce a magnetic field diminishing in power as the distance from it increases. This magnetic field, when cut by the helices, tends to generate currents in them. The commutator causes all the currents to flow through the galvanometer in one direction if the pointer is placed in a line perpendicular to the lode, but when the rod is suitably placed and the pointer is in the direction of the lode, the currents are directed half in one direction and half in the other through the galvanometer, which returns to zero. Thus if the galvanometer is deflected with the rod in any position, it shows the presence of a lode. By inclining the rod until no current is produced, the pointer is brought to a position in which it indicates the direction of the lode, and by taking two observations, one on each side of the lode, at which the pointer shows an angle of 45 degrees, half the horizontal distance between these two stations is the distance of the lode beneath the surface of the earth supposing the surface to be level or uniform. As cases may arise where it is not possible to place the apparatus on each side of the lode, for example, suppose the lode to be near the side of a sloping mountain, the apparatus may be provided with means of shunting the lower coil until the currents generated in the two coils are equalised, then by a little calculation based upon the known laws of electricity the distance of the lode from the surface is indicated.

Lastly, if desired, by making the resistance coils of the shunt suitable functions of the resistance of the coils, and making them into the form of a slide resistance box and numbering them, the position of the shunts at which neutrality is obtained may be arranged to indicate without calculation the number of metres that the lode is below the surface. The hollow helices at each end of the rotating bar may be varied in form and may be replaced by two bar electro-magnets.

THEILER'S TELEPHONE RECEIVER.

THE telephone receiver recently patented by Messrs. Theiler, of Canonbury-road, N., differs from its predecessors in dispensing with an armature, the lateral vibration of the electro-magnet itself being utilised. In previous systems in which an electro-magnet is used, the sonorous vibrations are due either to the motion of an iron diaphragm or armature placed close to the poles of the electro-magnet, or to the expansion and contraction of the magnet itself. In Theiler's telephone the electro-magnet may be of the usual U shape, and may consist either of soft iron or of hardened steel permanently magnetised, wound with a suitable number of turns of insulated wire. This electro-magnet is fixed in such a manner that the vibration of either one or of both its limbs is communicated to a diaphragm or diaphragms. The patentees also employ two or more electro-magnets in the same circuit, and utilise the vibration of both magnets in the manner described. By attaching a light disc or discs to the vibrating limbs the diaphragm may be dispensed with. Fig. 1 represents one of the telephone receivers provided with two diaphragms or sounding boards, connected to the two limbs or cores of the U shaped electro-magnet by short tongues. These tongues are firmly inserted in the diaphragms and fixed to the magnet, as shown. The poles of the electro-magnet are brought very close together by being shaped as shown, and the middle part of the magnet is firmly screwed to the case of the instrument. The ends of the helix surrounding the magnet-cores may be attached as usual to two terminals, or soldered to a flexible conductor communicating with the other parts of the telephone apparatus. When a vibratory current is sent through the helix of the electro-magnet, the extremities are rapidly attracted and repelled, and this vibratory motion of the magnet cores being communicated to the diaphragms or sounding boards, the latter are set in vibration of varying amplitude produced by a current of varying strength, as in all other telephones. Instead of making the electro-magnet of one continuous piece of iron, as represented in Fig. 1, the patentees find it more practicable to make it of the form shown in Fig. 2, where the electro-magnet represented consists of two limbs or cores, a sole piece, and pole extensions, the whole being screwed together and practically constituting one continuous piece of iron carrying the two coils. In Fig. 2 only one of the limbs or cores of the electro-magnet is attached to the diaphragm, the other limb being held fixed by a screw. Sometimes the patentees hinge one of the magnet cores, or both, in the sole-piece, in which case the diaphragms or sounding boards can be made much thicker than when the cores are rigidly fixed to the sole-piece, because the magnetic attraction of the poles has then only to overcome the resistance of the diaphragm. Instead of using a diaphragm, they sometimes fix a stem to one of the cores of the electro-magnet, and mount thereon a light disc of vulcanite, wood, ivory, guttapercha, or any other substance which is capable of vibrating. When using this telephone receiver, the disc is pressed to the ear in such a manner that its surface covers the aperture of the ear. When these telephone receivers are used on a line of some considerable length, the patentees prefer to magnetise the electro-magnet by a constant current from a local battery, and to effect the variation of this constant magnetisation inductively, and not directly. The electro-magnet is, then, not inserted in the line at all, but in the primary circuit of an induction coil, and connected with a local battery. The line is connected to the secondary circuit of the induction coil. This device possesses the advantage that the electro-magnet can be powerfully magnetised with very little battery power, no matter how long the line may be, and that steel magnets are entirely dispensed with. It is not necessary to have a separate battery for this purpose, as the microphone battery may also be used for the telephone receiver. The shape of the vibrating electro-magnets is immaterial, as they may be made of a variety of forms.

FIG. 1.

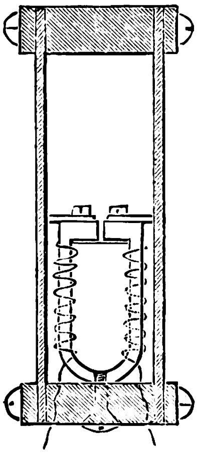

FIG. 2.

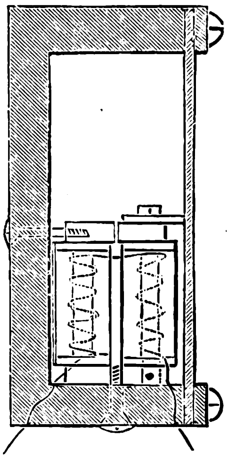


MERCURIAL AIR-PUMPS.

VARIOUS modifications of the so-called Sprengel or mercurial air-pump have been made from time to time; but since the introduction of the incandescent electric lamps, great improvements have been made, not so much, perhaps, in connection with the extreme rarity of the vacua produced, as in the speed of working, which is a consideration if the lamp is ever to be sold for the promised shilling. We have, in recent volumes, illustrated several mercurial air-pumps, which are highly useful appliances in many branches of science and some of the arts; but on p. 34 ante will be found one of the simplest and best, not only for the purposes of the electrical lamp-maker, but also for all purposes where a high degree of vacuum is required to be quickly produced. In the simplest form all that is required in a mercurial air-pump is an arrangement of glass tubes, with one tolerably large globe or oval vessel, which can be rapidly filled and emptied. This globe, at its upper side, is connected with an air-outlet tube, and at the lower side with the tube by which the mercury enters. Somewhere near the junction of the latter, the tube leading to the vessels that are to be exhausted is connected, and those three parts being clearly grasped the action is easily understood. The parts being adjusted, and all joints made air-tight, mercury is forced into the globe until it fills it, thus driving out the air, which, passing a bend in the exit pipe, finally escapes into the outer air from a tube dipping beneath the surface of mercury. It will be understood that no air can return. The mercury in the globe is now withdrawn, and it is obvious that it leaves a partial vacuum in the globe into which the air in the tubes and in the vessels to be exhausted expands. The mercury is again forced into the globe, driving out the air therein, and the process is repeated until the desired vacuum is obtained. In reality, the apparatus is rather more complicated than this, for it is necessary to absorb moisture, and that is accomplished, perhaps, in the simplest way, by compelling the air to pass through a vessel containing sulphuric acid, so placed that the acid can be easily renewed. A reference to p. 34, No. 886, will give the reader a good idea of the principle of all mercurial air-pumps, and will introduce him to one of the simplest, and, we believe, most efficient. In Sutton's air-pump, which is there illustrated, the mercury is caused to rise into the globe by the action of a force-pump, and it is obvious that the operations can be performed very rapidly; but the chief merit of the device is that the mercury is used in the form of solid columns, not drops. At the recent Crystal Palace Exhibition, Mr. Müller had a mercurial pump which also employed mercury in the solid column form, and, apart from some minor differences in the arrangements of the tubes, it was almost identical with Mr. Sutton's, save that, instead of employing a pump, Mr. Müller puts his mercury into a reservoir connected by a flexible tube and utilises gravity as the force. Thus his mercury reservoir, holding perhaps half a gallon, is attached to a cord working over a pulley in such a manner that the reservoir can be raised above the level of the globe in the pump. The mercury thus flows by gravity into the pumping-chamber, as we may call it, and the operations can be repeated with great rapidity. Both devices are notable for their simplicity and effectiveness, and are preferable to the elaborate arrangements adopted by rival inventors. We believe they are not patented. A more elaborate device, which has the not altogether established advantage of an automatic change of feed, has been recently patented by Mr. Stearn, of Osborn-road, in the city of Newcastle (No. 5,000, 1881), and is thus described:—The main feature of the invention is an automatic feed, by which the mercury is frequently returned from a lower to a higher level, whereby a large reservoir is dispensed with, and the quantity of mercury necessary to keep the pump in continuous action is greatly reduced. The fall tubes of the pump are inclosed in or connected at their lower ends with a partially exhausted vessel, and are made of less length than the barometric column, the vessel in which they are inclosed being exhausted by a mechanical air-pump or other exhausting mechanism. The atmospheric pressure is used to effect the raising of the mercury by allowing it to act intermittently, either directly on the surface of the mercury, or on a flexible diaphragm or indiarubber vessel containing the mercury. In mercurial pumps constructed according to this invention great uniformity and celerity of action are obtained by reason of the reduction in the length of the exhausting portion of the pump, and by keeping the mercury in closed and exhausted vessels during the period of its circulation. An immunity from danger to the operators from mercurial vapours is also insured by completely secluding the mercury from contact with the external atmosphere, and when a number of the pumps are combined together in a general system the mercurial portion of each pump is rendered completely independent of that of the others. The compound fall tube passes through a closely-fitting indiarubber or other air-tight stopper, which fits into the outer or inclosing vessel. This tube communicates by another tube with an upper mercurial receiver, and also is capable of being placed by means of a flexible tube and stopcock in communication with a mechanical air-pump or aspirator, or exhausted chamber, so that the vessel before referred to may be exhausted, after which the stopcock is closed. The lower mercurial receiver (which is constructed of iron or other material not acted on by mercury) consists of two hemispheres separated by a flexible diaphragm, by preference of indiarubber. This receiver is mounted so as to be capable of turning upon a centre, and is supported by a spring, the tension of which is adjusted so as exactly to counterbalance the weight of the receiver when empty or nearly so, and keep it in close contact with a valve or stopper, which is carried by a support and adapted to an orifice in the receiver. The receiver is provided on one side of its diaphragm with a tube in communication with another air-pump or aspirator, and on the opposite side of the diaphragm it communicates on the one hand by means of tubes and a valve with the lower end of the inclosing vessel, and on the other hand through the intervention of a narrow tube and a valve with the upper mercurial receiver. The latter receiver communicates by an outer tube surrounding the narrow tube, and by a supply pipe with the compound fall-tube, a trap being provided of ordinary construction.

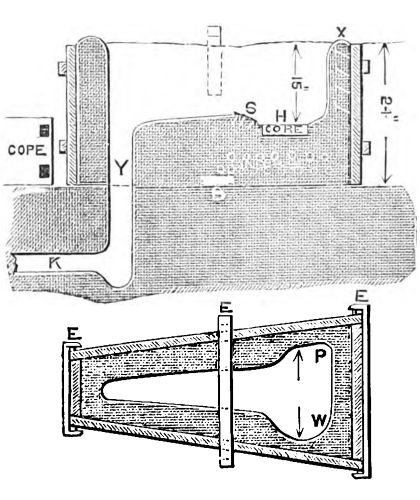
The lower receiver being full of mercury, so soon as the air-pump communicating with the inclosing vessel and the upper receiver is put in action, the air is partially exhausted from the vessel and receiver, and from a vessel attached to the inclosing vessel. On opening the stopcock (the valve or stopper of the lower receiver being also open) the atmospheric pressure on the indiarubber diaphragm forces the mercury into the upper receiver, whence it passes through the compound fall-tube of the apparatus in the usual way, the valve interposed between the lower receiver and the vessel which incloses the compound fall-tube closing and preventing the mercury from passing direct into the said vessel. So soon as the lower receiver is empty the spring draws it against the valve or stopper, and the air-pump or aspirator connected with it exhausts the air from one side of the flexible diaphragm, and the mercury passes from the vessel inclosing the compound fall-tube through the interposed valve into the lower receiver. The area of the valve or stopper of the lower receiver is such that the weight of the receiver when full of mercury is sufficient to overcome the atmospheric pressure and open the valve. By this arrangement, if connected with a constantly acting mechanical air-pump or other exhausting apparatus, the mercury is periodically returned to the upper receiver, and a very small quantity of mercury is sufficient to maintain the receiver in constant action. All contamination of the mercury and all loss by waste or danger to the operator is completely avoided, whilst at the same time the space occupied by the apparatus is extremely small, and there is little risk of breakage. The intermittent admission of the air may be effected by the use of an electro-magnet, the circuit of which is completed by the mercury on reaching a fixed point, the electro-magnet attracting a valve attached to its armature; or the closing of the valve may be effected by a counterpoise instead of a spring; or the air may be admitted by means of a stopcock, the lever of which may be turned at the right moment by any of the above-mentioned devices.

MAKING A GREEN SAND BASIN—RUNNERS AND GATES.*

In making castings, the basin, runners, and gates are often responsible for their being bad. There is nothing in the whole art of moulding that requires more care than the making of these parts of a mould. A moulder may slight the rest of his mould and have his casting come out all right, but any carelessness or ignorance in making the basins, runners, or gates, will almost always cause trouble. To get some idea of the action of liquid iron in the mould and in the basin, runners, and gates, think of a river in the spring of the year rushing into the ocean, or into a lake.

In pouring a mould, the iron first drops from the ladle into the basin; from the basin it runs with more or less of a rush into the upright runners, from the runners into the gates, and from the gates into the mould. With the exception of that portion of the mould which the iron onters or drops into, there is very little agitation of the metal as it gradually rises.

In the cut shown, H is the cavity into which the iron first drops as it is poured out of the ladle; Y is the runner through which the iron flows to the gate K, from which it runs into the mould.



For pouring five-ton ladles, the width of a basin should not be less than 18in. and the depth should be 9in. The bottom of the basin where the iron first drops should not be less than 2in. deeper than at S. From S down to the runner, Y, there should be an easy incline; the longer the basin, the more incline there should be. This assists the iron in flowing, making sure of keeping the runners full, and also prevents any iron remaining in the basin when the mould is full, except that which is in the cavity that is formed for the iron to drop from the ladle into. This cavity is provided for the purpose of preventing the cutting of the bottom of the basin, which would be the case were this part made even with the rest. This cavity, which is soon filled, allows the iron to fall into iron instead of on sand. When this cavity is filled, the iron runs easily from it to the mould, lessening the danger of cutting and allowing to be rushed in, so as to keep the runners full.

For the pouring of larger ladles than five tons, the width of basins should be from 18in. up to 30in., and the depth from 9in. to 15in.

When making green sand basins, the sand should be well mixed and riddled before it is shovelled into the basin box. The careless use of unmixed sand for making basins often causes bad castings.

There is one way of making basins that many moulders follow, but which a careful moulder will never do; that is, they will shovel in some sand, and form the shape of the basin by packing up the sides with handfuls of sand. This makes a loose basin, and that is liable to cause trouble.

To make a reliable basin, the box should first be evenly rammed full of sand, after which the shape of the basin can be dug out with a shovel or trowel, thereby giving a firm, solid basin, as far as the ramming of the sand is concerned. The trouble with basins usually commences at the bottom, and is caused by the falling iron cutting the sand and letting the iron get to the wooden bars. A good moulder will never have less than 3in. of sand between the bottom of his basin and the wooden bars.

There are two or three ways that the bottom of green sand basins may be secured so as to prevent cutting when used to pour heavy castings. The first is to stick nails all over the botton, having the heads even with the surface of the sand. The second and third ways are to set in a flat core, or two fire or common bricks to form the bottom. In either of the last ways there is very little danger of the falling iron causing any trouble.

For the pouring of heavy castings it is best when possible to build basins outside the copes instead of on the top of them, for the reason that high heads can thus be avoided, thereby not having so much strain upon the mould. The cut of basin shown is one thus made. In this basin will be noticed a coke or cinder bed placed underneath the basin, which is a very good plan for large surface basins, as it will carry off the gases and steam, and thereby prevent any boiling or scalding of the bottom of the basin. Sometimes dry sand basins are made and hoisted fron the oven carriage and placed where wanted for the pouring of very heavy castings. Some moulders prefer to use them instead of green sand basins.

Another part of a green sand basin that often gives way while the mould is being poured is the front X. Sometimes a moulder will cut out the front as if he were trying to make the end at exact right angles with the sides of the basin, as shown at P. This may do well enough for small basins, but for large ones it should never be done. The safest way is to form this end as shown at W, having the end very nearly a circle. Sometimes it is best in the instance of very large basins to have this end of the box full of nails, driven so as to stick out two or three inches to have a good hold on the sand.

How often have moulders seen castings lost by having the basin box spread open, which would have been prevented had there been some narrow strips of wood nailed accross the bottom, as shown at B; or cast or wrought iron clamps used to hold the sides together, as shown at E E E. Again, the iron will burst out from underneath the box, from the lack of weights or wedges to hold it down. There are very few moulders that can be trusted with the making of a basin to pour a large casting with. They *think* they know, and it is not until they have lost a number of castings that they are convinced of their carelessness or ignorance. They are not always convinced, but will lay the blame to the basin box, the sand, the helper, or will confidentially tell some of their friends they were made to pour the iron too hot, or too fast, and that no basin will stand such treatment.

The rammer and swab pot are very necessary tools in a foundry, but in the hands of a thoughtless or ignorant moulder they are about as dangerous as a loaded revolver in the hands of a child. There are no tools used in a foundry that are more responsible for bad casting than the rammer and swab. "Bring me that rammer," yells the moulder to his helper, and when he gets it he uses it lustily. "Bring me that swab pot." He gets it, and on goes the water, plenty of it too. What's the use of being afraid of water?

Around comes the ladle, and out of the ladle into the basin goes the iron. From the basin up to the roof it flies, the men let go the ladle and run to the corners to see if they are burned; then they will sit down and think of the moulder and his swab pot and rammer. When a good moulder, or one that thinks he is, loses a casting on account of his basin, he should never blame any one but himself; for he should know from experience what is required. A moulder can tell by the looks what sizes of runner sticks or gates he wants. If a moulder orders a runner or gate stick made without having one to get the size from, he will hardly ever be satisfied with it. In thinking of the number and size of runner or gate sticks for a mould, there are many points that should be considered. The first is the weight of the casting, and whether it should be poured fast or slow. The second, the form of it, and whether its proportions are heavy or light. The third, what temperature of metal will the mould require to be poured with; will it be run from the bottom or from the top of the mould; and also the height of the basin above the mould.

---

* By Thos. D. West in *American Machinist.*

As a general thing, the faster a mould can be poured with safety to all of its parts, the better it is. It is not always the weight of a casting that decides whether the runner and gate sticks should be large or small, to pour the mould fast or slow. The common, old style grate-bars that have thin openings or cores in them, is a good example to show why some moulds require to be poured slow.

Many very good moulders have worked on this class of castings, and have been astonished at their lack of success in making good ones. A grate-bar, or any mould that has similar thin green sand cores in it, should be poured with hot iron, and slow. Pouring them slow gives the gases and steam in the sand a chance to escape through the vents, and the iron being hot will easily run level, and not pile up higher nearer to the gates than in distant portions of the mould, as dull iron will generally do, thereby causing thin bodies of sand to be displaced. Hot iron will also admit of the pouring of such moulds slow without danger of the castings being cold shut.

Moulds having thin, dry sand cores in them, should often be poured hot and slow for the reasons above stated. Very heavy castings that have no dangerous dry or green cores in them, should have large runners and gates so as to admit of the iron being poured dull and fast, and the same with any moulds that the copes would easily draw down.

There are also large and small moulds that require hot iron poured in them fast, in order to have all the parts run and not be cold shut.

Again, there are some moulds that require the liquid iron to be forced into them as fast as possible, for which high heads or basins should be made. Castings, such as cylinder or pipe-shaped moulds, that are cast vertically, should have larger runners and gates where they are poured altogether from the bottom than where they are poured from the top, by dropping the metal down, as when the iron is all poured from the bottom it gets duller as it rises up in the mould. Many times such moulds poured from the bottom and top also, so as to avoid having any trouble from dull and dirty iron in the upper portions of the casting. As regards the making of different forms of gates, runners, and basins, the interested readers will perhaps remember some that have been published, while others that are to follow will illustrate some of the different ways of pouring castings.

ELECTRICAL ACCUMULATORS, OR SECONDARY BATTERIES.*

By Prof. Oliver J. Lodge, D.Sc.

(Continued from page 421.)

So far we have only considered in the roughest and broadest manner the chemical action going on in a Planté or Faure cell; but to understand all the details of their behaviour it is necessary to investigate these actions very closely. In this study we shall be greatly assisted by an excellent memoir of Messrs. Gladstone and Tribe, which is to be found in *Nature*, January 5th and March 16th, in the *Electrician*, March 25th, and doubtless also in other places. A letter of Professor A. S. Herschel, in *Nature*, February 16th, is also of great interest.

As a preliminary, the reader is recommended to try a few experiments with two simple lead plates, say about the size of a finger. Scrape them both bright, and immerse them in ordinary dilute sulphuric acid as mixed for charging batteries, supporting them by some convenient arrangement which will hold them steady and vertical, and permit either of them to be withdrawn and reinserted easily without disarranging the wires.

First connect them with a single Grove cell, and you will see a few minute bubbles of hydrogen rise from the plate connected with the zinc, while that connected with the platinum is slowly coated with a white crust of $PbSO_4$. In about a minute the current will be very much weaker, and no bubbles will be noticed, and presently all action nearly ceases. The discharge current which can be obtained is exceedingly weak and practically *nil*. No peroxide is formed with the EMF of one Grove, which, as is well known, is unable to decompose water.

Now put on two Grove cells instead of one. Immediately bubbles of gas rise from both plates. The darkening of the + plate shows that some peroxide is being formed, and in a few seconds a discharge current can be obtained from the two little plates sufficient to ring a bell. It dies away very rapidly, however, and requires a fresh application of the current to resuscitate it.

One may note in passing that it was by no means essential, or even helpful, to the success of this second experiment that the first should have preceded it. If two cells are joined up at once to the clean plates, without first clogging one of them up with $PbSO_4$, the same things go on and perhaps rather more easily. If a preliminary coat of sulphate has been allowed to form for a long time it exerts quite a serious clogging action, by reason of its want of conducting power.

Another experiment of Gladstone and Tribe's is this: Immerse the plates in plain water—or salt and water—and act upon them with twenty Groves if you like; no peroxide will be formed, but only hydrated protoxide, which refuses to give an appreciable counter-current.

One more experiment—this time Professor Herschel's. Having charged the two lead plates with a couple of Groves properly, remove the hydrogenised plate, insert in its place a bit of clean lead, and try for the discharge current. It is very weak and can scarcely ring a bell. Remove the clean and replace the hydrogenised lead, and a strong bell-ringing current is obtained for a few seconds; but it stops suddenly. Why does it stop suddenly? Modify the experiment by immersing only half the charged surface of the plates when you are going to discharge, and as soon as the bell stops depress one of the plates more so as to bring a fresh surface into action. It will be found on depressing the + plate that a fresh surface of peroxide does no good, showing that that is not what is exhausted; but a fresh surface of hydrogenised lead (i.e., depressing the — plate) rings the bell again instantly. The current stops, therefore, as soon as the hydrogen is exhausted. It is not correct to say the current stops though, but it is suddenly and seriously weakened: clean lead and peroxide do not give a powerful EMF; the current from clean lead and hydrogenised lead is nearly as strong in the opposite direction.

A further experiment is instructive. Having peroxidised a lead plate, insert it in a beaker of acid in opposition to a plate of platinum, and connect them both with a galvanometer. It will be found that the current sets out from the lead, showing that even platinum is electro-positive to peroxide of lead. If the platinum has been alloyed with hydrogen the current is strong, but if it is clean the current is still perceptible without a very delicate galvanometer.

If instead of hydrogenised lead we try zinc, we shall find a strong current; and it appears that hydrogenised lead and zinc are almost equal to one another at first, though the hydrogen gets exhausted, while the zinc does not. Doubtless amalgamated zinc keeps itself permanently coated with a layer of hydrogen. Amalgamating metals seems to make the layer of hydrogen adhere better, and even amalgamated copper acts extremely well if it has been charged with hydrogen. Indeed, as long as the hydrygen lasts, it is scarcely inferior to zinc or hydrogenised lead. A curious thing, however, is that clean copper opposed to peroxide of lead gives a bell-ringing current much stronger than clean lead, and nearly as strong as hydrogenised lead does. This, of course, is the foundation of Sutton's cell.

All these experiments show the high value of peroxide of lead as the electro-negative element of a cell. Peroxide of manganese is very good, but peroxide of lead beats everything with which I am acquainted. In order that any of these oxides may act in this way, it is of course necessary for them to be in good metallic contact with the electrode, so as to form its real surface.

We can further learn from the first three experiments that peroxide is not formed on the + plate until there is a visible evolution of oxygen gas; and one becomes convinced that its formation is due to some secondary action.

The action is probably this: Of the SO_4 liberated against the + plate, some combines with it, forming $PbSO_4$; but the whole is not thus consumed, if it is liberated sufficiently fast, and the rest decomposes the water, liberating oxygen, and forming free sulphuric acid. Of the oxygen atoms so liberated, some unite into molecules of oxygen, others into molecules of ozone; and perhaps all this escapes as gas. But another portion liberated in contact with $PbSO_4$, acts upon it thus: $O + PbSO_4 + H_2O = PbO_2 + H_2SO_4$, making some more sulphuric acid and also peroxide of lead. Another portion of oxygen may very likely attack the lead itself in its nascent state, peroxidising it directly; and perhaps it is the ozone which is active in this manner.

It is therefore not easy to say exactly what goes on at the + plate, though the broad facts are these—that some sulphate of lead is certainly formed, being visibly white; that as soon as oxygen gas is liberated some peroxide is formed; that some of this peroxide is in such close conducting contact with the lead plate—see above—as to justify the belief that it is formed by direct oxidation; that the sulphate of lead itself gets ultimately, though slowly, peroxidised; and as sulphate of lead is a non-conductor it can only be acted on by secondary action, as explained.

At the — plate nothing particular goes on. Hydrogen is liberated against it, and partly clings to it, but mostly escapes as gas. If the clean lead surface has stood in the acid a short time before charging, it will load itself very slightly with $PbSO_4$; but this substance dees not appear to be easily reduced by the hydrogen, and it is seen to fall off as a faint white filmy descending current.

BRENNAN'S TORPEDO.

This torpedo has been in process of manufacture and improvement for some considerable time at Melbourne, partly under the auspices and with the assistance of the Victorian Government. The invention has been patented in England and the Colonies, but it was not considered politic to exhibit it at the late Melbourne Exhibition, pending the negotiations with the British Government. It is difficult to convey a clear idea of such a machine as a locomotive torpedo to the general render without the aid of sketches; but compared with the Whitehead, Fiume, or the Woolwich Royal Laboratory patterns, the Brennan is simplicity itself. Its motive power is not compressed air, neither is it contained in the body of the torpedo. To propel the weapon through the water at a speed of from 15 knots to 20 knots an hour for 1,000 yards, a separate engine, or at least a special connection with an existing one, is necessary. This engine drives two drums, about 3ft. in diameter, with a velocity at their peripheries of 100ft. per second. Their duty is to wind in two fine steel wires No. 18 gauge, the same as used in the deep-sea sounding apparatus of Sir William Thomson. The rapid uncoiling of these wires from two small corresponding reels in the belly of the fish imparts to them, as may readily be conceived, an extremely high velocity. The reels are connected with the shafts of the two propellers which drive the torpedo through the water. The propellers work, as has long been known to be necessary to insure straight running, in opposite directions and both in one line, the shaft of one being hollow and containing the shaft of the other. At first sight it would seem as if hauling a torpedo backward by two wires was a sufficiently curious way of speeding it "full speed a-head," but it is found in practice that the amount of "drag" is so small, as compared with the power utilised in spinning the reels that give motion to the propellers, that it may be left out of calculation altogether. The steering-gear of the Brennan is a most ingenious contrivance, whereby the relative velocities of the two driving drums, and consequently of the two propellers, can be varied at any moment. The perpendicular rudder, which is marvellously sensitive, is reacted on by the screws, and in this way the torpedo may be made to follow as tortuous a path as a figure-skater. The course the torpedo is taking is indicated to the operator by a slight steel telescopic mast carrying a pennon, which, when not in use, is folded along the back of the torpedo.

FLAMELESS COMBUSTION.

At the soirée of the Society of Chemical Industry at Owens College, on Thursday, a new theory of combustion was practically illustrated by Mr. Thomas Fletcher, of Warrington. Mr. Jacob Reese, the inventor of the Reese fusing diic, has stated his belief that if it were possible to produce combustion without flame, the temperature and duty obtained from any fuel would be enormously increased. It has remained for Mr. Fletcher to not only prove the possibility of flameless combustion in more than one form, but also to demonstrate practically the enormously high temperatures which can be obtained by this means. Taking a ball of iron wire about three pounds in weight, Mr. Fletcher placed it on a slab of fire-clay, and directing a blowpipe flame on it for a few seconds he suddenly blew the flame out. The temperature increased so rapidly that in a few seconds the wrought iron fused and ran into drops, and this temperature was steadily maintained. The room was darkened, but the closest examination did not show a trace of flame, although the fact that the gas was burning was proved by repeatedly relighting and extinguishing it. The same experiment was repeated in another form by directing the flameless heat into a small fire-clay chamber, in which a refractory clay crucible, made specially for nickel melting, was partially fused and worked into a ball like soft putty, the sides of the fire-clay chamber being at the same time fused. The heat was so tremendous that the blowpipe laboratory, which was given up to Mr. Fletcher for the evening, was much too hot to be agreeable, in spite of open windows and ventilators. How far this discovery can be utilised remains to be seen; but it would appear that the presence of flame, usually considered to be a sign of combustion, is really an indication of imperfect results, and the best duty is to be obtained only when flame is totally absent. It is certain that such temperatures as obtained by Mr. Fletcher without flame have never previously been obtained with the fuel used, which was nothing more than a small gas supply for a ¼in. pipe, assisted by an air-blast.

---

* From the *Engineer*.

SOME POSSIBLE SOURCES OF ERROR IN COMPUTING THE AGE OF FOSSILS.

IN a paper on the "Limit of the Innuit Tribes on the Alaska Coast," contributed to the *American Naturalist* by Ivan Petroff, the writer gives some evidence that errors in computing geological time, and in reckoning the age of fossils, may be easily made through an imperfect acquaintance with the capabilities of natural forces. Mr. Petroff was compelled to reside for some months in Alaska, in that section where the Innuit and Thlinket tribes meet, and he formed a theory that the Innuits are comparatively recent immigrants. An argument in favour of the view that the Innuits spread over the Alaska coast may perhaps be found in the existence of a branch of this tribe on the Aleutian islands. I fully agree, says Mr. Petroff, with Mr. Dall, that the theory of an Asiatic influx of population over the Aleutian chain of islands is entirely untenable, and that they were peopled from the east, but I do not think that this migration took place before the invention of the kaiak. Timber evidently never existed on these islands; the only equivalent being the drift wood collected along the beaches and promontories; but this kind of material, waterlogged and sodden, was entirely unfit for the manufacture of wooden canoes, or even for the construction of rafts, by which means Mr. Dall supposes the early Aleuts advanced from island to island. The frequency of gales, the violence of currents and the width of channels between these islands would also prevent the use of rafts as a means of transportation and traffic. The assumption that the earliest inhabitants of the Aleutian islands were without a kaiak or boat of some kind, is based upon researches in the shell heaps of abandoned village sites on those islands; but a kaiak with a whalebone or even a wooden frame without its modern ornaments of ivory and bone, contained no material that would withstand decay and final absorption. The skin covering when worn out and unfit for use as such, was, no doubt, then as now, cut up into straps and patches, or served as food in time of famine, while the frame could be utilised in many ways that would leave no trace behind. The mere absence from the lower strata of shell heaps of anything pointing to the existence of the kaiak, can scarcely be considered as proof conclusive of its non-existence. My personal observations have led me to believe that the remains of former villages and dwellings found on the Aleutian Islands and on the continental coast of Alaska, are not of the antiquity ascribed to them. Wherever I had the opportunity to observe such localities at long intervals of time, I was astonished at the rapidity with which nature extinguished the traces of man by a growth of sphagnum and other vegetation, giving to the site of the village abandoned but a few years every appearance of great antiquity.

The absence of stone and bone implements of more delicate construction from the lower strata of the shell heaps can easily be attributed to the same cause that explains the absence of iron implements from the upper layers that must have accumulated within historic times. Such articles were the product of much labour, and consequently too precious to be lost. At every successive removal from one dwelling-place to another all such products of their ingenuity were carefully collected and removed by the ancient Aleuts, just as it is done now with regard to iron by the natives of the present day.

On these treeless isles, the removal from one hunting or fishing-ground to another of a few families or a community always involved the transportation of every log or plank, and every particle of wood to be found about the place. As an instance of this kind, I may point to the removal of the people of Makushin, on Oonalashka Island, which took place in the early part of the year 1879. In the summer of 1880, I visited the spot from which the people had removed, and found the outlines of every house indicated by a slight depression in the ground, and inclosed by low ridges of earth covered already with a dense growth of sphagnum and grasses. Every piece of wood about the whole settlement had disappeared simultaneously with the people; and I have no doubt that an explorer unacquainted with the circumstances could dig up these remains without finding a scrap of iron, or anything indicating their recent occupation by at least a semi-civilised people. Another example of this kind, and even more forcible in total absorption of all signs of recent occupation, can be found on the island of Atkha at the site of the former settlement of Korovinsky, the people of which removed to Nazan on the other side of the island less than fifteen years ago.

In the settlements remote from the trading centres the people of Innuit stock live to-day as they did probably centuries ago, in a manner not at all inconsistent with the remains found in the lower strata of shell heaps. Even the presence of stone and bone arrow and spear-heads is no true indication of age, as they are manufactured at the present day, as I had an opportunity to witness frequently during my travels in remote regions.

The time required for the formation of a so-called layer of "kitchen refuse" found under the sites of Aleutian or Innuit dwellings, I am also inclined to think less than indicated by Mr. Dall's calculations. Anybody who has watched a healthy Innuit family in the process of making a meal on the luscious echinus or sea-urchin, would naturally imagine that in the course of a month they might pile up a great quantity of spinous débris. Both hands are kept busy conveying the sea-fruit to the capacious mouth; with a skilful combined action of teeth and tongue, the shell is cracked, the rich contents extracted, and the former falls rattling to the ground in a continuous shower of fragments until the meal is concluded. A family of three or four adults, and perhaps an equal number of children, will leave behind them a shell monument of their voracity a foot or eighteen inches in height after a single meal. In localities in Prince William Sound, I had an opportunity to examine the camp-sites of sea-otter hunters on the coast contiguous to their hunting grounds. Here they live almost exclusively upon echinus, clams, and mussels, which are consumed raw in order to avoid building fires and making smoke, and thereby driving the sensitive sea-otter from the vicinity. The heaps of refuse created under such circumstances during a single season were truly astonishing in size. They will surely mislead the ingenious calculator of the antiquities of shell heaps a thousand years hence.

On the coast of Cook's inlet I have observed other instances of the rapid transformation of dwelling sites.

In the year 1869, I erected a substantial log-house in the vicinity of the village of Chkituk. I visited the spot last summer and discovered nothing but faint lines of the foundation of my house indicated by low ridges overgrown with mosses and grasses, and two young spruce trees growing up from the spot where my fireplace had been located. In the same locality, at the mouth of the Kaknu or Kenai river, the remains of the first log building erected there by the Russians in 1789, can now be seen protruding from the almost perpendicular river bank 15ft. or 20ft. under the present surface.

As an instance of the rapidity with which the tides of this region will change outlines of coast and other landmarks, I may cite an observation made by me during my stay on Nuchek Island last summer. At a short distance from the settlement there was a cave in a rocky cliff situated about three or four feet above high-water mark. I visited the place frequently, as it afforded a view over the approaches to the harbour. About the middle of June an eclipse of the moon occurred when it was full or nearly so, causing tidal commotion of unusual extent and violence. When I visited my cave on the day following the eclipse, I found it almost filled with shingles and débris. This cave was situated at about the same height above the water as the cave of Amaknak, from which Mr. Dall extracted such voluminous information as to the antiquity of strata of refuse found therein. I cite these instances only for the purpose of showing that it is not safe to ascribe great age to any and all accumulations of débris found on the coast of Alaska, and also as a support for my theory of a general Innuit migration along the coast at a comparatively recent period, subsequent to the invention of the kaiak or a similar structure.

WHAT IS ELECTRICITY?

ASKS Col. J. D. Shakespeare in the *Electrician*, and then continues—"To this question I have failed to see given any reliable answer, and my suggestion may be equally unsatisfactory. However, when endeavouring to solve a law of nature, my experience tells me to inquire into and search it out from the simplest form known to us in daily life. We know electricity is produced to our senses in one of two ways—either mechanical—i.e., by friction, or chemical, i.e., by the conversion of some sorts of matter into other sorts. I submit that, as electricity is common to all things, its mechanical production has precedence of the chemical, and that the electricity in things partakes of the principle of "storage." We only know things by what they do. Bearings heat by frictional contact to a very high and even visible temperature. Two rapidly revolving discs, not in contact, but so close together as to admit only of an air-space between them, develop electricity quickly and in a most powerful form from the rubbing together of the molecules of air between the discs.

Let me now observe that the world rolls round itself at the rate of 1,000 miles an hour, and travels round the sun at the rate of 6,500 miles an hour, the atmosphere travelling with it. Is it not a fact that our planetary system works from east to west by the south, and that our world revolves from west to east? Surely with such motion there must be a "slip" producing friction and electricity. If there is a "slip," then electricity would be an effect of Nature's laws of friction; but whether that friction produces it *de novo*, or stimulates it into action from a latent state, I am not prepared to say, but prefer the latter theory. If it is a "primary," there is no use in asking "What is electricity?" but we may ask—Where is its source?

PORTABLE DOOR-FASTENER.

A POCKET device for securing doors, that can be attached to any door rapidly without any implements, has been patented by Mr. Charles A. Crongeyer, of Detroit, Wayne county, Mich. U.S.A. A metal strip is provided at one end with a flat hook, and a rod is pivoted to its opposite end, and the outer end of the rod is screw-threaded. A U-shaped piece, whose shanks are of unequal length, has an aperture in its curved middle part through which the rod passes in such a manner that the ends of the shanks of the U-shaped piece project toward the hooked end of the strip. This piece is secured in any desired position on the rod by a milled nut screwed on the outer end of the rod. The ends of the shanks have a flat smooth surface to rest against the surface of the door and frame. The short shank is adapted to rest against a moulding or casing, and is provided with a swinging leg of such length that when it is swung outward its end will be flush with the end of the long shank. When used, the hook of the metal strip is placed against the jamb of the door, and the U-shaped piece is turned in such a manner as to permit the closing of the door, and when the door is closed the hook is forced into the wood of the jamb. The piece is then turned so that the long shank will rest against the surface of the door. The device does not mar the door and keeps it locked perfectly, and is applicable to doors of any thickness, and with little or no trouble.

RECENT ADVANCES IN PHOTOGRAPHY.—I.[*]

By Capt. Abney, R.E., F.R.S.

THE first germ of photography was when Scheele investigated the action of light on silver chloride, and found that it discoloured it. It was subsequently found that this discolouration of the chloride was due to a liberation of chlorine from the chloride of silver. In 1802, eighty years ago, Wedgwood read a paper before the Royal Institution, in which he described a method of taking profiles, and also copying painted pictures, by means of what we should now call photography. These profiles were taken on paper washed over with silver nitrate. In other words, the profile of the person to be portrayed was thrown against sensitised paper, in a strong light, and the outline was photographed or made visible by the strong light acting outside the profile. Of course, it produced a white profile on a black background. About the same time that Wedgwood read this paper, Sir Humphrey Davy was practising this process, and he found that silver chloride was preferable to silver nitrate. He also found that if he used white kid as a basis of what I will call the photograph, he got a stronger impression than if he used simply paper. In 1814, twelve years later, Niépce devoted himself to studying the action of light upon asphaltum, and he worked out a process which up to this day is still used, and which I shall not refer to more particularly now, as I shall hope to do so in a subsequent lecture. He developed the process which was then called heliography, which consisted in the production of a picture in bitumen on a metal plate, the light causing the oxidation of the bitumen or asphaltum, and rendering insoluble or less soluble those parts which had been acted upon.

In 1827, Niépce came to England, and endeavoured to introduce the results which he had obtained to the notice of the Royal Society; but, owing to the process being a secret one, the communication was not received.

---

[*] A series of Cantor Lectures delivered before the Society of Arts.

In 1824, Danguerre, a name to be remembered, a French painter, began similar experiments in the same direction, and, in 1829, he and Niépce entered into partnership to work out that which eventually received the name of photography. Now, Niépce has left it on record, that in his bitumen pictures he had one considerable trouble: he found that, instead of the lines of an engraving being represented by black stains on the white metal, the lines were represented by white metal on black bitumen. In order to overcome this difficulty, after coating the silver plate with his bitumen, and developing it by dissolving away the unaltered parts, he treated the metallic silver plate beneath with any ingredient which he might choose, and, amongst others, he has left on record that he treated it with iodine, and then rubbed off the bitumen. This, in the case of an engraving, would, of course, give dark lines on a white background. Here we have the first introduction of iodine and silver together.

Now, we cannot suppose that two such shrewd observers as Niépce and Daguerre could have used this combination of iodine and silver without noticing that it was altered by light; and I may say that there are a number of grave grounds for considering that this was really the origin of the daguerreotye process, which consists, as you know, in the treatment of a silver plate primarily with iodine, and subsequently with other substances, to cause sensitiveness. Daguerre and Niépce must have noticed the alteration by light in the siver iodide which they had formed on the silver plate, but up to that time of which I am talking, they had not discovered the secret of what we now call development; and when we come to consider the early history of photography, it is a most remarkable fact that the two first modes of development were discovered, if I may say so, by flukes. The discovery of the development of the daguerrean image was as follows:—He, Daguerre, had been trying to reduce the exposure of iodide of silver in order to get an image in a reasonable time. Instead of exdosing his plate for a quarter of an hour or an hour, he wished to obtain an image in one or two minutes, which, to him, would have been very quick. Many months were passed in these apparently fruitless researches, until one day he placed one of his iodised plates, which he had exposed to light for some short time, in his chemical cupboard. Now, in that chemical cupboard were a variety of bottles of all descriptions. He had worked hard, and as chemists know perfectly well, when a man is working at research, there is usually a collection of all sorts of chemicals. He placed his daguerreotype plate in the cupboard over night, and to his astonishment next morning when he opened the cupboard, he found that he had a fully developed daguerrean image. This was a discovery which he immediately turned to account. He exposed other plates, shifting first one bottle then another, and by this process of elimination, at last he was able to find that it was an open bottle of mercury which had caused the development of the image. This was really, I believe, the true history of the daguerreotype process, so far as the mercurial development was concerned. It was considered a very short exposure in those days if you sat five or ten minutes in the sunlight to have four portraits taken. We have changed all that now, and I dare say before this course of lectures is over, not only five or ten minutes will be considered a long exposure, but perhaps 5-100ths of a second will not be considered short.
